It is not always a welcome discovery to learn that the physical system one has created is operating in a chaotic mode. If this is not the desired operating condition, one can utilize methods to "control" that chaotic motion. The basic idea is to locate some of the infinite number of unstable periodic orbits that comprise a strange attractor, and, in a locally linear analysis about these periodic orbits, identify the stable and unstable directions associated with perturbations near the orbits. Then one can devise small changes in the parameters of the system that drive observed evolution onto the stable direction of one of these periodic orbits (Ott *et al.*, 1990). Repeated application of the required small parameter changes drives the system onto the stable direction of the unstable periodic orbit that was chosen. Basically, one is turning an autonomous problem where a parameter is held constant into a nonautonomous problem where an external force is altering the parameter according to the system location in phase space. Thus, we create a new system in which the previously unstable periodic orbit has become stable.

This method has proven successful in stabilizing the unstable periodic orbits of chemical reactions, cardiac cells, infrared lasers, magnetoelastic ribbons, and nonlinear circuits, among other systems. It suggests that one might actually wish to drive a system of interest into a chaotic regime where it visits an enormously larger piece of state space than in regular motion and then stabilize the evolution to one or more chosen periodic orbits at will. This kind of flexibility will no doubt be quite useful in applications of these methods.

GLOSSARY

Attractor: The set of points in phase space visited by the solution to an evolution equation long after transients have died out. An attractor can have an integer dimension—a regular attractor—or a fractional dimension—a *strange* attractor.

Average Mutual Information: The amount (in bits if base-two logarithms are used) one learns about one observation from another observation on the average over all measurements. This is a statistic introduced in communications theory by Shannon (1948), which describes chaotic nonlinear systems as they are information sources.

Basin of Attraction: The set of points in phase space that, taken as initial conditions for an evolution rule, lead to the same attractor. The boundaries between basins of attraction can be fractional dimensional.

Bifurcation: A change in the state or topology of the solution to an evolution equation when a parameter is varied. A bifurcation is associated with changes in stability of solutions to dynamical nonlinear equations.

Cantor Set: An uncountably infinite set of points in R^d (a) which contains no subinterval of R^d, (b) which is closed, and (c) each point of which is an accumulation point. The dimension of such a set is typically fractional. We have called this dimension d_A, since, in physical applications, the Cantor set is an attractor of a dynamical system.

Chaos: Deterministic evolution of a nonlinear system that is between regular behavior and stochastic behavior or " noise." This motion of nonlinear systems is slightly predictable and nonperiodic, and specific orbits change exponentially rapidly in response to changes in initial conditions or orbit perturbations.

Embedding Dimension: The dimension of phase space required to unfold the attractor of a nonlinear system from the observation of scalar signals from the source. This dimension is integer.

Flows and Maps: Flows are evolution rules in continuous time. Maps are evolution rules in discrete time. Maps can come from flows by finite sampling associated with real experiments or from Poincaré sections, which view a continuous orbit stroboscopically.

Fractal Dimensions: The dimensions of an infinite set of points associated with the way the density of points scales with small volumes surrounding the points. Fractional values for the dimensions are typical for strange attractors of nonlinear systems.

Hamiltonian Systems: Laws of evolution corresponding to closed systems or systems without dissipation. The equations of motion come from a scalar "Hamiltonian" and, when expressed in canonical coordinates, the Hamiltonian flow preserves volumes in phase space.

Lyapunov Exponents: The rate at which nearby orbits diverge from each other after small perturbations when the evolution of a nonlinear system is chaotic. There are M exponents for evolution of an M-dimensional flow or map. For a dissipative system, the sum of these exponents is negative. For a flow, one exponent must be zero.

Phase Space or State Space: Nonlinear systems are described by multidimensional vectors labeled by continuous or discrete time. The space in which these vectors lie is called state space or phase space. The dimension of phase space or state space is integer.

INTRODUCTION

2 December 1992 marked the 50th anniversary of the initiation of the first self-sustaining nuclear chain reaction of a manmade nuclear reactor in the world. That reactor, called Chicago Pile No. 1 (CP-1), was constructed in secrecy by the Manhattan Project at the beginning of World War II underneath the west stands of the University of Chicago squash court by a team of physicists under the leadership of Enrico Fermi (Smyth, 1945; Rhodes, 1986). CP-1 was composed of graphite blocks of varying lengths and pressed natural uranium oxide and uranium metal cylinders. It was designed and constructed to prove that a self-sustaining fission chain reaction could exist and to confirm theoretical physics calculations. The success of the self-sustaining chain reaction reactor in 1942 led to the design and construction of a large, graphite-moderated, natural-uranium–fueled, water-cooled plutonium production reactor at Hanford, Washington.

The plutonium production reactor used the nuclear reaction

$$^{238}\text{U} + \text{neutron} \rightarrow {}^{239}\text{U} \xrightarrow{\beta^-} {}^{239}\text{Pu}$$

for the production of plutonium for nuclear weapons. The chemical separation of plutonium from irradiated natural uranium appeared to be a much easier process at that time than the isotopic separation of the ^{235}U isotope from natural uranium. The Manhattan Project also initiated in 1942 the design and construction of a large ^{235}U isotope separation plant based upon a diffusion process at Oak Ridge, Tennessee. This led in 1945 to the production of sufficient quantitites of highly enriched uranium containing ^{235}U for the construction of the first atomic weapon.

The Soviet Union also started on the construction of a graphite-moderated natural-uranium reactor under the leadership of I.V. Kurchatov in Moscow in 1943. This resulted in the Φ-1 reactor achieving a self-sustaining chain reaction on 25 December 1946 at what is now known as the I.V. Kurchatov Institute of Atomic Energy in Moscow. Following attainment of the self-sustaining chain reaction in the Φ-1 reactor, the Soviet scientists and engineers designed and constructed graphite-moderated, water-cooled, natural-uranium–fueled reactors for the production of plutonium in the Urals region of the Soviet Union by 1948.

Although the first nuclear reactors were constructed for plutonium production for nuclear weapons, it was recognized early that the energy released from ^{235}U fission could be used for the production of electrical power, motive power for ships, and district heating. With the end of World War II, large quantities of separated ^{235}U isotopes, which could be used to fuel nuclear power reactors, became available from the separation plants at Oak Ridge.

Nuclear reactors to produce self-sustaining chain reactions utilize the following

nuclear reactions:

$$^{235}\text{U} + n \rightarrow \text{fission products} + \text{kinetic energy} + 2.42n$$

or

$$^{239}\text{Pu} + n \rightarrow \text{fission products} + \text{kinetic energy} + 2.87n.$$

The first nuclear reactor that produced electricity was Argonne National Laboratory's Experimental Breeder Reactor No. 1 (EBR-1) (Lichtenberger *et al.*, 1955), which was a 1.2 MW(t) [200 kW(e)] sodium-potassium–cooled fast reactor located at the National Reactor Testing Station (NRTS), which is now known as the Idaho National Engineering Laboratory (INEL), located about 60 miles west of Idaho Falls, Idaho. EBR-1 first produced electricity on 20 December 1951.

In the middle 1940s, the U.S. Navy under the leadership of Adm. Hyman Rickover became interested in developing nuclear power for powering submarines. This led to the establishment of the Knolls Atomic Power Laboratory (KAPL) near Schnectady, New York, and the Bettis Atomic Power Laboratory (BAPL) near Pittsburgh, Pennsylvania, for the development of a nuclear power system for submarines. The General Electric Company (GE) operated KAPL and the Westinghouse Electric Corporation operated BAPL for the U.S. Atomic Energy Commission. BAPL developed the concept of a pressurized, water-cooled and -moderated nuclear reactor, while KAPL developed the concept of a liquid-metal–cooled reactor for motive power for the submarines. The BAPL water-moderated and -cooled reactor became the forerunner of the commercial pressurized-water reactors (PWR) that were later manufactured by Westinghouse, Combustion Engineering, and Babcock & Wilcox corporations.

Argonne National Laboratory (ANL) originated the concept of the boiling-water reactors (BWR). The concept of the BWR was demonstrated by the BORAX [15 MW(t)] Reactor series of experiments (Dietrich *et al.*, 1955) at the NRTS begining around 1952, which led to the construction of the Experimental Boiling Water Reactor (EBWR) (Harrer *et al.*, 1955), a 20 MW(t) [5 MW(e)] prototype reactor at the ANL site near Chicago in 1961. The EBWR and the Vallecitos BWR (VBWR), later designed and constructed by GE in Vallecitos, California, were the forerunners of the large commercial BWRs.

Although fission reactors essentially produce heat energy, it is important to note the significant differences between fission reactors and chemical-combustion, fossil-fueled plants for electricity generation. Fission reactors produce heat through the fission process as a result of a nuclear interaction between a neutron and the fissile isotope nucleus. The fissioning of ^{235}U results in the energy release of 1 MW-d (24 000 kW h) per gram of ^{235}U. On the other hand, a chemical combustion (oxidation) process of methane gas, for example, is a result of the oxygen molecule combining chemically with carbon molecules, resulting in the heat energy release of about 1.6 kW h per gram of methane (CH_4) gas. This has the following consequences:

1. Fission reactors, in addition to producing heat energy, produce neutron and gamma radiation that must be contained by shielding.
2. Nuclear reactors produce gaseous and particulate fission products, which are radioactive and decay with the emission of beta, gamma, or alpha rays on varying time scales. The decay rate of a radioactive material represents the activity of the material. The time it takes for the activity to decay by a factor of 2 is known as the half-life of the radioactive material. Radioactive materials must also be contained by shielding. They must be handled carefully and prevented from being released to the environment for long periods of time.
3. Nuclear reactors have the ability to produce greater than design-basis heat energy; therefore, they require well-designed and reliable control mechanisms.
4. Finally, nuclear reactors, because of their varying half-life fission products, produce significant amounts of heat energy called decay heat even though the fission process has been terminated. This is in contrast to chemical-combustion plants, which produce no heat once the combustion process is stopped. The amount of decay heat produced after termination of the fission process is illustrated in Table 1. The existence of decay heat results in the requirement that nuclear fuel elements must be cooled for months or years after

Table 1. Decay heat from fission reactors.

Time after reactor shutdown	Approximate percentage of full power production
1 sec	6
1 h	1
28 h	0.5
12 d	0.3
4 m	0.13

the termination of the fission process in order to avoid melting of the fuel and releasing of the fission products.

The ability of the ^{235}U isotope nucleus to capture a neutron and either be fissioned or become the ^{236}U isotope and emit a gamma ray depends on the probability of interaction between the neutron and target nuclei, which is measured by the *interaction cross section*. Various types of interactions are possible depending on the kinetic energy of the neutron. Three principal reactions for the ^{235}U isotope and neutrons are scattering, capture, and fission at low neutron energies. Neutrons have a kinetic velocity or energy measured in m/s or eV. As an example, neutrons at equilibrium at room temperature have a velocity of 2200 m/s or an energy of 0.025 eV. Cross sections, which are conventionally designated by the symbol σ, are measured in units of cm^2 as a function of the kinetic energy of the neutron. A cross section of 10^{-24} cm^2 is called a cross section of 1 barn. The capture (σ_c) and fission (σ_f) cross sections for ^{235}U at 0.025 eV are 98 and 582 barns, respectively. Isotopes such as ^{233}U and ^{239}Pu, also, readily fission at low neutron energies since they have fission (σ_f) cross sections of 527 and 742 barns, respectively, at 0.025 eV, whereas ^{238}U fissions with neutrons having energies greater than about 0.68 MeV.

The fissioning of the nucleus of a fissionable isotope such as ^{235}U produces on the average two fragments called fission products plus on the average 2.44 neutrons. Fission products are isotopes having atomic mass about half of the uranium atomic mass and are usually unstable, which means that they are radioactive and decay by emitting a beta particles, gamma rays, or possibly alpha particles. The neutrons emitted at fission have an average energy of 1.98 MeV, and these neutrons could cause additional fissions if another ^{235}U isotope is in proximity. This could create a self-sustaining chain reaction. Unfortunately, natural uranium is a mixture of the two isotopes ^{235}U (0.72%) and ^{238}U (99.28%), which have fission cross sections of about 4.2 and ~0.6 barns at 0.025 eV and 2 MeV, respectively, and capture cross sections of about 2.7 and 0.4 barns at 0.025 eV and 2 MeV, respectively. The significance of these values is that it is not possible to have a self-sustaining chain reaction with natural uranium alone because the capture cross section at 2 MeV is not significantly less than the fission cross section, which means that most of the neutrons would be captured or escape out of the system without causing additional fissions.

In order to produce a self sustaining chain reaction, it is necessary either to separate the fissionable ^{235}U isotope from natural uranium and use uranium enriched in ^{235}U or to decrease the energy of the fission neutrons by neutron moderation. The original nuclear reactor CP-1 used natural uranium as fuel and pure graphite as moderator. The graphite, having a low capture cross section and low atomic mass, would slow the neutrons from 2 MeV to 0.025 eV without being captured by the graphite or escaping out of the reactor system. Neutrons, when slowed down, would be captured by the ^{235}U nucleus and cause fission. The trick in making a self-sustaining chain reaction is to minimize leakage and captures by the moderator or structural materials while maximizing fissions by the ^{235}U nucleus. It is necessary to use high-purity graphite because industrial graphite contains small amounts of such materials as boron and vanadium, which have high neutron absorption cross sections. Other materials, in addition to high-purity graphite, that could act as moderators are light water, heavy water (D_2O), and beryllium because of their low atomic mass numbers. Unfortunately, hydrogen has a fairly high capture cross section, and therefore it is not suitable as a moderator with natural uranium. Heavy water can be used as a moderator with natural uranium, but it requires considerable effort to separate heavy water from ordinary water. If natural uranium could have its ^{235}U content increased to between 2.5 and 3.2%, then you could have a self-sustaining chain reaction using light water as moderator.

Today, natural uranium consists principally of the two isotopes ^{238}U (99.2%) and ^{235}U (0.72%) with half-lives of 4.47×10^9 yr and

7.04×10^8 yr, respectively. Natural uranium had a higher content of ^{235}U (i.e., 1.6%) a billon (10^9) years ago because of the difference in the ^{238}U and ^{235}U half-lives. Two billion years ago the ^{235}U content in natural uranium was closer to 3%. Under proper conditions, the natural uranium of two billion years ago could have produced a self-sustaining chain reaction with light water as moderator.

In May 1972, H. Bouzigues, a staff member of the French nuclear fuel processing plant at Pierrelatte, discovered that some of the natural uranium coming from the Oklo region of the Republic of Gabon in West Africa had a ^{235}U content of 0.7171% instead of 0.7202% found in normal natural uranium (Cowan, 1976). Other samples contained only 0.44% of U^{235}. A serious investigation into this discrepancy by the French Commissariat à l'Energie Atomique (CEA) resulted in the discovery that nature had constructed the world's first nuclear fission reactor possibly 1.7 to 1.9 billion years ago in a rich deposit of uranium ore in the Oklo region. That a self-sustaining fission reactor had existed was deduced from the other stable isotopes that were located near the region where the uranium depleted in ^{235}U was found. A study of the absolute amount of such rare earth elements as neodymium, lanthanum, and gadolinium and metals such as zirconium, ruthenium, and rhodium, and of their isotopic composition, led to the firm conclusion that a natural uranum fission reactor had existed there. The concentration of the uranium ore, the availability of water possibly in the form of water of crystalization in sedimentary ore or saturated water in the ground, and the lack of neutron absorbers, such as boron or lithium compounds, resulted in a self-sustaining chain reaction, which released an estimated 15 000 MW y of energy. Estimates of the duration of the fission reactors range from 150 000 to 1.5×10^6 years, $(1.7 \text{ to } 1.9) \times 10^9$ years ago. In the Oklo region, the French have found six reactor zones that were located in regions with exceptionally rich ores. In all six areas, the ^{235}U was found to be significantly depleted, leading to the conclusion that reactors had operated at more than one site. It is, thus, concluded that CP-1, the graphite natural uranium reactor, was the first manmade fission reactor but not the world's first fission reactor.

1. REACTOR TYPES

One approach to catagorizing reactors is by their function or use. Three principal categories are research, power generation, and material production. In the research category can be included zero-power or critical experiments, training reactors, and reactors that are operated for the production of neutrons. Examples of research reactors are the High Flux Beam Reactor (HFBR), as shown in Fig. 1 (Hendrie, 1965), at Brookhaven National Laboratory (BNL), the High Flux Isotope Reactor (HIFR) (Swartout *et al.*, 1965) at Oak Ridge National Laboratory (ORNL); and the Advanced Test Reactor (ATR) at the Idaho National Engineering Laboratory (INEL) (IAEA, 1989). These reactors have beam ports through which beams of neutrons can be removed for neutron scattering and activation experiments. They can also be used for radioisotope production. Research reactors are operated at power levels from a few watts or kilowatts to tens of megawatts. The heat that is produced by the fission process in these reactors is essentially waste heat and is disposed to the environment. Included in the research category are zero-power reactors or critical experiments, which are flexible-geometry, low-power reactors and operate at a few milliwatts to about 100 W for short periods of time to verify reactor physics calculations. CP-1, the first manmade reactor, was essentially a critical experiment, since it was operated at very low power levels and was used to verify reactor physics calculations. The objective of critical experiments is to measure such parameters as critical mass, neutron flux and power distribution, neutron energy spectrum, etc., while varying the fuel composition or geometry. Since handling of fuel is usually carried out by hand, it is necessary to minimize the total amount of fission energy produced by the reactor for any given run to minimize radiation levels from the fuel. An example of an operating critical experiment is the Zero Power Plutonium Reactor (ZPPR) (Davey, 1972), as shown in Fig. 2, operated by ANL at INEL since 1967.

Power generation reactors are those reactors that have been designed for the generation of electricity or process heat. These reactors operate at power levels of a few hundred to thousands of megawatts. Since the thermal efficiency of power reactors is about $\frac{1}{3}$, it requires about a 3000-MW power plant

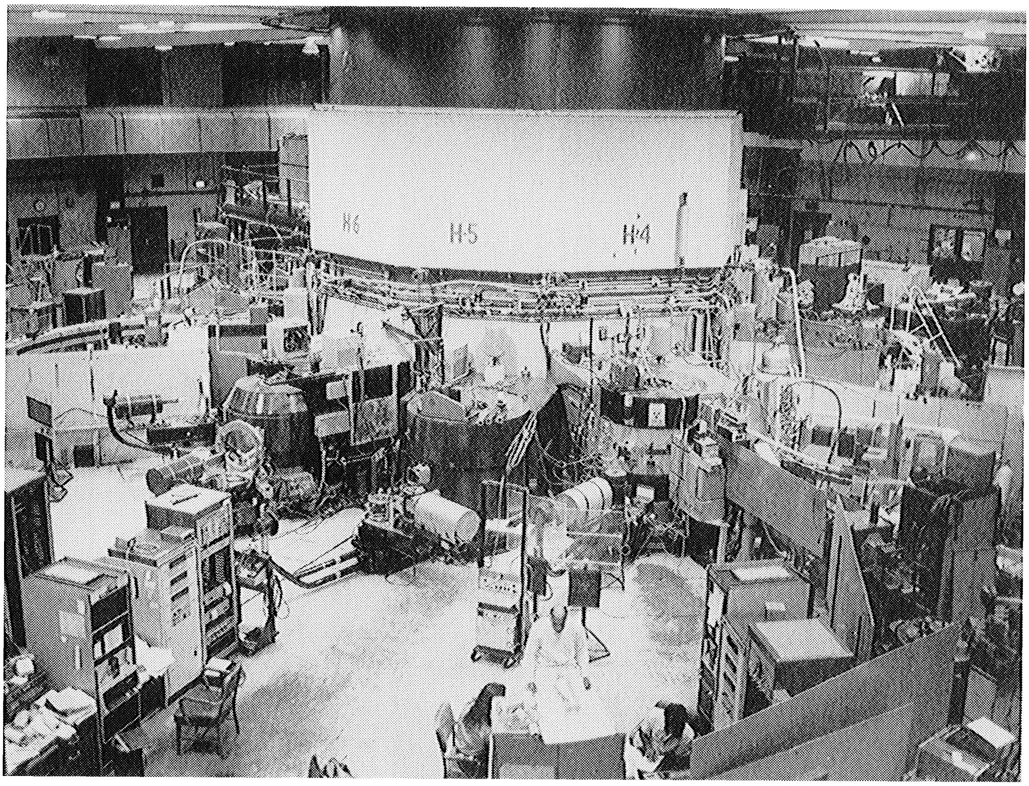

FIG. 1. Experimental area of BNL High Flux Beam Reactor (HFBR)

for the generation of 1000 MW of electrical power. There are a number of different types of power reactors, namely, light-water moderated and cooled reactors (LWRs), heavy-water moderated and cooled reactors (HWRs), heavy-water moderated light-water cooled reactors, graphite-moderated light-water cooled reactors, graphite-moderated gas-cooled reactors (HTGRs), and unmoderated sodium-cooled fast reactors (LMRs). Examples of these commercial power generation reactors will be given later.

A third category comprises the material production reactors. These reactors are designed for the production of large quantities of plutonium, tritium, or possibly ^{233}U isotopes for weapons use. These reactors are either graphite-moderated light-water cooled reactors, such as the production reactors at Hanford, Washington, or heavy-water moderated and cooled reactors, such as at the Savannah River Plant in South Carolina, and are operated at a few hundred to a few thousand megawatts.

2. NUCLEAR PHYSICS

An understanding of some nuclear physics is essential to the understanding of this brief exposition of nuclear reactor theory and operation. The reader is referred to such texts as Glasstone and Sesonske (1987), Lamarsh (1977), or Stamm'ler and Abbate (1983) for more detailed discussions on nuclear physics and nuclear reactor theory.

Neutrons and protons make up the the principal particles in atomic nuclei. Fission or breakup of heavy atomic nuclei, such as lead, tungsten, uranium, and heavier nuclei can occur by bombardment of these elements by particles such as neutrons, protons, alphas, or high-energy gamma rays. The higher the energy of the incident particle, the easier it is for fission to occur. Charged particles because of the Coulomb barrier must be accelerated to high energies to cause fission. Only neutrons, however, can cause fission at energies below 2 MeV and only in uranium or higher atomic mass nuclei. Neutrons can be

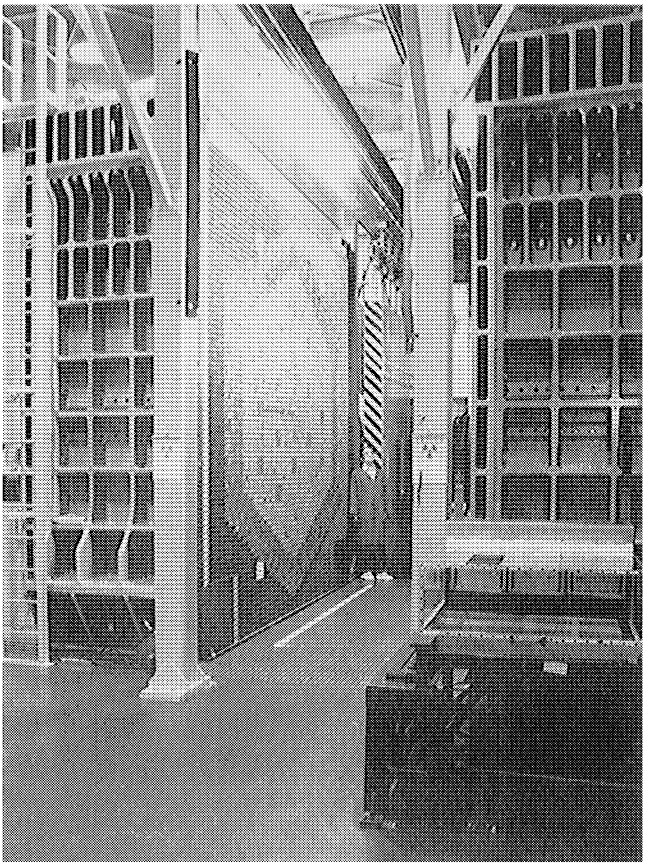

FIG. 2. Zero Power Plutonium Reactor (ZPPR) at ANL.

produced through such nuclear interactions as the (α, n) reaction using naturally occurring radioactive elements such as radium or polonium, which emit alpha particles during their decay, and elements such as beryllium. The incidence of alpha particles on beryllium nuclei results in the production of neutrons. Radium-beryllium neutron sources produce neutrons whose kinetic energy is about 4.8 MeV. With the availability of various isotopes of plutonium, plutonium-beryllium neutron sources have become available.

Although ^{235}U can fission at most neutron energies, it has a higher probability of causing fission when the incident neutrons have energies of about 0.025 eV. ^{238}U, on the other hand, will only fission with neutrons greater than 0.68 MeV. The probability of fission occurring in ^{238}U at energies greater than 0.68 MeV is considerably less than the fission of ^{235}U at 0.025 eV. The reason that the compound nucleus ^{236}U, which is formed by the absorption of a neutron by the ^{235}U nucleus, fissions is that the binding energy for the ^{236}U nucleus is less than the energy of the combined ^{235}U nucleus and neutron. The same is true for such isotopes as ^{233}U, ^{239}Pu, and ^{241}Pu, which are also fissile isotopes.

The breakup of the nuclei in the ^{235}U fission process produces on the average 2.44 neutrons and two nuclei, each having about half of the atomic mass of the original nuclei. The neutrons that are emitted at fission have a distribution of kinetic energy, as shown in Fig. 3, with an average value of 1.98 MeV. The technical problem in designing a self-sustaining reactor system is how to slow the neutrons to about 0.025 eV without the neutrons leaving the system or being absorbed by some other non-fissioning nuclei.

In addition to neutrons causing fission in ^{235}U or other isotopes, there are other reactions such as capture, elastic and inelastic scattering, and alpha, proton, or two-neutron production that can occur. Illustrations of absorption cross section values for various

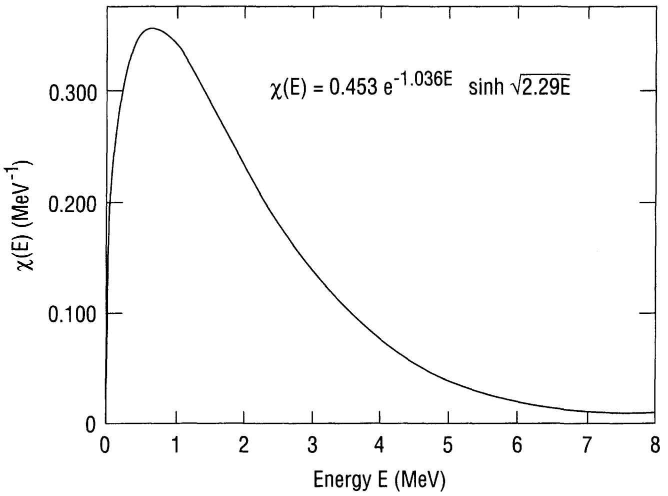

FIG. 3. Prompt neutron spectrum from fission.

isotopes at incident neutron energies of 0.025 eV are given in Table 2. The interaction of neutrons with different isotopic nuclei varies with the nuclei as well as with the energy of the incident neutrons.

Illustrations of the total neutron cross sections for ^{238}U and fission cross sections for ^{235}U nuclei are shown in Figs. 4 and 5, respectively. Typical neutron parameters for ^{235}U and ^{239}Pu are given in Table 3. Although ^{235}U fission has been used as an illustration in this discussion, isotopes such as ^{233}U and ^{239}Pu will also fission with neutrons at thermal energies. These isotopes do not exist in nature in any significant quantitites since they have shorter half-lives than ^{238}U and ^{235}U and have decayed since the beginning of the universe. Both ^{233}U and ^{239}Pu have been made in large quantities through the use of reactors.

Table 2. Thermal absorption cross sections of typical isotopes at $E = 0.025$ eV.

Isotope	Cross section (b)
^{1}H	332×10^{-3}
^{2}H	0.53×10^{-3}
^{6}Li	940
^{7}Li	37×10^{-3}
^{10}B	3837
^{11}B	5.5×10^{-3}
^{12}C	3.4×10^{-3}
^{54}Fe	2.25
^{197}Au	98.8
^{232}Th	7.4
^{235}U	680
^{238}U	2.7
^{239}Pu	1011

It can be seen from these illustrations that there are two components to the cross sections: a smoothly varying 1/v component and a resonance structure component. Single-level and multilevel resonance formulations based on the Breit–Wigner resonance formula have been developed to fit the resonance structure. The single-level Breit–Wigner resonance formula for neutron capture is

$$\sigma_c = \frac{\lambda_r^2 g}{4\pi} \frac{\Gamma_n \Gamma_\gamma}{(E - E_r)^2 + \Gamma^2/4},$$

where σ_c is the capture cross section of the resonance at energy E_r, λ_r is the wavelength of the neutron with energy E_r, g is a statistical factor, Γ_n and Γ_γ are the neutron width and radiation width, respectively, and Γ is the total width of the resonance at one-half its height.

Measurements, evaluations, and compilations of neutron cross sections for different reactions as functions of incident neutron energy for most isotopes have been carried out. In the United States, the National Nuclear Data Center (NNDC) at BNL is responsible for the compliation of neutron cross sections and resonance parameters for all isotopes. The NNDC has developed a CSISRS (Cross Section Information Storage and Retrieval System), which is an automated compilation of unevaluated experimental data. Originally, NNDC developed the Evaluated Nuclear Data Files (ENDF) A and B. ENDF/A contains both complete and incomplete data sets for many

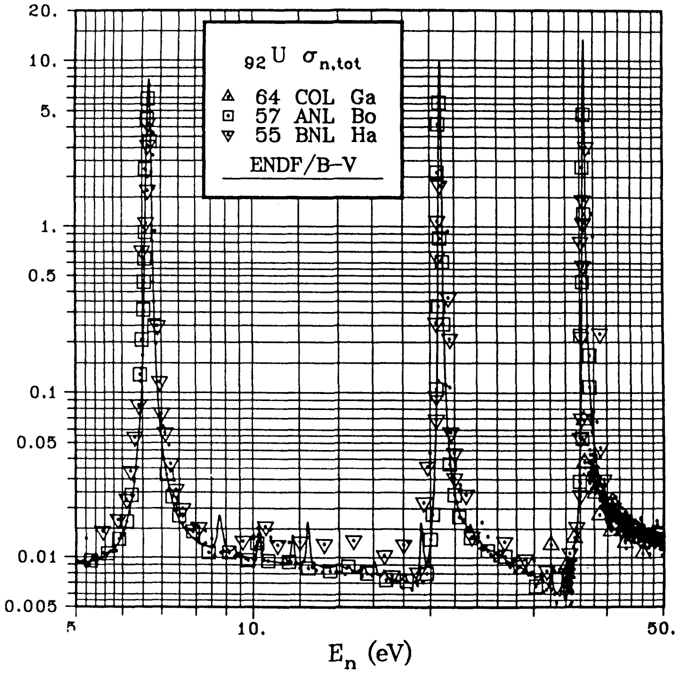

FIG. 4. Total cross section for ^{238}U

isotopes. ENDF/B, on the other hand, contains a unique complete cross section set needed for reactor design. Today, ENDF/B is the principal repository for evaluated neutron-induced–reaction data in the energy range from 10^{-5} eV to 20 MeV. The evaluation of the data for ENDF/B is carried out by the Cross Section Evaluation Working Group (CSEWG), a cooperative effort by technical experts from national laboratories,

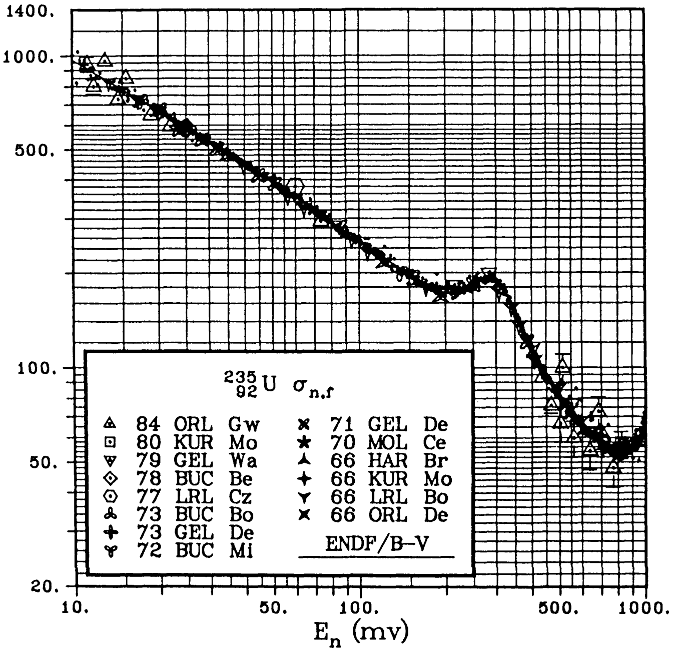

FIG. 5. Fission cross section for ^{235}U.

Table 3. Neutron parameters for ^{235}U and ^{239}Pu.

	Thermal $E = 0.025$ eV		Fast $E = 2$ MeV	
	^{235}U	^{239}Pu	^{235}U	^{239}Pu
Fission cross section (b)	582	742	2.7	2.2
Capture cross section (b)	98	269	1	0.71

No. of neutrons/capture	2.068	2.108	2.21	2.60
Fraction of delayed *n*'s	0.0065	0.0021	0.0064	0.00206

industry, and academia. The ENDF/B file and other data sets, in addition to being accessible on-line via computer terminals have been published by the NNDC (Mughabghab *et al.*, 1981; McLane *et al.*, 1988). The ENDF/B neutron cross section files are used extensively in reactor physics calculations to calculate fundamental parameters, such as critical mass and power distributions, for reactors. Measured cross sections and evaluations are routinely exchanged with nuclear data compilation centers in Europe, the Former Soviet Union, Japan, and China. Periodically, conferences are held among technical experts in nuclear data to exchange data, methods for evaluation, and low-energy nuclear theory.

When a low-energy neutron interacts with a ^{235}U nucleus and causes fission, on the average, 2.44 neutrons are emitted instantaneously and a small number of neutrons are emitted a fraction of a second or seconds later from the decay of unstable fission-product nuclei. These delayed neutrons enable us to control the chain reactions in fission reactors more easily. The total energy released during fission is on the average about 200 MeV, which includes the contributions from gamma rays, kinetic energy of the fission products, and neutron kinetic energy. It is this energy that is utilized for the generation of heat, which is subsequently converted to electrical power.

3. REACTOR DESIGN

Since 2.44 neutrons are produced on the average whenever the ^{235}U nuclei fissions, it is possible to have a continuing chain of fission events if at least one of the neutrons produced at fission causes fission in another ^{235}U nucleus. The job of a reactor designer is to maximize the probability of neutrons born in fission to survive and cause fission in a ^{235}U or other fissile nucleus by

a. minimizing the probability of a neutron leaving the system;
b. minimizing a neutron from being captured by nonfissile nuclei;
c. maximizing a fission event occurring by increasing the number of ^{235}U or other fissile nuclei per unit volume; and
d. slowing down the average velocity of the neutrons from that at 1.98 MeV to 0.025 eV.

The designer does a trade-off study of these four approaches in designing a reactor. To minimize the probability of a neutron escaping the system, the designer can surround the reactor core, which contains the fissile and moderator materials, with a reflector consisting of material that has a large scattering cross section and a low absorption cross section. Materials such as water, graphite, beryllium, iron, or stainless steel have been used as reflectors. To minimize the probability of a neutron being captured by nonfissile nuclei, it is necessary for the designer to use low-absorption materials that have high strength at operating temperatures, such as aluminum or zirconium for structural and fuel cladding materials, to minimize the amount of nonfissile material utilized. To increase the number of fissile materials per unit volume, the designer would have to use as high a density as possible of fissile materials, generally metals or oxides, with uranium enriched in the ^{235}U isotope. Increasing uranium enrichment increases the cost of the material as well as fabrication costs because of production and materials accountability issues. Finally, the designer selects the operating neutron energy spectrum of the reactor, which determines the type of coolant and moderator used. For a thermal energy spectrum reactor, whose average neutron energy is around 0.025 eV, the designer has the choice of moderating materials such as water, heavy water, and graphite. If water or heavy water is chosen, these fluids can also act as coolants or heat removal fluids at the same time. If beryllium or graphite is chosen as moderator, gases such as helium or liquids such as water could be selected as the coolant.

Some of the essential parameters that a reactor designer must determine by analysis so that the reactor can be started up, maintained at steady-state operation over its lifetime, and shut down as required are listed here:

1. Criticality: A reactor is said to attain criticality when the chain reaction in the system is self-sustaining.
2. Critical mass: The amount of fuel required to maintain a steady-state or self-sustaining chain reaction.
3. Multiplication: The ratio of the number of neutrons in one generation over the number in the previous generation is defined as the multiplication of the system and is usually designated by k. When $k = 1$, the reactor is said to be critical. The ratio of the change in multiplication, due to effects such as fuel or control-rod movement, material density changes resulting from temperature change, or fissile material depletion or buildup, to the multiplication itself ($\Delta k/k$) is called the reactivity of the system and is a measure of the supercriticality or subcriticality of the system.
4. Power distribution: The spatial distribution of heat energy generation throughout the reactor core and reflector as a function of fuel burnup.
5. Control worth: The amount of neutron absorber materials, such as boron, cadmium, etc., in solid or in liquid solution required in the core to control the reactor. The absorber materials are often called poisons since they tend to terminate the chain reactions. Absorber material, such as soluble burnable poisons, is introduced into the coolant at the initial stages of a new core to balance the later buildup of fission product poisons.
6. Temperature effects on operation: The effect on reactivity due to changes in the system due to temperature effects is called temperature coefficient of reactivity. Temperature effects on the system can be due to thermal expansion of fuel and structural materials, density changes in materials such as fuel and coolant due to temperature, and changes in the width of neutron resonance cross sections for the fertile and fissile material resulting from the Doppler effect.
7. Fuel burnup: The destruction of the fissile isotopes due to fission is called burnup.
8. Fission product production, which introduces absorption into the reactor core.
9. Kinetic parameters, such as neutron lifetime and effective delayed neutron fraction, for prediction of the transient behavior of the reactor under normal and abnormal conditions.
10. Effects of radiation damage on reactor core materials.
11. Radiation levels from direct core radiation, and activation of coolants and coolant impurities.

To give the reader an idea of how a reactor is designed, a brief description of the thinking process that a designer undertakes in reactor design is presented. Assuming that only purified natural uranium metal is available to the designer, he would have to select a neutron-moderating material that would have the smallest capture cross section and at the same time would have the largest slowing-down potential per collision. The average logarithmic fractional loss in energy due to an elastic collision of the neutron and a nuclei is given by

$$\xi \equiv \ln \frac{E_1}{E_2} = 1 + \frac{\alpha}{1-\alpha} \ln \alpha,$$

where

$$\alpha \equiv \left(\frac{A-1}{A+1}\right)^2 .$$

Here, A is the atomic mass of the scattering nuclei, E_1 is the energy of the incident neutron, and E_2 is the energy of the neutron after scattering. Some of the scattering properties for the lighter elements are given in Table 4. It can be seen that the designer has choices among heavy water (D_2O), graphite, and beryllium for a nuclear reactor using natural uranium. Of these, purified graphite is the most plentiful, least expensive, and easiest to manufacture. D_2O is very plentiful; however,

Table 4. Scattering properties of various materials.

Element	Mass no.	Average change in lethargy	Average number of collisions to 1 eV from 2 MeV
H	1	1.0	15
D	2	0.726	20
Be	9	0.207	70
C	12	0.158	92
O	16	0.120	121
U	238	0.0083	1700

it would require an isotope-separation plant to separate the D_2O from H_2O since D_2O constitutes only 1.5% of ordinary water in nature.

Now that the designer has selected graphite as the moderator and natural uranium metal as the fuel, he must choose the shape and dimensions of the fuel. Depending upon the purpose of the reactor (i.e., research, electrical power generation, or material production), the designer must decide upon the total amount of power to be generated by the reactor and its power density. He must also decide the type of cladding that the uranium metal fuel will require. The cladding is to prevent the oxidation of the uranium as well as to contain the fission products and avoid possible chemical interactions of the uranium with the coolant. The choice of a cladding material is determined by the desired operating temperature and the neutronic and structural properties of the proposed cladding material. The cladding material must be able to maintain its strength at operating temperatures as well as be able to withstand radiation damage due to neutron interactions with the cladding material during the lifetime of the fuel in the reactor. The fuel cladding material and the structural material must be chemically compatible with the proposed coolant. In order to minimize parasitic neutron losses to the cladding material, it is desirable to use materials such as aluminum or zircaloy, a zirconium–aluminum alloy. High-strength materials such as stainless steel would not be acceptible for natural uranium reactors because of high neutron capture cross section unless the designer decided to use higher enriched uranium as fuel. Even zirconium would have to be highly purified in order to remove the small amount of hafnium that normally occurs with zirconium, since hafnium has very large absorption resonances.

Assume that the designer has selected air as the coolant and aluminum as the cladding material. He must decide upon the shape and dimensions of the fuel and the cladding thickness. Uranium metal must be cast and machined in an inert atmosphere, since uranium metal is pyrophoric and will oxidize very rapidly in air. The designer must also conduct many reactor physics analyses to determine the shape and amount of fuel that must be embedded in the graphite in order to make a self-sustaining chain reaction of fission events.

Earlier, a chain reaction was described as one initiated by a neutron from a neutron source or cosmic-ray event causing a chain reaction by producing a fission event in a ^{235}U nucleus, which in turn produced neutrons that again caused fission in another ^{235}U nucleus. The occurrence of many parallel chain reactions without dying out gives rise to a self-sustaining nuclear reactor.

The self-sustaining chain reactions may be described quantitatively by the multiplication factor, k. If k is greater than 1, the number of fissions is increasing from one generation to another, which would mean that the total number of fissions in the system or reactor is increasing, therefore, the total power (energy being generated) of the reactor is increasing. If k is less than 1, then the power of the reactor is decreasing and the chain reactions will be terminated and the reactor is said to be shut down. If k is exactly equal to 1, the reactor is said to be stable and at a constant power level. The operator of a reactor must, therefore, bring together enough fuel in the form of ^{235}U or other fissile material and moderator material and remove any absorbing materials that might be used as control rods in order to achieve a $k = 1$ critical system. In order to be able to control the reactor, the designer will have designed into the reactor control rods, which consist of removable neutron absorber material such as boron, or cadmium. The operator attains criticality ($k = 1$) by the removal of the control rods after the reactor has been loaded with fuel. After attaining criticality, the operator can reach an operating power level by removing additional control rods, making the reactor supercritical, or $k > 1$. As the total power generation of the reactor is increased, the operator must now introduce coolant into the reactor to remove the heat generated. The operator balances the heat-removal capability of the system to the heat generation of the reactor. When the heat removal from the reactor is balanced with the heat being generated, the operator then inserts control rods so that $k = 1$ and the reactor operates at constant power. To shut down the reactor, the operator inserts the control rods so that $k < 1$ and the chain reaction is terminated.

The multiplication factor and other reactor parameters, such as power distribution, neutron flux distribution, etc., of a system can be analytically calculated by using the Boltzmann neutron transport theory to describe the geometry and material composition of the system (Lamarsh, 1977; Bell and Glasstone, 1970). The simplest approach would be to use a one-dimensional, one–energy-group diffusion-theory approximation to the Boltzmann transport equations to calculate the k of a system. If fission neutrons were born at thermal energy instead of with a distribution with an average energy of 1.98 MeV, it would be possible to describe a reactor analytically with a one–energy-group diffusion theory, where the rate of change with time of number of neutrons in a system is equal to the production of neutrons minus the leakage and the absorption of neutrons in the system.

Unfortunately, since fission neutrons are born with a continuous energy distribution up to about 10 MeV with an average energy of 1.98 MeV, it is necessary to solve multiple–energy-group transport or multiple–energy-group diffusion-theory equations to determine the reactor-physics parameters. In addition to being multiple-group, these equations may have to be multidimensional in order to describe a complex geometry system. Such systems of multidimensional, multiple-group partial differential equations were initially solved using finite-difference methods using fast, large-memory, mainframe computers. Today, diffusion-theory equations are usually solved using various nodal methods, while transport-theory equations still use finite-difference methods. Examples of reactor physics computer codes that numerically solve the diffusion- or transport-theory equations are given in Table 5 (National Energy Software Center, 1991). As work stations have become more powerful with larger memories and with higher computational speeds, many reactor physics computer codes have been adapted for use on work stations.

Table 5. Examples of reactor analysis computer codes.[a]

Title	Description
	Cross section generation
NJOY	Nuclear data processing code system for producing pointwise and multigroup neutron and photon cross sections from ENDF/B data.
	Static design studies
TWODANT	One and two-dimensional, multigroup, discrete-ordinates transport theory code.
1DB	One-dimensional, multigroup diffusion theory code.
3DB	Three-dimensional, multigroup diffusion theory code.
	Space-time–dependent kinetics
DIF3D	Three-dimensional, multigroup diffusion-theory, time-dependent code.
	Monte Carlo
MCNP	Monte Carlo neutron and photon transport code.

[a] For additional reactor codes, see Radiation Shielding Information Center (1993) or Energy Science and Technology Software Center (1993).

In the diffusion-theory approximation, the neutron is considered as a function of space and energy only. Because there is an angular dependence of elastically and inelastically scattered neutrons, it is necessary to take into consideration this angular dependence for accurate analysis. Simplifying assumptions in the usual diffusion equations introduce inaccuracies near interfaces of the reactor core with vacuum or at core-reflector, core-control rod, or core-blanket interfaces. Interfaces of the core and strongly neutron-absorbing media and fuel and coolant cells are also difficult to model accurately. In such cases, differential transport (Boltzmann equation) theory models, which include higher order angular elastic scattering effects, are used.

In order to determine the k of a system, it is first necessary to develop averaged group cross sections for each energy group that is planned to be used for the diffusion- or transport-theory equations. The averaged group cross sections are developed by averaging the microscopic cross sections in the ENDF/B file over an energy spectrum in each energy group. Computer codes such as NJOY (RISC Software Directory, 1993) may be used to generate the group cross sections. Of course, increasing the number of energy groups increases the complexity of the computation and the computer time required for the solution of the problem. Following the generation of the group cross sections, reactor-physics computer codes, as shown in Table 5, are used to calculate the reactor-physics parameters needed in the design, such as the multiplication, power distribution, etc.

Neutron movement from production, through migration, to absorption or leakage from the system can be considered a stochastic process or a random-walk process with a probability distribution for each type of interaction, such as angular scattering, energy loss or gain, or fission neutron energy, in the system. A process of following the transport of neutrons stochastically in the reactor system has been developed and is called the Monte Carlo method. This method essentially follows the life of a single neutron until it is absorbed or leaks from the system. Neutrons that are produced as a result of fission from this neutron are also followed as a chain of events or reactions. It is necessary to follow the history of many hundreds of thousands of initiating neutrons in order to obtain a statistically meaningful value for the multiplication constant or other physics parameter. Computer codes such as MCNP (Briesmeister, 1986) have been developed using the Monte Carlo method to model complex-geometry reactor systems. In order to model reactor systems accurately, it is necessary that a sufficient number of neutron interaction histories be calculated. The Monte Carlo method is a large consumer of computing time on the fastest mainframe computer, so that obtaining a million histories to achieve a convergence of k to $\pm 0.1\%$ is very time-consuming and expensive. With the advent of parallel computers and fast and relatively inexpensive work stations, using the Monte Carlo method to solve the neutron-transport problem has become routinely possible. It is anticipated that, in the near future, a fast parallel computer having 1000 or more parallel computing units could produce 10^7 to 10^9 histories in a short time. The reactor designer will then be able to carry out more accurate design analysis of complex reactor systems less expensively.

The use of diffusion or transport equations, discussed above to describe a reactor, results in a description of the steady-state condition of the reactor. In the steady-state condition, the neutron flux is independent of time and only a function of position in the reactor. The total power generated in the reactor is determined by integrating over space and energy the neutron flux, the number of fissile atoms, and their fission cross section. The reactor can be critical at any power level from a few microwatts or milliwatts to many thousands of megawatts provided that the heat generated is removed from the reactor to avoid melting of the fuel. The power level of the reactor is controlled by inserting or removing neutron absorbers from the reactor. Decreasing the neutron absorbers in the reactor will increase the k_{eff} so that, when the multiplication becomes greater than 1, the neutron flux will start to increase exponentially. The fact that some of the neutrons produced at fission are delayed and are not emitted instantaneously allows the reactor power to be increased slowly under control. It would be difficult without delayed neutrons to control the reactor, because the reactor power would increase very quickly exponentially with a short reactor period when the multiplication became greater than one. The reactor period is defined as the time required for the power to increase by a factor e. The rate of increase of the neutron density is a function of the prompt-neutron lifetime of the system and the degree to which k_{eff} is greater than 1.0. The prompt-neutron lifetime, l_p, is the average time elapsed between the time when the neutron is born at fission and the time it is absorbed or lost out of the reactor. It can be considered as having two components: the time it takes for the neutron to be slowed down to thermal energy from fission energy and the time it takes for the neutron to diffuse and become absorbed or lost out of the reactor. The slowing-down time is much smaller than the diffusion time, so that the prompt-neutron lifetime may be equated to the diffusion time. The prompt-neutron lifetime for thermal reactors can vary from a few tenths of a millisecond to over a hundred milliseconds, depending on the moderator. The neutron lifetime for fast-spectrum reactors is in the range of a few tenths of microseconds to a few microseconds.

In a thermal reactor, where most of the fissions occurring in the reactor are from ^{235}U, the fraction of delayed neutrons is approximately 0.0065. When the k_{eff} is >1.0 but <1.0065, the reactor is said to be delayed critical and the reactor power will increase with a period of seconds to minutes. An illustration of how rapidly the reactor power would increase is shown in Table 6, where the reactor period is given as a function of neutron lifetime and the reactivity of the system. When k_{eff} is >1.0065, the reactor is said to be prompt critical and the reactor power will increase exponentially with a very short period, as can be seen in the last line of Table 6. The rate of increase of the reactor power above prompt critical is dependent on the degree of prompt criticality and the neutron lifetime of the system. The reactor that becomes prompt critical will increase its power level by many orders of magnitude in a very short time until other mechanisms, such as temperature effects or destruction of the core configuration, terminate the reactor power excursion.

The k_{eff} of the reactor at any given time is determined by the geometry and the materials in the reactor, as well as the temperatures of the fuel, moderator, and coolant of the reactor. The temperature changes the density of the materials as well as their position in the reactor and, hence, the k_{eff} of the system. An increase in temperature also changes the effective width and height of the resonance cross sections in such materials as ^{238}U and ^{235}U through the Doppler effect. This effect increases the number of resonance level neutrons absorbed in these materials. An increase in ^{238}U absorptions would tend to decrease the reactivity, while increasing the number of fissions in ^{235}U would tend to increase reactivity. This change in reactivity due to the broadening of the resonance levels by a change in fuel temperature is called the Doppler temperature coefficient. The reactivity effect due to the creation of voids in the coolant due to vaporization of the coolant is called the void coefficient of reactivity. In calculating changes in power level due to changes in reactivity, it is necessary to take into consideration the reactivity coefficients due to such effects as Doppler, void formation, expansion effects, and density changes.

The reactor designer must choose the appropriate geometries and materials for the reactor core so that it will have an overall negative power reactivity coefficient, so that when the power increases the reactivity of the reactor decreases. Usually, for thermal reactors, where the ^{235}U enrichment is only a few percent, the ^{238}U Doppler effect will provide a negative Doppler fuel-temperature coefficient. The coolant or moderator void coefficient could be positive or negative depending on the degree of moderation. In the western world, LWRs are designed with a negative void coefficient so that the reactor's reactivity will decrease with an increase in power due to decreasing moderator density and increasing fuel temperature. On the other hand, the Soviet-designed RBMK, a graphite-moderated, light-water–cooled reactor, had a positive void coefficient of reactivity, which led to the catastrophic Chernobyl-4 accident.

The study of the behavior of the time variation of the neutron flux when the multiplication is greater or less than unity is called reactor kinetics. To calculate accurately the neutron flux when the reactor becomes superdelayed critical or subdelayed critical, it is necessary to solve a time-dependent diffusion or transport set of equations. For simple geometry systems, it can be assumed that the spatial and energy distribution of the neutron flux does not change with time. This significantly eases the effort to calculate the neutron flux change with time. It is, however, necessary to take into consideration the fact that the rate of emission of delayed neu-

Table 6. Reactor period (s) for various values of reactivity for ^{235}U system.

Reactivity	Lifetime = 10^{-3} s	Lifetime = 10^{-4} s	Lifetime = 10^{-5} s
0.001	60	60	60
0.003	10	10	10
0.004	3.5	2.5	2.5
0.007	0.8	0.2	0.14
0.010	0.3	0.04	0.0003

trons falls into six different time-decay groups, each of which is characterized by a definite exponential decay rate. The average energy of the delayed neutrons emitted is also substantially lower than the average prompt neutron energy at fission. The variation of the neutron flux with time is calculated by solving the point reactor kinetics equation (Glasstone and Sesonske, 1987), which incorporates the effects of the six groups of delayed neutrons.

In complex-geometry reactor systems where there is asymmetry in reactivity changes due to nonuniform control rod movements or temperature effects, it may be necessary to use one-dimensional or multidimensional kinetics equations in order to analyze power transients accurately. Large neutron flux asymmetries due to nonuniformities in neutron absorber distribution or spectral changes due to temperature effects require the use of multidimensional and multiple–energy-group time-dependent solutions of the transport equations for transient analysis. The transient excursion of the Chernobyl-4 reactor is a good example of a transient that requires the solution of such multidimensional, time-dependent equations.

4. POWER REACTORS

The development of ^{235}U enrichment production plants during World War II made possible the development of large nuclear power plants for electricity generation in the 1950s and 1960s because of the availability of large quantities of enriched uranium. Although highly enriched uranium or 93% ^{235}U was used primarily for weapons and naval reactors, enriched uranium also became available for the development of research, test, and demonstration power plants. Eventually in the United States, the utility and reactor vendor industry settled down on the choice of either boiling-water or pressurized light-water reactors using 2–5% ^{235}U-enriched uranium oxide fuel. The light-water reactors have become the predominant type of reactors used for electric power generation in the world. In the late 1960s through the 1980s, GE was the BWR manufacturer in the United States, while Westinghouse, Combustion Engineering Co., and Babcock and Wilcox were the PWR manufacturers. Since the early 1980s, only Westinghouse, GE, and ABB (ASEA Brown Boveri) Combustion Engineering have remained in the reactor vendor business. Combustion Engineering was taken over by ABB, which formed ABB-CE.

In 1991, there were approximately 111 nuclear power plants licensed to operate in the United States with a total operating capacity of 101 GW(e), which resulted in about 22% of the total electricity being generated from nuclear plants. There are nuclear power plants operating in 32 countries worldwide, which supply more than 17% of the world's electricity. In 1992, there were at least 411 reactors with a net electrical power capacity of over 320 GW(e). In 1991, France generated 72.7% of its electricity from nuclear plants, as compared with Belgium with 59.3%, and Sweden with 51.6%. A list of nuclear capacity, in countries worldwide, is shown in Table 7.

As of 1992, there were 237 PWRs [207 GW(e)] and 88 BWRs [72 GW(e)] out of a total of 411 nuclear power plants in worldwide operation. In both categories, ordinary water is used as moderator and coolant. The fuel is uranium dioxide enriched in ^{235}U content to between 2.5 and 5%. In the BWR case, the coolant pressure and temperature are such that water is in a boiling state as it exits from the core region, and steam is directly passed into a turbine for electric power generation. A schematic diagram of a BWR is shown in Fig. 6. A detailed schematic of the reactor portion is shown in Fig. 7, followed by a schematic arrangement of the steam supply system in Fig. 8.

In the case of the PWR, high coolant pressures are maintained so that water does not reach the boiling temperature and the heated water is fed directly into a steam generator. The secondary side of the steam generator produces steam, which is then fed into a turbine for electricity generation. A schematic diagram of a PWR is shown in Fig. 9. A schematic diagram of the reactor coolant system for a four-loop PWR is shown in Fig. 10, while the details of the core of a PWR are shown in Fig. 11. A typical PWR fuel assembly is shown in Fig. 12, while a steam-generator cross section is shown in Fig 13.

The Soviet Union developed light water reactors designated VVER, which are similar to the western pressurized-water reactors.

Table 7. World commercial reactors in 1991.

Country	Number of operating reactors	Capacity [GW(e)]	Electricity generation % nucl., 1990
S. Africa	2	1.8	5.6
Argentina	2	0.69	19.8
Belgium	7	5.5	60.1
Brazil	1	0.62	1.0
Bulgaria	6	3.7	35.7
Canada	20	14.0	14.8

Significant differences between the early VVERs and the western PWRs include the lack of a containment, the lack of multiple-loss-of coolant emergency cooling systems, and horizontal steam generators. Containment buildings are constructed around the newer VVERs.

Three other types of reactors have been built in western countries for electric power generation. These include the CANDU, a heavy-water–moderated, heavy-water–cooled tubular reactor designed and built by Atomic Energy of Canada, Ltd. (AECL), and a high-temperature gas-cooled reactor (HTGR) built by General Atomics Corporation of San Diego, California, which is shown schematically in Fig 14. Liquid-metal–cooled reactors (LMRs) (Waltar, 1981) have been built by ANL (EBR-I and EBR-II), GE (SEFOR), and Westinghouse (FFTF) (Peckinpaugh, 1982, 1986). A schematic view of a liquid-metal–cooled reactor (LMR) is shown in Fig 15.

The liquid-metal–cooled reactors designed and constructed by ANL, under the sponsorship of the Atomic Energy Commission, are based upon a metallic fuel element with a sodium-potassium (NaK) alloy as coolant for the EBR-I and sodium as coolant for the EBR-II. Both EBR-I (Lichtenberger *et al.*, 1955) and EBR-II (Lentz *et al.*, 1986) were built at the National Reactor Testing Station (NRTS) in Idaho. The EBR-I had a small compact core and produced 1.2 MW of heat energy. The NaK alloy conducted heat away from the reactor core to a steam generator, where the heat energy produced steam. A small turbine produced about 200 kW of electricity in EBR-I. EBR-I operated with neutrons whose spectrum had an average energy of about 100 keV as opposed to thermal reactors whose average neutron energy is 0.025 eV. In addition to demonstrating the possibility of electricity generation, EBR-I showed that it was possible to produce more plutonium than the amount of ^{235}U consumed. It was a converter of ^{238}U atoms into plutonium, ^{239}Pu, with a conversion ratio of a little greater than 1.0. The conversion ratio, or the breeding ratio, is defined as the ratio of the average of number of fissile atoms pro-

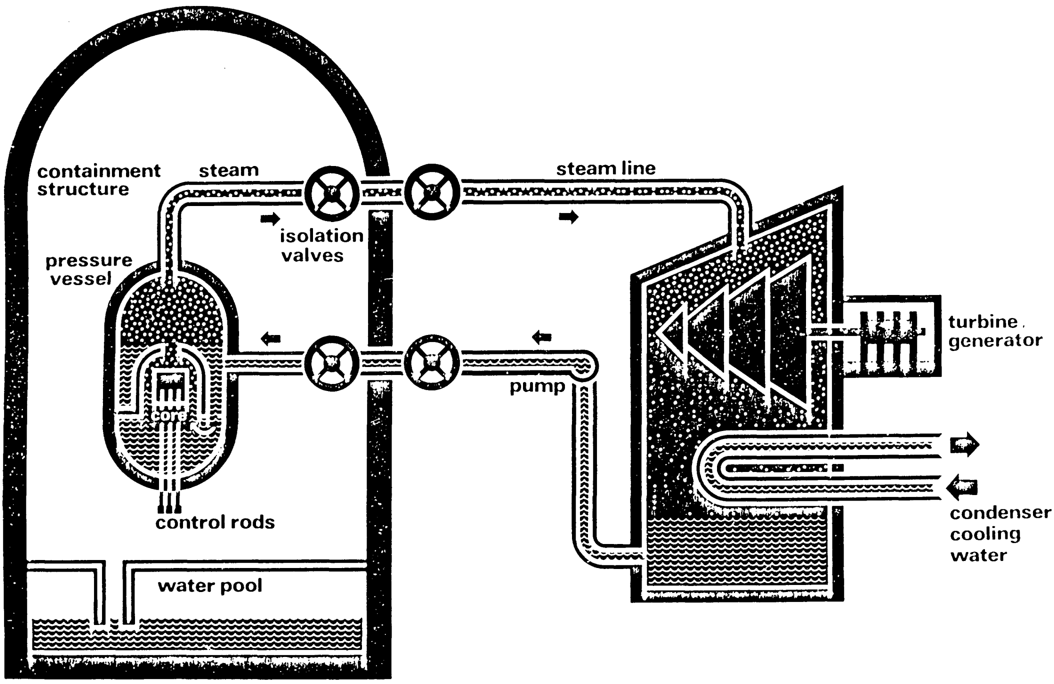

FIG. 6. Schematic diagram of BWR.

duced per fissile atom consumed in the reactor. When the new fissile atoms produced are different from the fissile atoms consumed, the reactor is said to be a converter, while if the new fissile atoms are the same as the fissile atoms consumed, the reactor is said to be a breeder reactor. Since ^{235}U constitutes only 0.72% of natural uranium, a breeder reactor could utilize the remaining ^{238}U to produce fissile atoms. During the early development of the nuclear industry, it had been forecast that there would be many 1000 MW(e) nuclear power reactors in operation. It was anticipated that these thermal reactors would consume the world's available ^{235}U in about half a century, indicating the necessity for near-term plutonium breeder reactors in order to maintain the nuclear option. Following the accident at the Three Mile Island–2 (TMI-2) nuclear power plant in April 1979, there was a considerable slowdown in the construction of power plants, because it was necessary for the existing plants and plants under construction to meet additional regulatory requirements. This gave rise to significant construction cost increases as well as operation and maintenance costs. As of 1993, there had been no new orders for nuclear power plants in the United States since 1978 because of a number of factors including no urgent need for additional generation capacity, the uncertainy in financing large capital projects, the uncertainty in regulations, and increased public opposition.

The FSU, in addition to the VVER series, which is similar to the western PWRs, built the RBMK type of power generation plant, which is a variation of their plutonium production reactor. It is a graphite-moderated, light-water–cooled, boiling-water, channel-type reactor. The Chernobyl-4 reactor, which exploded catastrophically in April 1986, is a typical RBMK-type reactor, which generated about 1000 MW(e). Instead of the reactor being contained in a thick pressure vessel, fuel elements were located in 1661 vertical high-pressure pipes or tubes. The reactor is designed so that water reaches saturation temperature about $\frac{1}{3}$ of the way up the channel with nucleate boiling in the remaining $\frac{2}{3}$ of the channel. The fuel was 2% enriched uranium oxide clad with zirconium containing 1% niobium. It was designed so that it could have on-line refueling, thus increasing its op-

erating capacity. Its inlet temperature was 270° C and average outlet temperature was 284° C, with an operating pressure of 986 psig. Although the reactor itself was contained in a steel compartment, the entire reactor did not have a containment building in the Western sense. The RBMK was also designed with a positive void coefficient of reactivity, as well as having a control-rod design such that, when the rod was being inserted into the core from its full out position, it would add reactivity instead of decreasing reactivity. Following the accident at Chernobyl, the RBMK reactors were modified so that the insertion of the

5. REACTOR SAFETY

Fissile isotope fuel in commercial nuclear power plants is consumed generating electricity in the range of 30 000 to 50 000 MW-d per metric ton of uranium. The energy produced by the fuel in MW-d per metric ton is a measure of the fuel consumed or burned. Since about a third of the fuel load is replaced per year after a year's operation, there is considerable buildup of fission products in the fuel at any given time. It is essential that these radioactive fission products be prevented from being released to the environment. This is accomplished by maintaining a defense-in-depth concept by, first, using an oxide fuel which has a high melting point. Second, the fuel has zircalloy cladding, which has high heat-transfer characteristics and high mechanical strength. Third, various engineered safeguards are built into the design of the plant to maintain core cooling under most accident conditions. Fourth, the reactor core is placed inside a high-strength pressure ves-

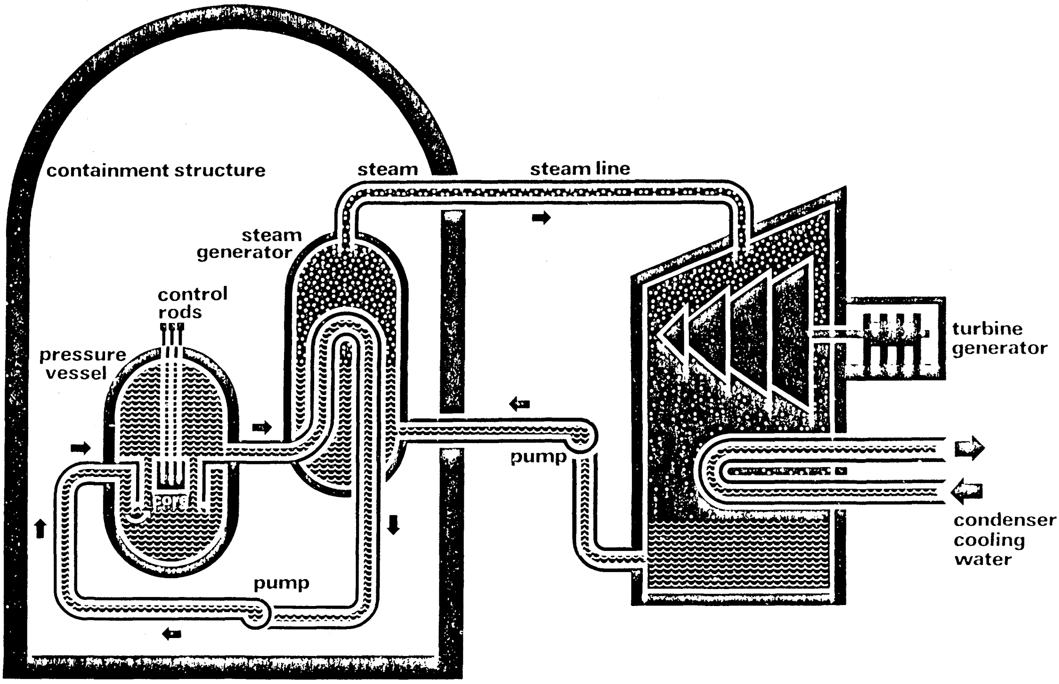

FIG. 9. Schematic diagram of PWR System.

sel and primary circuit. Fifth, the entire reactor and primary circuit are placed inside a steel and/or concrete containment building. Sixth, instrumentation and controls are built into the system so that automatic shutdown of the reactor and automatic operation of the engineered safeguards will take place without operator intervention. Highly trained operators, maintenance personnel, and supervisors complete the safeguards for the safe operation of a nuclear power plant. In addition, the Nuclear Regulatory Commission (NRC) has resident site inspectors at each nuclear power plant to audit the operations of the plant continuously.

It is of interest to consider the engineered safeguards that have been built into the power plant to maintain adequate cooling of the reactor core at all times. Maintaining core cooling of the reactor for a significant period of time after shutdown is important because of the need to remove the decay heat associated with fission product decay.

The engineered safeguards consist of instrumentation and control circuits, redundant heat-removal systems, emergency core-cooling systems, redundant emergency power sources, containment cooling systems, and strong steel and concrete containments. The instrumentation and control system is probably the most important engineered safeguard, since it is through this system that the reactor can be automatically shut down and the operators can detect abnormal situations and take corrective action. Since a reactor can generate more power than its design cooling capability, it is necessary to have instrumentation that continuously monitors the rate of power increase as well as controlling its operating power level. Usually, neutron and fission detectors are used to monitor the rate of change of power as well as the power levels. Neutron detectors are usually ion chambers filled with boron trifluoride gas and operated in an ion-current or pulse mode. Neutrons interacting with ^{10}B produce alpha particles that cause ionization in the ion chamber. Fission detectors are ion chambers filled with argon gas and internal plates or cylinders coated with fissile material. Neutrons causing fission in the ion chamber result in ionization of the gas in the chamber by the fission products. Again, the ionization current in the chamber, which is proportional to the fission

rate, is measured. In addition, instrumentation is available to monitor the distribution of power being generated in the core. Reactors have automatic power trip or "scram" circuits that will automatically cause insertion of the control and safety rods when the power level exceeds preset limits, or when the rate of increase of power exceeds preset limits. There are also temperature gauges that monitor coolant temperatures in various parts of the primary circuit and can also cause reactor scram when the values exceed preset limits. Radiation detectors throughout the containment building and turbine building monitor these areas for possible inadvertent release of radioactivity through leaks in piping coupled with defective fuel cladding or cladding rupture, which would allow fission products to escape from the fuel.

Since it is essential to maintain coolability of the reactor core by avoiding loss of circulation capability or loss of coolant, a number of redundant systems to maintain coolability have been installed in LWRs. The operation of valves and pumps requires electrical power; therefore, off-site power is brought into the plant by two redundant approaches. In addition, a battery system and emergency diesel generators are provided at the power station for operation in the event of loss of off-site power.

In the case of PWRs, which have primary and secondary coolant systems for heat removal, two or more auxiliary feed-water pumps and corresponding feed-water circuits and supply are provided to maintain adequate secondary water supply to the steam generators. During certain modes of normal

operation and in emergency situations, steam can be released to the atmosphere as a heat sink. Two separate emergency core-cooling systems (ECCS) are also provided that can introduce water into the primary circuit. One system is composed of several large-volume accumulators containing borated water, which will automatically supply water to the primary system when its pressure drops below preselected values. A second ECCS system is available, where a pump supplies borated water from a large-volume supply tank. The ECCS was designed to handle large pipe-break loss-of-coolant accidents (LOCA). Since the Three Mile Island Unit 2 (TMI-2) accident in April 1979, where the core was uncovered because of a stuck-open pressurizer valve resulting in a loss of primary coolant water, consideration is also given to the prevention of small-break LOCAs (SBLOCAs). In addition to these mechanisms for heat removal, there is a smaller capacity residual-heat–removal system that is available to the primary system for removing heat from the core after it has been shut down. Since large pumps require their own cooling water for operation, there are redundant service water systems for maintaining the operation of pumps. These varied and redundant safety systems have been introduced to be able to maintain core cooling under all circumstances.

Before a nuclear power station can be constructed and operated, the NRC requires for review and approval technical information about a proposed nuclear power plant, such as detailed descriptions of the site, design of the power plant, operation, maintenance, and management procedures; probabilistic safety assessment; accident analysis, including deterministic normal and abnormal transients;

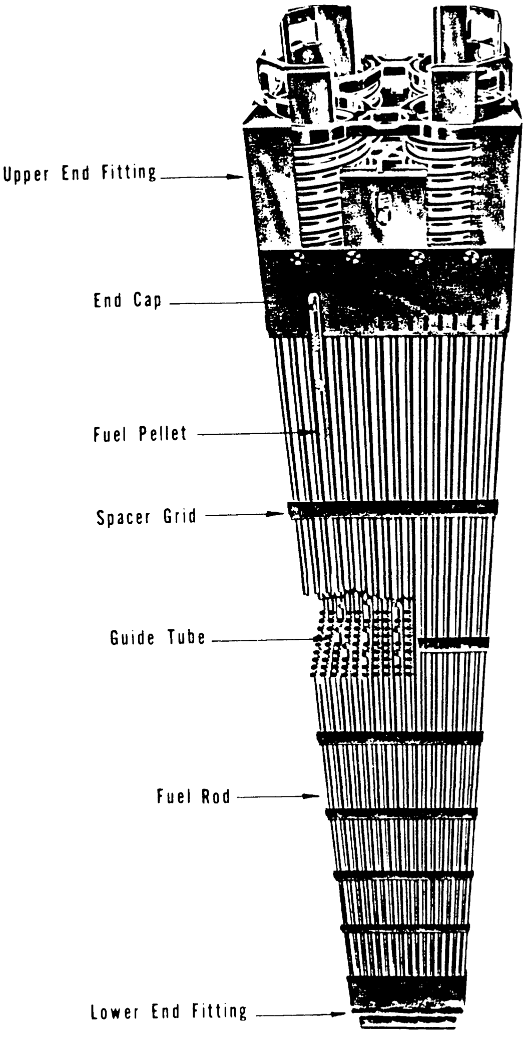

FIG. 12. PWR fuel assembly.

and beyond-design-basis accident analysis. To carry out reactor accident analysis, it is necessary to have an understanding of reactor physics (i.e., neutronics) of the reactor as well as the thermal hydraulics or heat-transfer mechanisms of the plant. In some instances, coupled neutronics and thermal hydraulics analysis is essential for the analysis of transients during operation.

A great deal of LWR safety research under the sponsorship of the U.S. Atomic Energy Commission (USAEC), the U.S. Nuclear Regulatory Commission (USNRC), industry, and the Electric Power Research Institute (EPRI) has been carried out since the late 1960s in the development and verification of complex thermal hydraulics accident analysis computer codes. The RELAP (Ransom *et al.*, 1985, 1987) and TRAC (Schnurr *et al.*, 1992; Borkowski *et al.*, 1992) family of computer codes have been developed by the Idaho National Engineering Laboratory (INEL) and Los Alamos National Laboratory (LANL), respectively, under the sponsorship of the USNRC for the thermal hydraulics analysis of LOCAs and SBLOCAs. RELAP-5, for example, is a complex computer code that solves six thermal hydraulic equations and considers energy, mass, and momentum for water in the liquid and vapor phases for the modeling of various components of the primary and secondary circuits of a PWR. A version of RELAP-5 also exists that can model BWRs. The reactor core is usually modeled on a three-dimensional basis, whereas the remainder of the components are modeled on a one-dimensional basis. Such complex computer codes as RELAP-5 to simulate SBLOCAs have required, until recently, the use of large mainframe computers such as the IBM 3090 or Cray high-speed computers. With the introduction of high-speed and large-memory work stations, such codes as RELAP-5 have been adapted to these smaller computers. A significant amount of experimental work, such as the LOFT (Loss of Flow Test) series of experiments at INEL as well as separate effects experiments, has been carried out to verify RELAP-5 analyses. In addition, international cooperative programs under the leadership of the USNRC for RELAP-5 verification have been carried out by research groups in the European Community, Japan, Korea, and Taiwan.

The TMI-2 accident showed the necessity of improving our understanding of severe accidents, since a large fraction of the core became molten and flowed to the bottom of the pressure vessel. Thermal hydraulic computer codes such as RELAP-5 are adequate for analyzing a transient to the onset of core uncovery but breaks down when there is massive degradation of the fuel. In order to simulate the degradation of the fuel mathematically, computer codes such as MELCOR (Summers *et al.*, 1991) have been developed by Sandia National Laboratory (SNL) and SCDAP/RELAP5 MOD2 (Allison *et al.*, 1989) by the INEL under the sponsorship of the USNRC. MELCOR is an attempt to follow the severe-

accident phenomenon from the overheating of the fuel rods to the molten core slumping to the bottom of the pressure vessel, interacting with the steel pressure vessel, and finally flowing out of the pressure vessel onto the reactor cavity concrete pad beneath the reactor. Core–concrete interaction is then followed by a buildup of pressure and rupture of the containment due to combustion of hydrogen produced from the oxidation of the zirconium of the cladding combined with other phenomena such as direct containment-atmosphere heating by molten-core particles. The rupture of the containment with the subsequent release of fission products to the environment and its consequences are simulated by other computer codes such as the Melcor Accident Consequence Code System (MACCS) (Chanin *et al.*, 1990). Severe-accident analysis is an attempt to provide a quantitative basis to define emergency preparedness and evacuation zones surrounding a nuclear power plant, as well as to determine the design safety margins in the con-

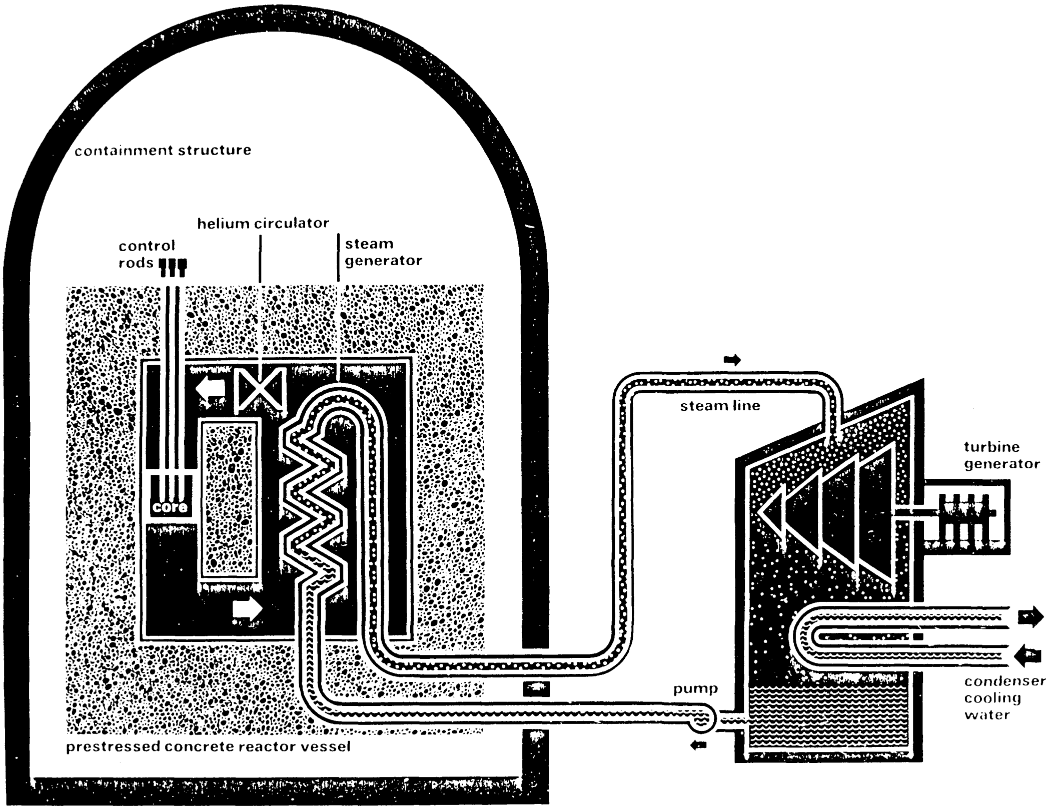

FIG. 14. Schematic diagram of HTGR.

tainment structures and other barriers to fission product release.

Since the mid-1970s probabilistic risk analysis (PRA) (Fullwood and Hall, 1987), more recently called probabilistic safety assessment (PSA), has become a popular way to analyze complete power plants to identify design deficiencies. The approach is to develop fault trees for all of the systems in a plant and to try to quantify overall failure probabilities of systems by providing failure probabilities of components based upon experience. The probability of a core becoming molten, or core melt probability, is calculated. The rupture of containment and resulting release of fission products to the environment can also be calculated on a probabilistic basis. Finally, with use of wind pattern frequencies and other weather statistics and population densities surrounding the plant site, consequences such as deaths and early cancers can be calculated on a probabilistic basis. The first complete analysis of power plants using PRAs was carried out in the Reactor Safety Study, WASH-1400 (NUREG 75/014) in 1973–1975. A more recent study on the assessment of severe accident risks for a set of commercial LWRs in the United States by the USNRC resulted in the report "Severe Accident Risks: An Assessment for Five U.S. Nuclear Power Plants," published by the USNRC as NUREG 1150 in October 1990. Although these studies indicated that the probability of a core melt was in the range of 10^{-5} to 10^{-6} per reactor year with accompanying release of fission products, there has been a significant decrease of public confidence in commercial nuclear power as a result of the accidents at TMI-2 in April 1979 (Rogovin *et al.*, 1980) in the United States and Chernobyl Unit 4 (U.S. Nuclear Regulatory Commission, 1987; IAEA, 1992) in the Soviet Union in April 1987.

In the case of TMI-2 core, uncovery took

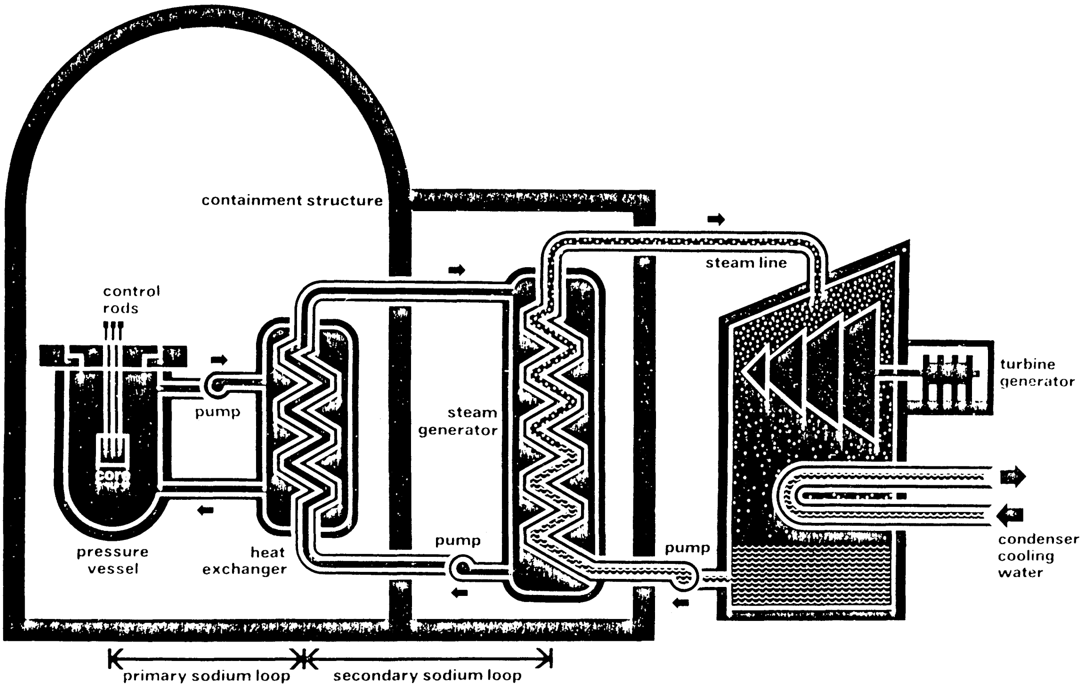

FIG. 15. Schematic diagram of LMFBR.

place as a result of a stuck-open motor-operated pressurizer relief valve coupled with operator errors. As a consequence, a large fraction of the core became molten and settled in the bottom of the pressure vessel. Fortunately, a sufficient amount of core cooling water was poured into the pressure vessel so that the vessel remained intact. Although the core was completely destroyed, most of the fission products were contained in the primary circuit. Some gaseous fission products such as the noble gases and radioiodine were released to the containment building, with only a small quantity of radioactivity being released to the atmosphere and surrounding environment. The report of Rogovin *et al.* (1980) estimates that about 2.4×10^6 Ci of short-lived noble gases and 15 Ci of ^{131}I in gaseous form were released to the environment. Because of the uncertainty in the status of the reactor in the early stages of the accident and media confusion, there was consideration given to large-scale evacuation of the population surrounding the TMI site. However, this was not carried out because the primary circuit and the containment remained intact and most of the fission products were contained. Although the reactor plant was a financial loss and the cleanup required large expenditure of funds, no lives were lost. The probability of any latent cancers has been estimated to be very small, such that it is not possible to distinguish cancers resulting from the accident from cancers due to other sources. A consequence of the TMI-2 accident has been the requirement of an emergency preparedness zone, as well as emergency procedures for evacuation and public notification, around nuclear power plant sites.

The Chernobyl-4 accident, on the other hand, released large quantities of radioactivity to the environment, required significant evacuation of the population around the site, and has taken considerable land out of use because of radioactive contamination of the soil. The Chernobyl nuclear power station is located about 60 miles north of the city of Kiev in Ukraine, one of the former Soviet Union republics. There were four RBMK-type nuclear power plants in operation at the station with an additional two under construction at the time of the accident in April 1986. The Chernobyl-4 accident was a result of design deficiencies and gross operator error. The lack of an adequate containment compounded the consequences because of the release of such long-lived radioactive isotopes as cesium-137 and strontium-90 and short-lived iodine-131 on a worldwide basis in the northern hemisphere. The Chernobyl-4, as described earlier, was a graphite-moderated, light-water–cooled, pressure-tube reactor. Design deficiencies, such as the reactor having a positive coolant void coefficient, control rods adding reactivity when being inserted from their full out position, and reactor instability at low power, coupled with operator error, such as bypassing scram circuits, operating with too many control rods in their full out position, and conducting an experiment without fully understanding the physics and thermal hydraulics of the system, caused the catastrophic accident. Decreasing the flow in the pressure tubes by deactivating the coolant pumps during a special experiment caused water boiling in the core, which resulted in increased reactivity. Power, pressure, and temperature increased. Coupled with the addition of reactivity from control rod insertion, this caused the rupture of pressure tubes, adding further voiding which in turn added more reactivity. The addition of large amounts of reactivity made the reactor superprompt critical, which essentially blew the reactor apart, resulting in molten fuel, fission products, and hot graphite being expelled out of the building and destroying the building structure itself. It has been estimated that about 50×10^6 Ci of noble gases and another 50×10^6 Ci of other radionuclides, which constituted about (3–4)% of the total fission-product inventory, were released to the environment (U.S. Nuclear Regulatory Commission, 1987). The initial wind pattern at the time distributed the fission products and fine vaporized fuel toward the west and northwest. Significant quantities of radioactivity were detected a few days after the accident in Finland and Sweden. Later, winds dropped the fission products in Eastern and Western Europe.

The magnitude of the potential property loss and health effects from the release of large quantitites of fission products and other radioactive reactor components make it mandatory that designers, constructors, operators, and regulators of nuclear power plants take utmost care in carrying out their respective responsibilities, with emphasis on reactor safety, to avoid future release of significant quantities of radioactivity.

6. ADVANCED WATER REACTORS

Since 1985, EPRI has led a utility, government, and industry advanced light-water reactor program. This program includes the simplification of overall design, including the design of passive emergency core-cooling, decay-heat–removal, and containment-cooling systems. The objective of the program is to seek greater safety margins, greater ease of construction, improved reliability and availability, improved maintainability, lower costs, and greater ease of operation over existing large LWRs (Stahlkopf *et al.*, 1988). The U.S. Department of Energy (DOE) since 1986 has had contracts with Westinghouse and GE for the detailed design, development, and certification for the APWR, AP600, and ABWR and the SBWR, respectively. The Westinghouse APWR, GE ABWR, and ABB Combustion Engineering's System 80 PWR are evolutionary LWRs improving upon the current version of LWRs. The GE SBWR and Westinghouse AP600 are mid-sized LWRs with passive safety features.

In addition to the LWRs being developed in the United States, other reactors such as the Modular High Temperature Gas-Cooled Reactor (MHTGR) by General Atomic; the advanced liquid-metal–cooled fast-spectrum reactor (PRISM) by GE; the light-water reactor (PIUS) by ABB Atom; and the heavy-water–moderated and –cooled reactor (CANDU-3) by Atomic Energy of Canada, Ltd. (AECL) are some of the advanced reactors that are being designed. A compilation of the characteristics of some of these reactors is provided in Table 8. Institutes of the Commonwealth of Independent States (CIS), states of the former USSR, which are forming private and independent organizations, are also working on advanced pressurized light-water reactors such as the VVER 91 and 92 (Gagarinski *et al.*, 1992). A French and German consortium, NPI, is also working on advanced PWRs.

An ABWR (Anon., 1992) of 1350 MW(e) has been developed jointly by GE, Hitachi, and Toshiba. The Tokyo Electric Power Company initiated the construction of two ABWRs in

1989 at its Kashiwazaki–Kariwa Nuclear Power Station. Some features that improve construction costs and maintainability and provide additional margins of safety include internal recirculation pumps, which eliminate external recirculation pumps and piping; no large coolant nozzles below the top of the core; new pressure suppression containment, which permits rapid vessel depressurization; improved core and fuel design that maximizes performance and fuel economy; and a triple-redundant ECCS core protection system.

The APWR (Anon., 1992) that has been designed by Westinghouse, Mitsubishi Heavy Industries of Japan, and five Japanese PWR owner utilities is a four-loop, 1350-MW(e) power plant. Its most significant difference from the exisiting PWRs is that it has a 15–20% lower power density, which provides a greater margin of safety. In addition, a larger pressure vessel provides a larger core inventory of water above the core, which enhances safety and decreases the required capacity of the ECC system. A larger diameter containment building provides greater ease in maintenance. Economic goals are to reduce the capital costs by 15% and fuel-cycle costs by 20% over existing PWRs. The reduction in the fuel-cycle cost is achieved by the reduction of the power density, which leads to a reduction of the initial enrichment required to achieve the same energy output. A further reduction of the initial enrichment is accomplished by shifting the spectrum of the core during early operation of the core by displacing the moderator with a mechanical water displacer. This results in increased production of plutonium by slightly hardening the spectrum for increased resonance neutron absorption. This plutonium is then burned later in the cycle when the displacer is removed, producing a softer spectrum and increased core reactivity.

The AP600 (Anon., 1992; Vijuk and Bruschi, 1988; Bruschi and Anderson, 1991) is a two-loop, 600-MW(e) PWR system that includes a simplified reactor coolant system and a balance of plant, passive safety, and plant arrangement systems with a modular construction approach. Some of the key design features include a reactor coolant system that uses sealed canned motors mounted directly on the steam generators, a core design resulting in a low core power density (80 kW/L), a reactor core surrounded by a stainless steel and water reflector, and passive safety features that operate following plant transients or accidents. The passive safety system provides for residual heat removal, reactor coolant makeup for inventory control, safety injection, and containment spray cooling. A passive residual-heat–removal heat exchanger (PRHR-HX) has been provided to remove the decay heat by natural circulation from the core in the event that the normal or startup feedwater systems (i.e., steam-generator heat-removal systems) are not functioning. In the AP600, if there is steam released to the atmosphere inside the steel containment, natural circulation is used to transfer the heat to the steel shell. The AP600 has been designed to have significantly fewer valves and large pumps, less piping, and less control cabling and ducting in order to minimize construction costs.

General Electric has been working on the design of the Simplified Boiling Water Reactor (SBWR) (McCandless and Redding, 1989) since 1982 with the objectives of providing power generation costs cheaper than coal, simplified safety systems, shorter construction schedules, and a 600-MW electrical rating. In the SBWR design, the power density was decreased to 42 kW/L, and natural circulation was chosen for providing coolant flow through the core. A gravity-driven core-cooling system provides a simple approach to emergency core cooling, which eliminates the need for pumps and emergency diesels. It has a gravity driven cooling pool that can keep the core covered. The SBWR pressure vessel is designed so that there are no large pipes attached to the pressure vessel near or below the core elevation, which ensures core coverage for all design basis events. In addition to the passive cooling pool, the SBWR uses a pressure suppression pool, isolation condenser, and passive containment cooling system for its passive emergency response.

The PIUS (Process Inherent Ultimate Safety) reactor concept by ABB Atom of Sweden (Hannerz, 1988) is a 640-MW(e) PWR-type reactor that is located near the bottom of a deep reactor pool. The pool is compartmentalized so that the reactor core is near the bottom of a chimneylike structure submerged in a large pool. The pool contains water with a high boron concentration in a prestressed concrete vessel. The reactivity is controlled by the boron concentration in the coolant water and by temperature so that there are no control rods in the reactor. The moderator temperature coefficient is strongly negative throughout the operating cycle. During normal operation, the power is controlled by using the negative moderator temperature coefficient without adjusting the coolant boron concentration. The PIUS is an innovative concept since fuel integrity is maintained by an inherent passive coolant system, and there should be no core uncovery or fuel overheating in any credible accident because of the large volume of available coolant water.

7. ECONOMIC CONSIDERATIONS

The generation of electricity through the use of nuclear energy must be competititve with the cost of power generation from the burning of fossil fuels such as coal and oil. The cost of electricity generation may be considered to be composed of capital carrying charges, operation and maintenance costs, and fuel costs. The capital carrying charges include the depreciation and amortization of the costs of building and financing the plant. The capital costs of a plant may also change depending on the amount of additional investments required during its operating life. In the case of nuclear plants, the capital carrying charges are the predominant costs for the generation of electricity. The large capital carrying costs include the high cost of construction, as well as the interest charges accumulated during the length of time required to construct the plant, and decommissioning costs.

The Ahearne Committee Report on Nuclear Power (National Research Council, 1992; Ahearne, 1993) presents the Energy Information Administration's 1988 figures for the comparison of nuclear- and coal-generated electricity. Table 9 lists the highest, lowest, and average total generation costs for nuclear and coal in 1988.

Table 9. Average electricity generation costs for 1988 (cents/kWh) (National Research Council, 1992).

			Highest/Lowest	
	Nuclear	Coal	Nuclear	Coal
Capital carrying	3.4	1.1	9.4/0.4	5.4/0.3
Operation & maintenance	1.5	0.4	1.2/0.8	0.7/0.5
Fuel	0.8	1.7	0.7/0.5	2.5/1.4
Total	5.6	3.1	11.3/1.6	8.5/2.2

The reasons that existing nuclear power plants have higher capital carrying charges than coal plants are that the nuclear power plant equipment and building have been more expensive to construct, they have taken longer to construct and hence accumulate more interest charges, and finally they have decommissioning costs that must be taken into consideration. In the late 1960s and early 1970s, at the beginning of the commercial nuclear power industry, it was believed that operation and maintenance (O&M) costs would be fairly low. After the TMI-2 accident in April 1979, there was an increase in regulatory requirements, which significantly increased the O&M costs.

The Ahearne committee reports that plants that went into commercial operation during the period 1978–1989 required an average construction time of 11.1 years in the United States as compared with 5.9 years in France and 4.7 years in Japan. Since a lengthy construction period with the attendant interest charges has a significant impact on the capital costs, there is a strong incentive to minimize the construction time in the United States.

As there have not been any orders for new nuclear power plants since 1979, it is difficult to estimate the cost of electricity generation from new nuclear power plants because of the uncertainty of the capital costs for the advanced light-water reactors (ALWR) that the reactor vendors would probably supply to the utilities. The ALWRs are being designed with simplification as well as ease in construction, operation, and maintenance in mind. In addition, with the NRC tending toward a single construction and operating license approval process, which would decrease the construction time, the capital cost should be more predictable for the new plants.

In 1992, there were a couple of nuclear power plants that the utility owners decided to shut down because of the costs to replace steam generators, such as in the case of Portland General Electric's Trojan power plant whose alternate source of electricity from hydropower is cheaper. The Yankee Rowe plant in Massachusetts was shut down because of the uncertainties in radiation embrittlement of the pressure vessel, which caused concern in the NRC. As the nuclear power plants begin to approach the end of their 40-year operating license period, the owners must consider the cost effectiveness of pursuing license extension. Such an extension might require additional capital investment, which, together with higher O&M costs, may make nuclear electricity less competitive compared with electricity generated from other sources. Nuclear electricity is highly competitive in countries such as Japan and France, which have no indigenous fossil fuels. Limitations on the production of greenhouse gases, such as CO_2, and acid rain restrictions on fossil fuel combustion in both electricity generation and transportation may result in the increased use of nuclear power plants for electricity generation in the future in the United States.

8. RADIOACTIVE WASTE MANAGEMENT

Although the production of electricity using fission energy has a number of advantages, one of the disadvantages is that the resultant radioactive substances created must be prevented from being dispersed in the environment for many years. In addition to the high-level waste (i.e., fission products and transuranium isotopes) that is produced during reactor operation, there are other low-level wastes generated during the fuel cycle that must be managed (see NUCLEAR WASTE MANAGEMENT).

During the fuel production process from the mining and milling operation through the conversion to uranium hexafloride, the gaseous-diffusion, centrifuge, or atomic-vapor–laser enrichment processes, and the fuel fabrication process, there are mill tailings, sludge from chemical processes, scrap, and fabrication residue containing uranium and its daughter products that must be considered as low-level waste. During reactor operation, resins from the cleanup of the primary cooling water, filters from air cleaning, sludge and waste from evaporator concentrates, and airborne releases of radioactive noble gases and tritium are additional sources of low-level radioactive waste. If the spent fuel from commercial nuclear power plants is reprocessed, as it is in France, the United Kingdom, Japan, and the Former Soviet Union, and as is the fuel from military reactors in the United States, there is high-level waste consisting of the fission products and transuranic elements that must be disposed of. In addition, there will be cladding hulls with residual fuel, transuranic solids from the chemical processing, and gaseous radioactive wastes such as the noble gases, tritium, and iodine. Finally, in the decontamination and decommissioning of the nuclear plant, there will be large components, such as the pressure vessel and the reactor internals including the control rods, internal shield, etc., which will have become radioactive from interactions with neutrons. In all of the components of the primary circuit, there will be activated residue from small impurities in the water, which is difficult to remove. These components in total must be considered for radioactive material disposal. The concrete shielding and other support structures surrounding the pressure vessel will also have become activated to some small degree so that they may have to be considered as low-level waste.

The United States national policy in 1994 is to not reprocess spent fuel from commercial nuclear power plants but to develop a final storage facility for the spent fuel to discourage the use of plutonium so as to encourage nonproliferation. Although it had been planned by the Department of Energy (DOE) to characterize three possible sites for permanent storage of spent fuel, the U.S. Congress in 1987 enacted legislation restricting site characterization to the Yucca Mountain site in the State of Nevada. Because of public opposition from the State of Nevada and its citizens, initiation of the characterization studies was delayed until late 1991 by the refusal of the State to issue various permits required for the study. The spent fuel contains long-lived fission products and transuranic elements, which must be contained for tens to hundreds of thousands of years. The proposed concept is to encapsulate the spent fuel and then store the fuel in underground storage facilities at Yucca Mountain. The controversy involves the question of whether the Yucca Mountain area will remain stable against earthquakes or volcanic action for a long period so that the disposal facility will be free from ground water.

In countries such as France and Japan, where fuel reprocessing is carried out, the fission products are separated from the transuranic elements. The fission products are then vitrified (i.e., embedded in glass) and then encapsulated for final disposal in underground salt mines. The transuranic elements such as plutonium are separated for use as fuel in liquid-metal–cooled breeder reactors or are mixed with enriched uranium oxide for light-water reactor fuel [mixed oxide (MOX) fuel]. A high degree of separation of the transuranic elements from the spent fuel in fuel reprocessing would ease the requirements for the high-level waste respository, since most of the fission products have significantly shorter half-lives than the alpha-active transuranic elements.

The DOE, in 1993, carried out alternative studies for the disposal of the transuranic elements. Concepts such as developing reactors specifically for burning or transmuting the transuranic elements, or using high-current, high-energy proton accelerators for transmuting the transuranic elements to fission products with shorter half-lives, are being considered. The principle in transmutation is to design a system with as hard a neutron energy spectrum as possible so that the capture-to-fission ratio for the transuranic elements is as low as possible. This minimizes the number of higher isotopes being produced and maximizes the fission of the fissionable transuranic elements. In addition, it is desirable, from a safety point of view, to have a system which has as high a power density as possible to minimize the total amount of transuranic inventory in the system. The concept of using accelerators for transmutation is based on the ability to construct a linear proton accelerator that produces high-energy protons in the range of 1.6 GeV with currents of 25 mA or greater. The high-energy, high-current protons are targeted on a heavy element such as lead or tungsten, which produces copious amounts of high energy neutrons. These neutrons then cause the fission of the transuranic elements in the system. The long–half-life transuranic elements are, thus, transmuted by fission into shorter–half-life fission products. Since the accelerator system can be operated with a multiplication of $k < 1$, or less than critical, the concern for supercriticality accidents would be diminished.

Very hard-spectrum reactors using liquid-metal cooling could be designed for the transmuting of transuranic elements. Such reactors could also be designed to produce electrical power.

9. NUCLEAR REGULATION

9.1 USNRC

The federal government in the United States has the responsibility for regulating the production and utilization of atomic energy in accordance with the Atomic Energy Act of 1946 and the Atomic Energy Act of 1954. The Energy Reorganization Act of October 1974 (Public Law 93–438) established the Nuclear Regulatory Commission (NRC) and separated the regulatory functions from the promotional functions of the Atomic Energy Commission (AEC). The Energy Reorganization Act, at the same time, created the Energy Research and Development Administration (ERDA), which took over the other functions of the AEC including its promotional developmental functions. The ERDA eventually became the Department of Energy by the Act of 1977. The NRC is composed of five members appointed by the President of the United States. Its principal functions are the licensing and regulation, including safeguards, of the construction and operation of nuclear reactors and the facilities for processing, handling, and transporting nuclear materials, including special nuclear materials, and the transport and storage of radioactive waste. It also has the responsibility for conducting research necessary for the performance of its licensing and regulatory functions. In carrying out its regulatory functions, the Commission reviews designs and construction quality assurance procedures, as well as conducting inspections of nuclear facilities and enforcing its regulations. The NRC maintains site inspectors at each of the commercial nuclear power plants in the United States.

The Commission carries out its responsibilities by promulgating rules and regulations, which become a part of the Code of Federal Regulations (CFR), a manual for the executive departments and the agencies of the federal government. Title 10, Chapter 1 of the CFR has been reserved for the NRC regulations. This chapter is divided into various parts, as shown in Table 10. The NRC also issues Regulatory Guides which

1. describe methods which the regulatory staff finds acceptable in implementing regulations;
2. discuss techniques used by staff to evaluate specific problems; and
3. provide guidance to license applicants.

The Commission has the three statutory offices of Nuclear Reactor Regulation, Nuclear Regulatory Research, and Nuclear Material Safety and Safeguards to carry out its principal duties. It has an Executive Director of Operations who coordinates the activities of the three principal offices, as well as five regional offices, as of 1993, which provide oversight of the nuclear facilities in their respective geographical areas. It also has the Advisory Committee on Reactor Safeguards (ACRS), the Advisory Committee on Nuclear Waste, and Atomic Safety and Licensing Boards to provide the Commission with advice.

The Commission had, up to 1990, required the submission of a preliminary safety analysis report (PSAR) for review and approval prior to the initiation of construction of a nuclear facility and a final safety analysis report (FSAR) before initiation of operation of the facility. The content requirements for SARs are given in NRC Regulatory Guide 1.70 and include such items as detailed description of the site, plant, reactor, engineered safety features, radioactive waste management, radiation protection, conduct of operations, safety assessments including accident analyses, and technical specifications.

Table 10. Code of Federal Regulations, Title 10, Chapter 1.

Part 1:	Statement of Organization and General Information
Part 2:	Rules of Practice
Part 20:	Radiation Protection Standards
Part 50:	Licensing of Production and Utilization Facilities
Part 51:	Licensing and Regulatory Policy and Procedures for Environmental Protection
Part 52:	Early Site Permits; Standard Design Certifications; and Combined Licenses for Nuclear Power Plants
Part 55:	Operators' Licenses
Part 70:	Special Nuclear Materials
Part 100:	Reactor Siting Criteria

The objective of the safety assessment of nuclear power plants is to provide an analysis and evaluation of the design and performance of the structures, systems, and components of the facility to assess the risk to public health resulting from operation of the plant. The analysis must include margins of safety during normal and transient conditions anticipated during the life of the facility and adequacy of the facility to prevent accidents and mitigate the consequences of accidents.

The range of accidents which should be considered are

1. events of moderate frequency with no abnormal radioactive releases from the facility,
2. events of small probability with potential for small radioactive release from the facility,
3. potentially severe accidents of extremely low probability to establish performance requirements of engineered safety features and to evaluate the acceptability of the site.

For new nuclear power plants, the Commission now also requires the submission of a Probabilistic Safety Assessment (PSA) [formerly called Probabilistic Risk Assessment (PRA)] based upon the detailed design of the plant. It should also be recognized that the Environmental Protection Agency (EPA) requires an Environmental Impact Statement for new large projects.

Following a detailed review of the SAR by the Commission staff, a review by the ACRS is conducted. Before a license is granted for the start of construction, the Commission usually conducts a public hearing at which any opposition views are heard.

In 1990, the NRC promulgated 10CFR52, "Early Site Permits; Standard Design Certifications; and Combined Licenses for Nuclear Power Plants," which significantly changed the rules and regulations governing the licensing of nuclear power plants. The NRC now issues a Combined Operating License (COL), which essentially combines the former construction permit and the operating license. Reactor vendors now submit an application for design certification of a specific nuclear reactor design. In parallel, a utility may submit an application for an early site permit. Following completion of the design certification process and an early site permit, an application for the COL may be considered. The technical information that is required of applicants for a COL is essentially the same as for the previous construction permits and operating licenses except for information technically relevant to a specific site. In addition, such analysis as a design-specific probabilistic risk assessment and proposed tests, inspections, and acceptance criteria are also required. The NRC staff and ACRS conduct a thorough review of the COL application, which is followed by a mandatory public hearing before a COL is issued. Construction of the nuclear power plant may be started after the issuance of the COL. Following completion of the construction, the NRC must issue a finding that the plant as constructed meets all acceptance criteria before operation is permited.

9.2 IAEA

The International Atomic Energy Agency (IAEA) (Scheinman, 1987) was originally established to prevent the proliferation of nuclear weapons and to encourage the use of nuclear energy for peaceful uses. Since the Chernobyl accident in 1986, there has been increased emphasis on helping member states with reactor safety. Before Chernobyl, the IAEA organized international conferences and workshops on nuclear safety, as well as providing operational safety review teams (OSART) for the evaluation of the safety of nuclear power plants at the request of member states. In the late 1970s, the IAEA developed an Incident Reporting System (IRS) for the compilation and distribution of unusual events occuring at nuclear power plants. The IAEA IRS contains unusual-event reports compiled by the Agency as well as those compiled by the Nuclear Energy Agency (NEA) of the Organization of Economic Cooperation and Development (OECD). Also included in the complilation of the unusual events is the analysis of unusual events.

Following the Chernobyl-4 accident in 1986, an International Nuclear Safety Advisory Group (INSAG) was established by the Director General of the IAEA with the intention of strengthening the IAEA's contribution to ensuring the safety of nuclear power plants. The INSAG's responsibilities include "serving as a forum for the exchange of information on nuclear safety issues of international significance and formulating where possible common safety concepts." One of its first products has been the issuance of the "Basic Safety Principles for Nuclear Power Plants" (IAEA, 1988), which outlines specific safety principles that should be followed for the design, construction, and operation of nuclear power plants.

The IAEA at the request of member states will conduct peer review of safety activities in those states. Peer review of three categories of activities has been carried out. These are regulatory activities, engineering matters, and operational safety. The IAEA has organized independent regulatory review teams and developed nuclear safety standards under the heading of regulatory activity peer reviews. They have conducted peer reviews of PSAs, safety analysis, siting, and design concepts under the category of engineering safety review service. In the operational safety category, they have conducted reviews of the operating process, event assessment, and feedback of experience.

Another area where the IAEA has been very active is in the organization of Assessment of Safety Significant Events Teams, which are sent to plants that have had unusual events. They have had over 50 separate missions to over 21 countries.

In the early 1990s, experts from the IAEA and NEA [the Nuclear Energy Agency of the Organization for Economic Cooperation and Development (OECD)] developed the International Nuclear Event Scale (INES), shown in Table 11, which would categorize unusual events so that it would be easier for the public to understand the severity of unusual events or incidents. The INES has categories

Table 11. International nuclear event scale (INES).

0	Below scale (deviation, no safety significance)
1	Anomaly
2	Incident
3	Serious incident
4	Accident without significant off-site risk
5	Accident with off-site risk
6	Serious accident (significant off-site impact)
7	Major accident (widespread health and environmental effects)

from 0 to 7, where 7 represents a major accident that has widespread health and environmental effects. The TMI-2 accident would be a category 5, whereas the Chernobyl-4 accident would be classified as a 7. Although some member states such as Japan, France, and the United States have developed their own nuclear event scale, the IAEA INES is becoming accepted on a worldwide basis.

10. CONCLUSION

This has been a brief review of the development of nuclear fission reactors over the past 50 years. Although nuclear energy was born of military necessity, commercial nuclear electricity with over 411 large nuclear power plants in operation worldwide in 1993 has become a mature, major new source of energy for the world. In 1953, 10 years after the construction of the first nuclear reactor, President Eisenhower of the United States initiated the Atoms for Peace Program, which has since spread the knowledge of nuclear fission technology worldwide. It is up to mankind to determine whether nuclear fission will be used as a source of clean energy for the improvement of man's living standards throughout the world or for destructive purposes through its use for nuclear weapons. If used carefully and properly, nuclear fission, as described in this article, is an environmentally benign technology which can provide clean heat and electrical energy to help fulfill the increasing energy demands by the world's current population of about 5×10^9 people and for a projected $(8–9) \times 10^9$ people in the years 2020–2030 and beyond. With the depletion of fossil fuels such as wood, oil, and coal and the concern over the increasing greenhouse gases in the atmosphere from combustion of fossil fuels, it is urgent that people universally accept the use of nuclear fission for peaceful purposes. Issues such as prevention of nuclear weapons proliferation, radioactive waste management, safety, and economics must be addressed to the satisfaction of the concerned communities before there will be universal acceptance of this very important and useful technology.

INTRODUCTION

This article addresses the necessary or desirable operations that are performed to prepare the nuclear fuel required to sustain nuclear reactors and to manage the fuel constituents after removal from the reactor. Taken collectively, these operations are called a *nuclear fuel cycle*.

These operations include the following:

1. obtaining raw materials to make fuel;
2. processing the fuel materials to achieve the desired chemical and isotopic composition;
3. fuel manufacture;
4. processing of used fuel to recover valuable constituents, including optional recovery of radioactive isotopes for beneficial uses; and
5. transportation and storage of fuel materials at various facilities.

The design and operation of the nuclear reactors and the management of nuclear wastes are described in separate articles in this series entitled NUCLEAR ENERGY, FISSION, and NUCLEAR WASTE MANAGEMENT.

1. OVERVIEW

Since the practical implementation of nuclear power during World War II, many different types of nuclear reactors have been conceived, and many of these have been built. For most of these, multiple fuel cycles are possible, yielding a large number of reactor–fuel cycle combinations. However, for descriptive purposes, these can be grouped into three categories: once through, reprocessing and recycle, and continuous recycle. These three fuel cycle categories are depicted in Fig. 1.

A *once-through fuel cycle* involves the production of fissile material having a concentration and total mass adequate to sustain a nuclear chain reaction. This material is then fabricated into fuel assemblies that have optimal nuclear physics properties, provide for removal of the heat generated during fission, and keep the radioactive products of fission separated from the coolant. This fuel (called fresh fuel) is transported to the reactor, where it is inserted into a core containing many assemblies and used to generate heat, which then generates high-pressure steam that is used to generate electricity. At some point, the fissile material is sufficiently depleted so that fission will no longer occur (i.e., the reactor is subcritical). The oldest fuel in the reactor core is then discharged and stored in a manner that provides protection from its intense radiation and heat removal. At some point, the spent fuel will be packaged and sent to a deep-mined cavern (i.e., a repository) for permanent disposal.

The spent fuel from a once-through fuel cycle contains significant amounts of residual fissile material. In a fuel cycle involving *reprocessing and recycle*, the fuel is reprocessed to recover the fissile material, and this material is refabricated into recycle fuel for use in another reactor. The most promising of these cycles involves recovering the slightly enriched uranium and plutonium from the spent fuels. The uranium would be re-enriched to concentrate the fissile isotope ^{235}U. The plutonium (produced by irradiating ^{238}U with neutrons) is typically composed of about $\frac{2}{3}$ fissile isotopes and would be diluted with natural uranium to achieve the proper fissile enrichment, which can range from 3 to 25%. Systems have also been proposed in which ^{232}Th is irradiated to generate fissile ^{233}U, which is then diluted with ^{232}Th to form recycle fuel. The fuel assemblies made from these materials are then inserted into the reactor and used to generate electricity. Upon

discharge, they are again reprocessed, and the cycle is repeated. Depending on the specific features of the reactor design, the overall recycle loop may be a net producer (i.e., a breeder) or net consumer (i.e., a converter) of fissile material.

In a fuel cycle involving *continuous recycle*, the fuel is dissolved or suspended in a liquid such as water, molten salt, or molten metal. The liquid is continuously circulated through a loop. At some point in the loop, its configuration is such that it is critical, generating the desired heat. At other points, the heat is removed to generate steam, and, at still other locations, the fuel is continuously reprocessed to remove unwanted by-products. Many such systems have been proposed since the 1940s, but they have not been well developed as compared to the batch systems described above.

The remainder of this article will more specifically address most of the steps depicted in Fig. 1. Exceptions to this are descriptions of specific types of nuclear reactors and management of radioactive wastes, both of which are the subject of separate articles (see NUCLEAR ENERGY, FISSION; NUCLEAR WASTE MANAGEMENT).

2. URANIUM MINING AND MILLING

2.1 Uranium Sources and Mining Techniques

The only naturally occurring fissile isotope is ^{235}U, which constitutes 0.71% of natural uranium. It is this material that is the wellspring of all nuclear fuel cycles. Uranium is a ubiquitous element, being widely distributed in the earth's crust at an average concentration of about 0.0003%. At this concentration, recovery is not economic. However, as a result of geologic and environmental processes, uranium has been concentrated in veins at many locations. A few high-grade veins containing the mineral pitchblende (U_3O_8) have been found to contain uranium at concentrations of 30–70% U_3O_8, mostly in Africa. Significant ore bodies having uranium concentrations up to 15% are now being developed in Canada. However, these are relatively uncommon, and most of the high-concentration veins were mined decades ago. Much more common are veins of carnotite ($K_2O \cdot 2UO_3 \cdot V_2O_5 \cdot 3H_2O$) ore that contain 0.1 to 0.2% uranium, typically in a sandstone matrix. These are widely distributed in the western United States and Canada in a band covering the eastern to middle portion of the Rocky Mountains, and in similar geologies in other countries. It is economically feasible to mine carnotite ores at uranium concentrations of 0.1% or above. Total known world resources of uranium outside the centrally planned economies are estimated to be 3.1 million metric tons (OECD, 1992).

The mining of carnotite ores is accomplished using a variety of methods. Standard tunnel mining has often been used, although less commonly so now because of the relatively high cost of such operations in combination with low uranium prices. Open-pit mining is often used for deposits relatively near the surface. A newer technique, called *in situ* leaching, involves injecting leaching solutions into a subsurface ore zone through a well and then drawing the uranium-bearing solution back to the surface through another well. The leaching chemicals are very similar to those used in uranium ore milling, described below.

Other dilute sources of uranium are also economic to mine when the uranium is a by-product of the production of other economic values. Significant amounts of uranium are generated as a by-product of phosphate mining. Most of this production occurs in the Gulf Coast states in the United States, and similar locations elsewhere. Uranium is also produced as a by-product of copper and gold mining at various locations throughout the world.

Recovery of uranium from seawater has been and continues to be studied, typically using ion-exchange technology. While the "ore" is easily accessible, the low concentration of the uranium and fouling of the ion exchange material continue to make this an uneconomic source.

2.2 Uranium Milling and Refining

Uranium milling is the concentration and purification of the uranium in ores. Ores are typically ground to 20 to 200 mesh to provide adequate contact with reagents. The ground ore is then contacted with an aqueous acid or alkaline leach, depending on the specific properties of the ore. Sulfuric acid is most commonly used, but all of the mineral acids are used to some extent. Alkaline leaching is performed with solutions of the carbonates and bicarbonates of sodium or ammonia. The acid-based process is generally more economic unless the ore contains large amounts of alkaline materials, which would require excessive acid consumption. In either case, the result is a selective dissolution of uranium from the ore.

The acid or alkaline slurry of uranium-bearing solution and solids is then filtered to remove the solids. These solids are somewhat radioactive, containing all of the decay products of the uranium that have achieved equilibrium levels during millions of years of decay. Most noteworthy of these are ^{226}Ra (with a half-life of about 1600 years) and its chemically inert gaseous decay product ^{222}Rn. These radionuclides are primarily responsible for the radiological effects of the tailings. The tailings are typically managed by simply creating small hills of the solids near the mill, along with engineered features to manage the runoff resulting from rain and to control the release of ^{222}Rn.

The uranium is recovered from the aqueous leach solution by precipitation using a variety of chemicals such as ammonia, magnesia, or caustic soda. The product of the precipitation is the diuranate of ammonia, magnesium, or sodium, with a typical chemical formula being $(NH_4)_3U_2O_7$. Depending on the specifics of the process, this product is then washed and dried to yield a 75-to 100%-pure U_3O_8 product. Although all of the diuranate intermediates and the impure product are commonly called *yellowcake*, only ammonium diuranate has the characteristic yellow color and these products are more properly called *uranium ore concentrates* (UOC).

2.3 Purification and Conversion of UOC to UF_6

The impure UOC product must be purified to be acceptable in subsequent processes. This is generally performed at a centralized facility separate from the mine and mill, and this same facility often includes the processes for conversion to UF_6. Purification is typically accomplished by dissolving the yellowcake in concentrated nitric acid and extracting the uranium from the acid by *solvent extraction*: contacting it with immiscible tributylphosphate (TBP) diluted with kerosene or *n*-dodecane and then back-extracting the uranium from the TBP solution using dilute nitric acid. Purification may also be accomplished using other solvent extraction reagents or ion exchange techniques. The uranium solution is then typically evaporated and calcined (to yield high-purity UO_3) and then reduced by hydrogen gas to yield uranium dioxide (UO_2) and nitric acid for internal recycle.

Uranium dioxide can be taken directly to fresh fuel fabrication for reactors that do not require isotopically enriched uranium. However, many reactors require uranium enriched so that it has a ^{235}U concentration of 1–5%, with the required concentration depending on the reactor design and operating parameters. All currently operating enrichment processes require the feed material to be in the form of uranium hexafluoride (UF_6), thus requiring *conversion* of the oxide to the hexafluoride. This conversion is accomplished in two steps. The first is to react the UO_2 with anhydrous hydrogen fluoride (HF) in a multiple-stage reactor, which yields uranium tetrafluoride, UF_4. The UF_4 is then reacted with elemental fluorine gas (F_2) to yield UF_6.

Purification and conversion can be carried out simultaneously by fluorinating the UOC directly by first using the HF-F_2 sequence described above. The result is that the uranium and a few other elements form fluorides that are easily volatilized, leaving most of the impurities in a solid residue. The gaseous fluoride stream is then further purified by fractional distillation to yield a pure UF_6 product.

3. ISOTOPE ENRICHMENT

The function of *isotope enrichment* processes is to increase the relative abundance of selected isotopes in an element. This also necessarily produces another output stream (typically called *tails*) that is depleted in the particular isotope. In some cases, the degree of enrichment is almost complete. For example, to produce "heavy water," the relative abundance of deuterium ($^2H_2$) is increased from the very low 0.015% natural abundance in water to about 99.75%. In other cases, the concentration of a particular isotope may be increased only a few percentage points. For example, uranium is enriched from its natural 0.71% ^{235}U concentration to less than 5% for most reactor applications.

3.1 Uranium

Uranium is the most extensively enriched material in the world. The first successful large-scale enrichment of uranium isotopes was achieved during World War II by the United States in its effort to obtain enough highly enriched (>90% ^{235}U) uranium to produce a nuclear weapon. A large number of uranium isotope separation methods were studied during this period, and most were able to enrich uranium to varying degrees. However, the cost of enrichment was very high for many of these processes, and less costly alternatives were subsequently developed. The following discussion describes uranium enrichment processes in their approximate order of large-scale development or use.

3.1.1 Electromagnetic Isotope Separation (EMIS) EMIS capitalizes on the fact that charged particles move in circular paths when subjected to a magnetic field perpendicular to the particle path. Different paths are followed by charged particles of different masses, with the path of a heavier particle having a slightly larger diameter. Thus, when ionized (charged) atoms such as those of uranium are injected into a strong magnetic field, the ^{235}U ions follow a different path than the ^{238}U ions, and the former may be collected in a different location from where the latter impinge (Fig. 2). Recovery of the separated material is then simply a matter of chemical processing.

The separation factor (a measure of the amount of enrichment attained with a single enrichment stage) is very large for the EMIS process. In theory, complete isotopic separation can be achieved in a single stage. In practice, the extent of enrichment attained is limited by ion beam dispersion, interactions with solid materials, and other second-order effects. However, highly enriched uranium can be produced with only two consecutive stages of EMIS.

The EMIS machines used during World War II in the United States to enrich uranium were called *calutrons*. Although the enrichment achieved in a single stage was high, the throughput of any one device was relatively small. As a result, a large number of calutrons were operated in parallel to produce the required amount of product (several tens of kilograms).

Although the calutrons were successful, they were expensive to operate because they used large amounts of electricity for the amount of enriched uranium produced and because they were very labor intensive. As a result, use of this technology for uranium enrichment ceased soon after the War, and most of the calutrons were dismantled.

3.1.2 Gaseous Diffusion Another method of uranium enrichment studied during World War II—*gaseous diffusion*—proved to be much less costly than EMIS, requiring far fewer people, operations, and units of electricity per unit of product. In the gaseous diffusion process, UF_6, which is gaseous at relatively low temperatures and pressures, is allowed to diffuse through very small openings in porous tubes called *barriers* contained within large cylindrical housings. The $^{235}UF_6$ molecules go through the pores a little faster than the heavier $^{238}UF_6$ molecules, and so the gas that passes through the barrier is slightly enriched in the lighter isotope. The slightly enriched product from this stage is then pumped to the next-higher stage, where the process is repeated. The gas that does not pass through the tubes is slightly depleted in $^{235}UF_6$ and is pumped to the next lower stage, where the process is repeated. In this way, the enriched uranium is moved continuously upward and repeatedly enriched in ^{235}U, while the depleted uranium is moved continuously downward and repeatedly depleted in ^{235}U. The assemblage of interconnected stages is called a *cascade*. Along with the housing and tubes (called a *convertor*), each stage also requires a compressor to recompress the gas received from other stages and a heat exchanger to remove the heat of compression. Such an arrangement is shown in Fig. 3.

As implied above, the amount of enrichment achieved by a single stage is small. In fact, the maximum theoretical amount by which the ^{235}U can be enriched in a single stage is given by the square root of the ratio of the masses of the heavier and lighter uranium molecules, which is $(352/349)^{0.5} = 1.004$. As a consequence, to enrich natural uranium containing 0.71% ^{235}U to 3% (an enrichment typically required by reactors) while produc-

ing a tails stream containing 0.2% ^{235}U would require 1272 theoretical stages. This number is increased by the inevitable inefficiencies in any real process.

Despite the large number of stages required, the large physical size of the plants (which are multi-story buildings about 1 km long and 100 m wide), and the relatively large amounts of electricity required (a single plant requires on the order of 1000 MW), the large throughput of the plant and the low operation and maintenance cost resulted in the product cost being sufficiently low to make nuclear fuels economic. Gaseous diffusion plants for enriching uranium for both power reactors and military purposes have been built in the United States, Russia, France, Great Britain, and China. Construction of additional plants is not expected because the high electricity consumption makes the product relatively expensive compared to other technologies that have become available.

3.1.3 Gas Centrifuge A *gas centrifuge* separates uranium isotopes by placing UF_6 in an artificially created high-gravity environment, thus magnifying the importance of the small mass difference between ^{235}U and ^{238}U. The high-gravity environment is created by spinning a right-circular cylinder called a *rotor* around its axis at very high speeds, conceptually similar to the spin cycle on a washing machine. For a given rotor diameter, the separation factor is a function of the rate at which the centrifuge rotates. This rate is limited by the mechanical properties of the ro-

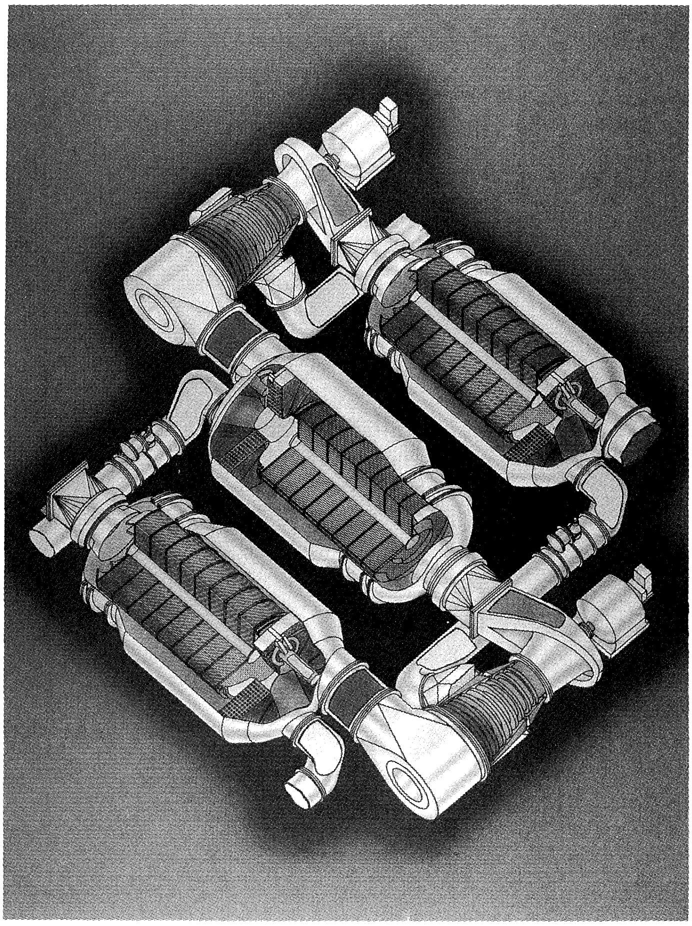

Fig. 3. Diagram of interconnected stages in a gaseous diffusion plant cascade.

tor materials, which may be advanced metal alloys or composites.

Because of the circulating flow within the centrifuge, each functions as a "miniature cascade," with multiple effective stages within each physical device. A schematic of one of the early centrifuge designs depicting this circulation is shown in Fig. 4. The net result is that the number of physical stages (i.e., centrifuge machines) required is far fewer than that required for gaseous diffusion, although a number of centrifuges may have to be operated in parallel to achieve the desired throughput. As a result of the processes within the centrifuge being reversible (the pressure drop in gaseous diffusion is irreversible), the electricity requirement for gas centrifuges is estimated to be about 4% of that for gaseous diffusion. However, the centrifuges are very sophisticated devices, requiring advanced materials to achieve economic operating speeds without destroying themselves. On balance, the cost of product from the gas centrifuge process appears to be less expensive than that from gaseous diffusion, but not greatly less.

Gas centrifuge plants for uranium enrichment are currently operating in the Netherlands, Great Britain, Germany, and Russia. Plants are under construction in other countries. A small pilot plant was built and operated in the United States, and construction started on a demonstration plant, but the project was cancelled in favor of a laser isotope separation process.

3.1.4 Laser Isotope Separation (LIS) A *laser isotope separation* (LIS) process separates uranium isotopes by capitalizing on slight differences in the wavelength of light

that will excite uranium metal or uranium-bearing molecules to a species that can be readily separated. The variation in wavelengths is a result of the differing atomic properties of ^{235}U and ^{238}U that are a consequence of the difference in the masses of the two nuclei. The laser power requirements are significant (multikilowatt to megawatt). It was only with advanced developments in high-power lasers that the wavelengths could be adequately controlled to achieve the desired enrichment while producing the power required for the needed throughput.

As with EMIS, the selectivity of LIS processes is very high. In theory, only one stage would be required to separate the isotopes completely, while in practice, only two stages may be needed. The process requires much less electricity than EMIS. However, the cost of the equipment (especially the high-powered lasers) required for LIS and the precision with which it must be controlled is high. While this process is still under development, it is thought that the initial cost of product will be about the same as that from gas centrifuges.

The *atomic vapor laser isotope separation* (AVLIS) process (Fig. 5) is carried out by introducing uranium metal (or uranium metal alloy) vapor into a sealed vessel under low-pressure conditions. The uranium is exposed to laser light at one or more suitable wave-

lengths, resulting in the selective ionization of the ^{235}U fraction. The ionized material can then be diverted from the un-ionized (^{238}U) material with an electrostatic field and collected.

The *molecular laser isotope separation* (MLIS) process is conceptually similar to AVLIS. However, in this case, the feed material is the molecule UF_6. Upon exposure to laser light of suitable wavelengths, the UF_6 is dissociated by photolysis to form UF_5 and atomic fluorine (which may quickly combine to the more stable F_2 molecule). The UF_5 is a solid entrained within the flowing UF_6 gas, and can be separated from the gas stream by standard techniques such as by filtration with gaseous-diffusion–plant barrier material. Rapid separation of the UF_5 is required to prevent recombination with the atomic and molecular fluorine present in the gas stream.

3.1.5 Aerodynamic Processes Aerodynamic processes capitalize on the centrifugal forces resulting from forcing a gas (in this case, a mixture of UF_6 and hydrogen) through a small, curved nozzle shown in Fig. 6 (Becker *et al.* 1975) at high speed. The heavier fraction tends to be concentrated near the periphery of the nozzle, allowing a knife edge to separate it from the lighter fraction. The enriched and depleted streams from each stage are moved to other stages in a manner very similar to that used in gaseous diffusion.

As with gaseous diffusion, aerodynamic processes are inherently irreversible. As a consequence, the cost of enriched product appears to be at least as large as that of gaseous diffusion and higher than that of gas centrifuges. Small production plants based on these processes have been built and operated in Brazil and South Africa.

3.2 Stable Isotopes

A wide variety of separated *stable isotopes* (i.e., nonradioactive) are used for various aspects of nuclear power, in scientific experiments, and as precursors for production of radioactive isotopes (via irradiation in particle accelerators or small reactors) used in an expanding variety of medical procedures.

3.2.1 Deuterium Deuterium (^2H or D) is a heavy isotope of hydrogen containing one proton and one neutron in the nucleus as compared to the single proton in normal hydrogen (^1H). Deuterium occurs naturally (DHO at low concentrations, D_2O at high concentrations) in concentrations of about 0.015 at.% in all water. While it has some minor scientific uses, by far the predominant use of heavy water is as a neutron moderator in some types of nuclear reactors such as the Canadian CANDU. Deuterium's nuclear properties result in its having an exceedingly small chance of undergoing undesirable neutron absorp-

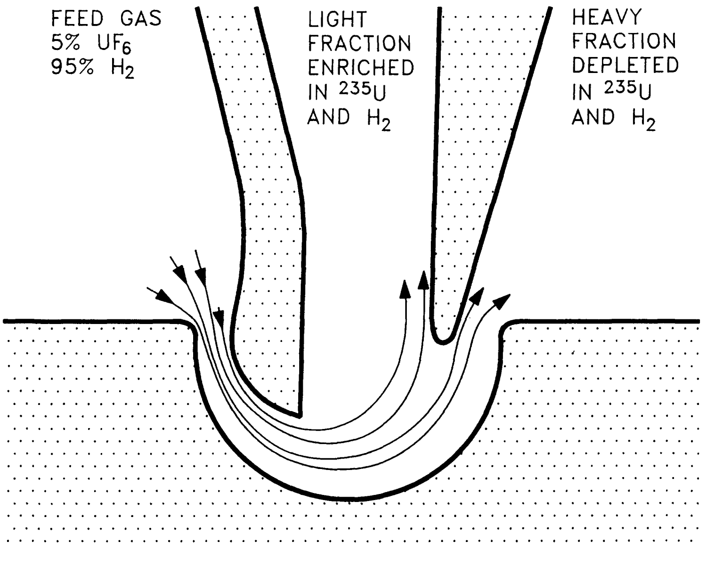

Fig. 6. Cross section of a basic separation nozzle used for uranium enrichment.

tion reactions, thus allowing a practical reactor to be operated using only natural (i.e., not enriched) uranium fuel. However, the savings in uranium enrichment costs are approximately balanced by the cost of having to enrich the deuterium to nearly 100% and the fact that a 600 MW_e CANDU reactor requires an inventory of about 450 metric tons of heavy water.

Many processes have been proposed and used since the first known heavy-water production plant was operated in 1934. Early plants were typically based on electrolysis of water, which, like the EMIS process for other stable isotopes, was effective but costly. Over the years, a wide variety of alternative processes have been developed and deployed to produce heavy water. The two general categories of processes that have been developed involve exchange of D and H between various chemicals such as ammonia, water, or hydrogen sulfide, and distillation of various chemicals such as water, ammonia, or methane.

After decades of experience, the preferred approach to producing essentially pure heavy water is the Girdler-sulfide, dual-temperature water–hydrogen-sulfide exchange process (GS) followed by water distillation. A flowsheet of the GS process is exceedingly complex because it involves extensive measures to conserve heat within the process. However, in conceptual terms, a tall vertical vessel is fed at the top with natural water at about 0° C. This is contacted with a gaseous stream of D_2S injected at the bottom of the vessel. The net result is that the deuterium preferentially moves to the aqueous phase (which becomes heavy water) and hydrogen to the gaseous phase. The D_2S is generated in a separate vessel by reacting part of the heavy water product with H_2S at a much higher temperature, where the formation of D_2S is favored, producing water depleted in deuterium. The sulfide compound is continuously recycled within the process. The product enrichment of this process is typically about 15 at.% deuterium.

The second step of this approach involves taking the partially enriched product from the GS process and fully enriching it in a simple water distillation column. The lighter H_2O favors the gaseous (steam) phase. Thus, injecting the partially enriched liquid product from GS into the top of a vessel which has H_2O steam rising from the bottom has the effect of stripping the rest of the H_2O from the liquid, yielding the desired high-purity product.

3.2.2 Lithium Lithium has two stable isotopes. Lithium-7 (abundance of 92.5 at.%) has a relatively low probability of undergoing undesirable interactions with neutrons, and its compounds have found limited use in controlling the water chemistry in nuclear reactors. ^{6}Li has a relatively large probability of undergoing interactions with neutrons, with the products being stable helium and radioactive ^{3}H (called tritium). Tritium is used in industry in a variety of applications related to radioluminescence. Tritium production does not require that the precursor material be enriched in ^{6}Li, and so the demand for enriched lithium products has been limited to the small demands for ^{7}Li and enrichment activities related to the production of ^{6}Li for nuclear weapons.

As with heavy water, a wide variety of processes have been investigated for the purpose of enriching lithium. In fact, the general categories of processes are the same as those for heavy water production (i.e., electrolysis, distillation, and chemical exchange), along with ion exchange processes. As a result of the limited demand for enriched lithium, the preferred process is not evident. However, there appears to be a tendency to favor a chemical exchange process involving contact of an aqueous solution of LiOH with a lithium amalgam (a solution of lithium in mercury).

3.2.3 Boron Boron has two stable isotopes. ^{10}B (abundance of 19.6 at.%) has an extremely high probability of undergoing reactions with neutrons, and it is used as a neutron absorber to control the chain reaction in nuclear reactors. Worldwide production is on the order of a few tons per year. ^{11}B has a relatively low probability of undergoing nuclear reactions. Although only a few small plants have been built, the preferred process involves a chemical exchange reaction between boron trifluoride (BF_3), which is gaseous at modest temperatures, and a complex of boron trifluoride and dimethyl ether [$(CH_3)_2O$], which acts as the liquid phase.

3.2.4 Other Light Isotopes There is also limited enrichment of the low-abundance, stable isotopes of carbon (^{13}C, abundance 1.11 at.%), nitrogen (^{15}N, abundance 0.365 at.%), and oxygen (^{17}O, abundance 0.037 at.%, and ^{18}O, abundance 0.204 at.%). All of these are used in scientific research to make biological compounds that can be traced through organisms and chemical reactions because of their enrichment. As with the other isotopes mentioned above, the preferred production methods involve distillation and chemical exchange. Worldwide production is estimated to be several kg/yr or less for these isotopes.

3.2.5 Heavier Stable Isotopes Beyond the stable isotopes listed above, demand for enriched products is typically small and depends on the identification of a specific use for the isotope. Most elements have been isotopically enriched in small amounts to provide relatively pure materials upon which to perform experiments concerning the unique nuclear properties of each. Other selected isotopes continue to be separated in larger quantities to provide precursor material to produce useful radioactive isotopes, especially for medical applications.

Although a few specialized enrichment processes have been used, most of the heavier elements are enriched using the EMIS process described earlier. While it is expensive to operate for the purpose of producing large quantities of enriched uranium, its flexibility and high enrichment per stage make it cost-effective for small scale separations.

4. CONVERSION OF UF_6 TO OTHER SPECIES

The fact that UF_6 is gaseous at modest temperatures makes it very useful for enrichment processes. However, this compound is not useful for the end applications of the uranium. As a result, the UF_6 must be converted to a chemical species that has properties appropriate to its end use.

4.1 Conversion of UF_6 to UO_2

Uranium dioxide (UO_2) is the species used to manufacture most nuclear reactor fuels, and it has few uses beyond this application. Three different processes have been developed to perform this function. All are used commercially.

The first method of production involves two steps. The first is gas-phase reduction of UF_6 by elemental hydrogen, yielding UF_4 and HF. The UF_4 is then reacted with steam, yielding UO_2 and a solution of HF.

The second method involves direct reaction of UF_6 with water to form UO_2F_2 and aqueous HF. This solution is then reacted with ammonium hydroxide (dissolved ammonia) to precipitate ammonium diuranate [$(NH_4)_2U_2O_7$) and ammonium fluoride. The ammonium diuranate is then filtered from the solution, dried, and reduced with hydrogen gas to yield ammonia and UO_2.

The third method involves reaction of the UF_6 with carbon dioxide and ammonia in aqueous solution to produce a precipitate of ammonium uranyl carbonate, $(NH_4)_4UO_2(CO_3)_3$. The ammonium uranyl carbonate is converted to UO_2 by reaction with steam and hydrogen gas at elevated temperatures.

In all cases, the characteristics of the product must be carefully controlled. Not only is the chemical composition of the product important, but its physical attributes such as grain size and sinterability are also very important in subsequent manufacture of fuel.

4.2 Conversion of UF_6 to Uranium Metal

Uranium metal has a variety of uses. It is used in nuclear fuels, typically alloyed with other metals (e.g., aluminum, zirconium) to provide acceptable mechanical properties. It is used to manufacture armor-piercing bullets for the military. The high density (19.1 g/cm^3) and pyrophoric nature of uranium metal when finely ground or molten make it preferable to lead (11.7 g/cm^3) or other materials in some applications. Uranium is also used to form radiation shields, especially for gamma rays. It has occasionally been used in other applications, such as counterweights in airplanes, where space is at a premium and its high density makes it cost-effective.

Only one process is used for the large-scale production of uranium metal. The first step is to reduce the UF_6 to UF_4 with hydrogen gas, as described in the previous section. The UF_4 is then mixed with a metal more reactive than uranium, typically magnesium or calcium, and an iodine catalyst. This mixture is placed in a sealed chemical bomb (a sturdy closed vessel), and the mixture is ignited electrically. The result is the reduction of the uranium to molten metal and the production of the molten fluoride of the reducing agent (e.g., CaF_2). The metal and fluoride salt are immiscible, and so, after cooling, the result is a solid layer of the fluoride salt atop a mass of uranium metal, often called a *button*.

5. FUEL FABRICATION AND REFABRICATION

The purpose of fuel fabrication and refabrication is to process raw nuclear materials into a form and configuration that are appropriate for the fuel of a particular reactor design. *Fabrication* involves processing unirradiated nuclear materials (i.e., uranium or thorium). *Refabrication* involves processing of materials recovered from spent fuels for recycle, with plutonium and ^{233}U being the most common examples.

Typically, the nuclear material begins in powder or metal form. This material is formed into larger shapes, generically called *fuel*, to withstand irradiation in the reactor better and to facilitate handling. The fuel is then enclosed in a metal container, generically designated as *cladding*, which serves the purpose of separating the radioactive fuel from the relatively clean fluid (e.g., water, liquid sodium, CO_2, gaseous helium) required to cool the fuel during irradiation. The units of clad fuel are called *fuel rods* or *fuel elements*. The fuel elements are then arranged into a fixed geometric array, called a *fuel assembly*. Dozens, if not hundreds, of fuel-cladding-assembly combinations have been developed over the last five decades of nuclear power. The following sections describe two of the more preferred combinations that have received some degree of large-scale use.

5.1 Oxide Pellet Fuels

By far the most popular fuel type is formed from uranium dioxide produced as described earlier. Most large reactors that produce electric power use this type of fuel, primarily because it is stable at relatively high temperatures. The following steps are typically followed to make oxide fuels:

1. If the fuel is to be composed of oxides of several elements (e.g., Pu-enriched uranium dioxide or $[Pu,U]O_2$), the oxides are thoroughly blended to achieve the desired enrichment, which would typically range from a few percent Pu (for thermal reactors) to 25% (for fast reactors).
2. The oxide powder is blended with binding agents and die lubricants.
3. The mixture is pressed into pellets that are the shape of a right circular cylinder, typically about the diameter of a pencil or somewhat larger.
4. The pellets are sintered at high temperatures to consolidate the powder into a solid pellet.
5. The pellets are inspected, ground to size, and placed in a vacuum to remove atmospheric gasses.
6. The pellets are then loaded into empty cladding tubes, which are typically 1–5 m long and made of Zircaloy (an alloy of zirconium with minor amounts of tin and iron) or stainless steel, and an end cap is attached by welding, yielding fuel rods.
7. The rods are inserted into *grid spacers* (metal squares subdivided into smaller squares sized to hold the rods in place with springs), and the entire assembly is bound together axially with end pieces that are connected with hollow tubes similar to those used for cladding.
8. The assembly is cleaned and readied for transport to the reactor.

A cutaway drawing of a typical fuel assembly is shown in Fig. 7.

5.2 Metal Fuels

A second common fuel type is made of metal and is commonly employed in test and research reactors where achieving high temperatures (which is required to produce electricity efficiently) is irrelevant. Following are the major steps typically required to make such fuel:

1. Uranium dioxide with an appropriate isotopic enrichment (which could range from natural to about 93% ^{235}U) is reduced from the oxide to the metal as described earlier.
2. The uranium metal is often alloyed with other metals (e.g., Al, Zr, Mo, Nb) to improve its physical characteristics.

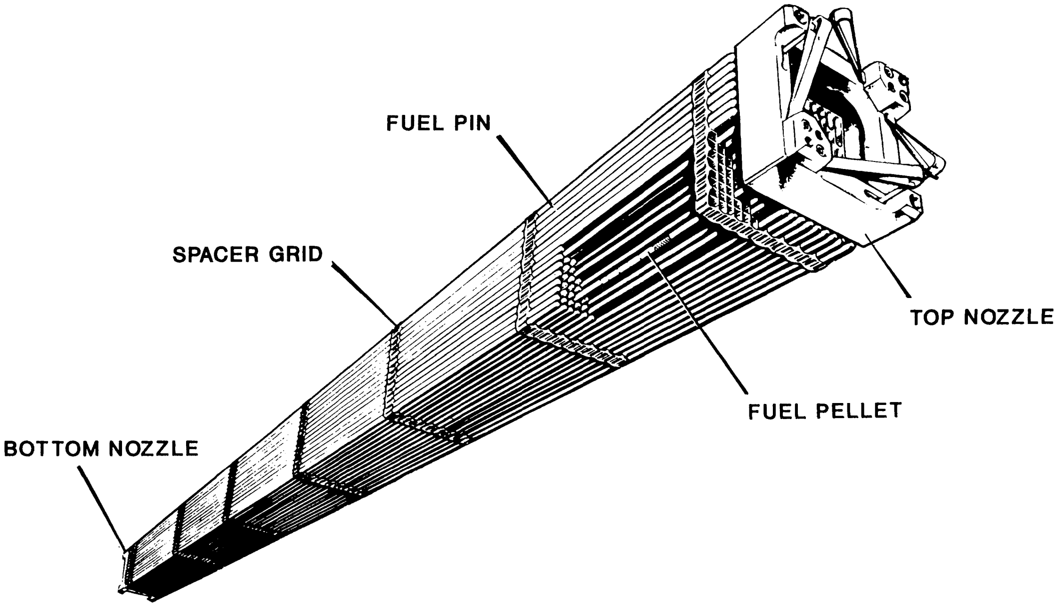

Fig. 7. Major components of a typical fuel assembly from a pressurized water reactor.

3. The alloy is then hot rolled and sized into plates in the range of 0.5–2 mm thick.
4. The plates are placed between two larger plates of cladding metal (typically Al or an Al alloy), which are then hot pressed to seal the edges into a fuel element.
5. The elements are then put into slots in two of four larger flat metal plates that form a box surrounding the plates but open at the ends to allow coolant to pass through. This assembly is typically about 1 m long and 10 cm on each side, although annular designs are also employed and size can vary widely.
6. The assembly is cleaned and prepared for transportation to the reactor.

There is substantial variability in these fuels, with fuel material made of uranium hydrides being relatively common and more advanced materials such as uranium silicides being developed.

6. EFFECTS OF FUEL IRRADIATION

6.1 Irradiation Processes and Products

As noted previously, there is a wide variety of fuel material, cladding material, coolants, and moderators in reactors throughout the world. Despite this diversity, the effects of irradiation are similar in all cases.

Conceptually, a nuclear reactor is a vessel in which a sufficient number of fuel assemblies are placed in close proximity in the *core* and controlled such that a stable fission rate is established in the fuel. Fission generates a significant amount of heat, and one purpose of the vessel is to contain the coolant required to remove the heat from the fuel. Each fission generates about 200 MeV of energy that is recovered as heat, and about 2.5 neutrons. As a consequence, a typical large nuclear power plant generating 1000 MW of electricity has a fission rate of about 9.4×10^{19} fissions/s and produces 2.3×10^{20} neutrons/s.

The 2.5 neutrons produced by each fission reaction are consumed by the nuclei of all elements in the reactor in the following ways:

1. Exactly 1.0 of the neutrons interacts with a nucleus and results in another fission, thus sustaining the chain reaction. This nucleus must be able to be fissioned by the neutrons produced by previous fissions. These neutrons have a spectrum of kinetic energies (i.e., speeds) ranging from fractions of an eV to about 3×10^{6} eV. The only elements that can be fissioned by neutrons having this range of energies are

the actinides. By definition, this includes all elements with atomic numbers greater than 89 (that of actinium). In practice, only a few actinides occur naturally or can be produced in sufficient quantities to constitute a fuel material: Th, U, and Pu. Isotopes such as ^{235}U and Pu^{239} can be fissioned by neutrons of all energies and are called *fissile*. Isotopes such as ^{238}U and ^{240}Pu can be fissioned by only high-energy neutrons and are called *fissionable*. The sum total of the interaction of the 2.5 neutrons with the various actinide isotopes present in the reactor at a given instant results in 1.0 producing a fission that sustains the chain reaction. The other 1.5 neutrons interact as described below, with the proportions of these reactions varying significantly depending on the reactor design.

2. A significant portion of the neutrons interact with the actinides by *neutron capture*. In this case, the actinide is not fissioned. Instead, the neutron combines with the actinide nucleus to form the next heavier isotope of the same actinide element. For example, ^{238}U captures a neutron to form ^{239}U. Uranium-239 has a relatively short half-life and decays to ^{239}Np, which also has a relatively short half-life and decays to ^{239}Pu. During the residence of the fuel, dozens of actinide isotopes are produced by a complex chain of neutron captures and radioactive decays. Many of these are sufficiently long-lived so that they remain in the fuel when it reaches the end of its useful life. All are radioactive, and the dominant decay mechanism is alpha decay, although the decay of some radionuclides results in the emission of neutrons.
3. In the fission process, the actinide nucleus is split into two separate nuclei having much lower atomic numbers. These nuclei are called *fission products*. The split is usually not symmetrical (i.e., the two fission-product nuclei have very different masses). Further, an entire range of fission product elements and isotopes are produced. The distribution of these is shown in Fig. 8 (Katcoff, 1958). As produced, they are all radioactive, and the dominant decay mechanism is beta decay. Many have short half-lives, and these decay to long-lived or stable (i.e., nonradioactive) fission products that are present when the fuel reaches the end of its useful life.

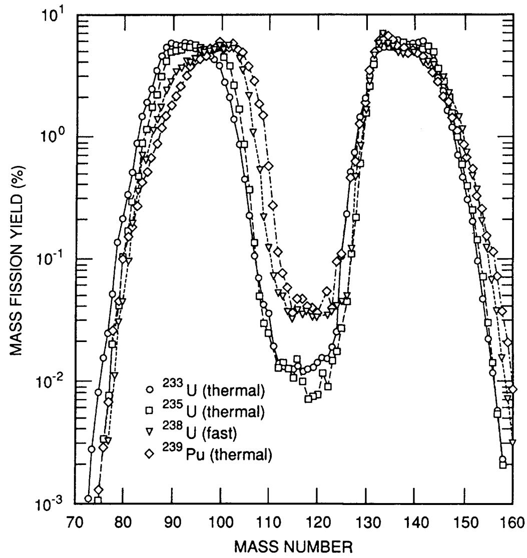

Fig. 8. Fission-product yield as a function of atomic mass number for 0.025 eV-neutron-induced fission of ^{233}U, ^{235}U, ^{239}Pu, and 14 MeV-neutron-induced fission of ^{238}U.

4. Another fate of the 1.5 neutrons not involved in sustaining the chain reaction is to interact with nonactinide nuclei by neutron capture, resulting in *activation products*. The nonactinide nuclei are most often the other materials present in the reactor (e.g., cladding metal, the reactor vessel, or neutron absorbers used to control the chain reaction). The neutron capture process is the same as that described previously for the actinides. Most of the activation products are relatively short-lived and decay to innocuous levels during irradiation. However, a few have longer half-lives and are present in the fuel and reactor structural materials when it reaches the end of its useful life.

At the end of its useful life, the uranium dioxide fuel typically used to generate electricity contains about 1% actinides heavier than uranium (primarily Pu), 3% fission products, a variable but very small amount of activation products, and about 96% uranium isotopes (^{238}U with about 0.8% ^{235}U and 0.4% ^{236}U). The proportions of constituents other than uranium isotopes are increased as the amount of power extracted from a unit of fuel (called *burnup*) increases. The useful life of the fuel is limited by the consumption of fissile isotopes, production of fission product neutron absorbers, and physical degradation of the fuel assembly structural materials (e.g., cladding).

6.2 Distribution and Properties of Fuel Irradiation Products

This section discusses the characteristics of the fuel after it reaches the end of its useful life. At this point, it is removed from the reactor vessel (i.e., *discharged*) and becomes known as *spent fuel*. The characteristics to be discussed are the location of the various products within the fuel assembly and the salient properties of the various products.

6.2.1 Distribution of Irradiation Products

The actinides in the spent fuel are contained almost exclusively within the fuel matrix. "Tramp" fuel on the cladding may result in a small amount being associated with it, but this is usually negligible.

The fission products are mostly contained within the fuel matrix. However, some of the fission product elements are gaseous (e.g., Kr, Xe) or are somewhat volatile at reactor operating conditions (e.g., Cs, I). Some of these elements will be present in nonfuel areas where it is relatively cool, such as in the top end of the fuel rod, which is designed as a gas plenum, or on the inside of cladding.

The activation products are distributed more widely. Impurities and the oxygen within the fuel are activated by irradiation and tend to remain there. The cladding and other metals used to make the fuel assembly and impurities within them also become activated. Most remain contained within the metals, although a small amount is dissolved by the coolant and finds its way to the reactor plant wastes. Although activation rates decrease as the distance from the reactor core increases, all of the other fixed internal parts of the reactor and the structure (typically steel and concrete) immediately surrounding the reactor become activated to varying degrees during their useful lives (typically 2–3 decades) and must be treated as radioactive waste when the plant is decommissioned. Finally, the coolant circulating through the core and the chemicals within it (if any) become activated to varying degrees, and the resulting radioactive isotopes find their way into reactor plant wastes during operation. Most of the activation products in the coolant are short lived, although a few are produced in significant quantities and are long lived (e.g., ^{3}H, ^{14}C).

6.2.2 Properties of Irradiation Products

The irradiation products in spent fuel could be characterized in a variety of ways, including element concentrations, isotope concentrations, chemical form, etc. However, the most relevant property of these products is that they are radioactive. As such, they have emissions of varying energy that include photons (gamma rays, x rays, bremsstrahlung), electrons (beta particles, Auger electrons), alpha particles, neutrons, neutrinos, and (very seldom) positrons. These emissions are generally well characterized and documented in large volumes (Lederer and Shirley, 1978).

These emissions have impact in two important ways. The first is that some of them (photons and neutrons) are considered to be *penetrating radiation* because they are capable of passing through a significant thickness of shielding material before being absorbed. As a consequence, any significant source of these must be shielded to protect human health. Calculation of this impact, called the *radiation dose*, is very complex because of its dependence upon the specific mix of isotopes, the age of the source, the geometric relationship of the source to the target, and the composition and thickness of materials between the source and target. Results of a calculation giving the dose rates from an unshielded, 10-year-old spent-fuel assembly are shown in Fig. 9 (Croff *et al.*, 1979). As a basis for comparison, a dose of about 500 rem has been considered to be lethal to 50% of human recipients, although medical advances evident in treating the casualties of the accident at the Chernobyl reactor in the Ukraine now indicate that the dose required to cause a 50% fatality rate may be significantly higher.

The second important impact of the radioactive emissions is that all (except neutrinos) are eventually absorbed in the material surrounding the spent fuel. The energy of these emissions is manifested as energy deposited in the material and the resultant heating of the material. A typical fuel assembly from a modern power reactor generates

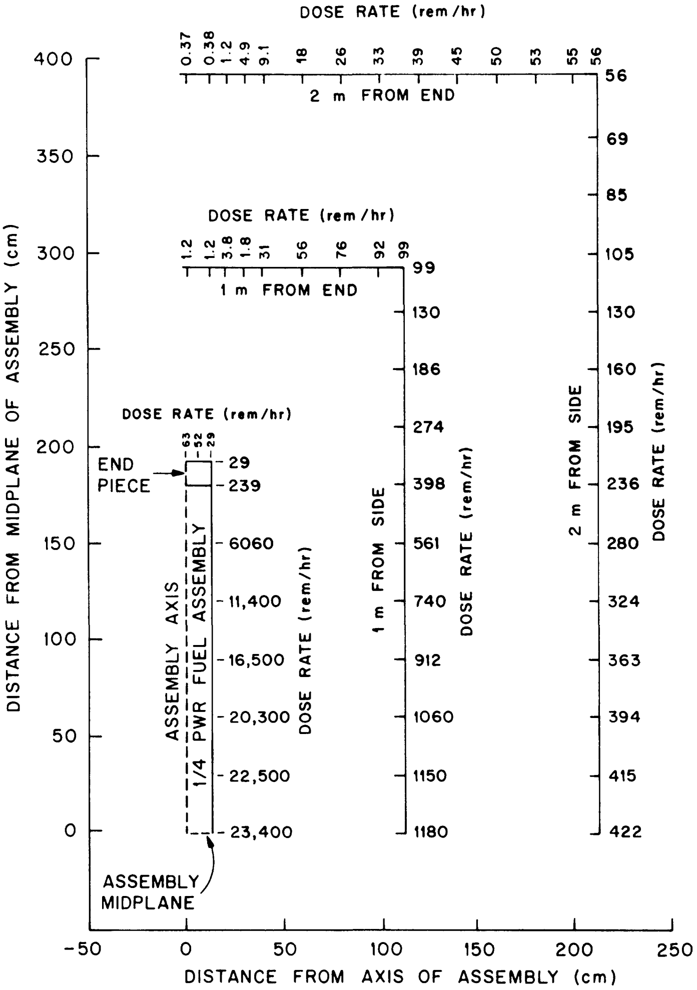

Fig. 9. Radiation dose from a 10-year-old spent pressurized water reactor fuel assembly that has been irradiated to 33 GWd per Mg of initial uranium.

heating of the material. A typical fuel assembly from a modern power reactor generates 17 300 kW of thermal power during irradiation. When the chain reaction ceases, the thermal power immediately declines to about 1200 kW. As shown in Fig. 10 (Croff and Alexander, 1980), the thermal power continues to decline at a decreasing rate thereafter until it finally attains negligible levels. However, for many years, the thermal power is sufficient to threaten the integrity of the fuel assembly if provisions are not made to remove the heat.

Radioactive isotopes can also impact living organisms if ingested or inhaled. For more discussion of these subjects, see ENVIRONMENTAL HEALTH AND SAFETY and NUCLEAR WASTE MANAGEMENT.

7. SPENT-FUEL REPROCESSING

After irradiation in a reactor and discharge from the reactor at the end of its useful life, spent fuel is stored for a significant amount of time (at least a couple of years, often many years) to allow shorter-lived irradiation products to decay. At this point, it becomes available for one of two possible dispositions. The first is that a determination is made that further chemical processing of the spent fuel is not worth while, and the spent

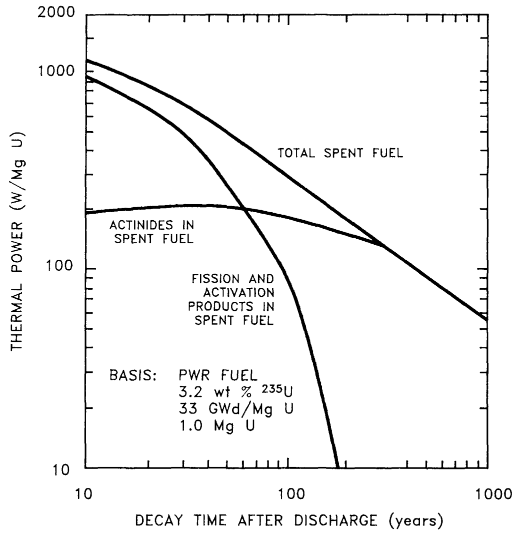

Fig. 10. Thermal power of major constituents in spent pressurized water reactor fuel that initially contained 1.0 Mg of uranium.

fuel should be treated as a waste (i.e., to have a once-through fuel cycle as described at the outset; see Fig. 1). In this case, the spent fuel would typically be stored for an extended time, sealed in a multiple-layer package, and sent to a permanent disposal site, where it would be buried deep underground (see article on NUCLEAR WASTE MANAGEMENT).

The second possible disposition is that further chemical processing of the spent fuel is worth while. This could be the case to recover various valuable constituents of the spent fuel, to change the form of the spent fuel to one more acceptable for waste disposal, or a combination of the two. The processing of the spent fuel is called *reprocessing*. The operations required for reuse of fissile and fertile constituents of the spent fuel are called *recycle*. Because of the intense radiation from the irradiation products, reprocessing must be carried out in remotely operated facilities that have thick, dense walls called *shielding* interposed between people and the nuclear material.

By far the most widely used reprocessing technology is the Plutonium-Uranium Extraction process, which is shortened to *Purex*. It has been used for decades to reprocess defense fuels to recover Pu for military purposes. More recently, large plants have been built in France and Great Britain to implement this process on civilian fuels, and more plants are under construction. The Purex process is described in some detail below as it is applied to oxide fuels clad in metals such as Zircaloy and stainless steel. This is followed by brief descriptions of variants of the Purex process and major alternative reprocessing technologies.

7.1 Purex Reprocessing

Reprocessing involves the application of a number of chemical processing steps to separate and purify the uranium and plutonium constituents of the spent fuel and to manage the residuum, which is considered to be waste. These are described in the following sections in the order in which they are performed.

7.1.1 Head End The *head end* of a reprocessing plant involves operations (generally physical) to expose the fuel material.

7.1.1.1 Remove Nonfuel Components. The first operation is to remove structural components that do not contain the fuel, such as end fittings and possibly the grid spacers. This may be accomplished by unscrewing threaded components or sawing and cutting. The removed metal pieces are treated as waste.

7.1.1.2 Segmentation of Fuel. The second operation is to expose the fuel material within the cladding in a process step called *segmentation*. This is typically accomplished with a mechanical shear, which is simply a mechanism to clamp a group of rods together with the ends projecting beyond a flat surface and chop off 2–4-cm segments with a hydraulically driven metal blade (much like chopping a bundle of celery stalks with a knife). It can also be accomplished with an abrasive saw or with a high-power laser.

7.1.1.3 Dissolution. The third operation is to dissolve the exposed fuel material in hot, concentrated nitric acid in an operation called *dissolution*. After being sheared off, the rod segments with the fuel exposed drop into a metal basket with small perforations. When the basket is sufficiently full, it is lowered into a vessel containing the acid. The acid is heated and sparged with air, and, over a period of time, most of the fuel matrix is dissolved. Fuel constituents that are not dissolved fall into three categories: cladding, insoluble metals, and volatile elements. The cladding does not dissolve in nitric acid, and remains in the basket in the form of *cladding hulls*. When fuel dissolution is complete, the cladding hulls are removed from the dissolver and treated as waste.

The insoluble metals typically comprise a small fraction of the fission products, which are themselves a small fraction of the fuel. It is the more noble fission products (i.e., Pd, Rh, Ru, Tc, Mo) that tend to be insoluble under dissolver conditions. These are typically removed from the nitric acid solution by centrifugation and may then be leached with more aggressive reagents (e.g., HNO_3-HF) to remove residual actinides before being treated as a waste or dissolved in aqua regia for further processing.

The volatile elements that evolve from the dissolver solution are called *off gas*. They may subsequently be captured to prevent their release to the environment and treated as waste. The inert gases Kr (which contains radioactive ^{85}Kr) and Xe are released quantitatively from the dissolver solution. Also released quantitatively under the highly acidic conditions are iodine (containing radioactive ^{129}I) and carbon as CO_2 (containing the radioactive activation product ^{14}C). Other species that are volatilized to some significant extent are activation- and fission-product tritium and Ru as RuO_4 (which contains radioactive ^{106}Ru). Nonradioactive oxides of nitrogen are also evolved from the dissolver solution.

7.1.2 Product Recovery The nitric acid solution containing most of the fuel constituents is then sent to two successive solvent extraction operations to recover impure uranium and plutonium in separate streams.

7.1.2.1 Primary Decontamination. In the first operation, the nitric acid solution undergoes multistage contact with a 30-vol% solution of tri-*n*-butyl phosphate (TBP) dissolved in an organic diluent such as *n*-dodecane. The aqueous and organic streams are immiscible and can be easily separated by gravity or centrifugation. The organic phase extracts virtually all (99+%) of the U and Pu (which are in the +6 and +4 valence states, respectively), a significant amount of the Np (which is in multiple valence states), and a significant amount of a few fission products such as Zr, Nb, and Ru. These leave the solvent extraction equipment in the organic stream. The nitric acid solution contains virtually all of the fission products, Am and Cm, and some of the Np. This solution is evaporated to concentrate it and recover the nitric acid. The remaining solution is called *high-level waste* and has little further value, except possibly for the recovery of small amounts of isotopes for specific beneficial uses.

The organic chemicals are recycled within the plant. However, because of the fission products, the organic extractant is exposed to intense radiation (primarily beta particles and gamma rays) while it is in contact with the aqueous solution. The result of this exposure is that some of the TBP is degraded to form undesirable impurities, with the levels increasing with increased exposure. It is necessary to remove the impurities from the solvent to make it acceptable for reuse. This can be accomplished by various means such as contacting it with an aqueous solution of sodium carbonate or passing it over a bed of silica gel.

7.1.2.2 Partitioning. The second product-recovery operation separates the U from the Pu. This is accomplished by contacting the organic stream laden with U and Pu with a dilute nitric acid stream containing a reductant such as ferrous sulfamate, hydrazine, or electrolytically generated U^{4+}. The reductant changes Pu to the +3 valence state, which is readily extractable by the nitric acid stream while the U remains in the organic stream.

7.1.2.3 Solvent Extraction Equipment. The key pieces of equipment in the above operations are the solvent extraction contactors. This is especially the case in the primary decontamination operation, where fast, efficient contact between immiscible phases followed by rapid, complete separation is important. The first equipment used was called a *mixer-settler*, which amounted to little more than mixing the organic and aqueous streams in a vessel using a powered agitator and then allowing the phases to separate by gravity in a baffled portion of the device. The two phases were then routed to neighboring mixer-settlers in counter-current fashion, much like the enriched and depleted streams in uranium enrichment described in Sec. 3.1.2. This equipment had relatively long contact times and low efficiencies, resulting in the development of more advanced equipment.

The successor to the mixer-settler in nuclear fuel reprocessing is the *pulse column*, which is presently in widespread use in most reprocessing plants. In this device, an aqueous (more dense) stream is introduced into the top of a vertical cylindrical column, and an organic (less dense) phase is introduced into the bottom. Spaced throughout the column are *sieve plates*, which are perforated horizontal metal plates. As the liquids pass through the plates, they are dispersed to promote intimate contact of the two phases. A *pulser* (much like a hydraulic cylinder) is periodically activated to force a small amount of liquid upward through the plates into the next stage. While this device was a distinct improvement over the mixer-settler, it still suffers from long contact times and requires large (and expensive) shielded process cells because the contactors are relatively tall.

The most recent advance in solvent extraction equipment is the *centrifugal contactor*. This is a piece of rotating equipment much like the gas centrifuge described in Sec. 3.1.3. The two streams are introduced, and, in one portion of the equipment, an agitator ensures good dispersion and contact between the phases, which quickly exit to another portion where they are quickly separated by centrifugal force. The equipment is relatively small and appears to meet the demands of fuel reprocessing quite well.

7.1.3 Product Purification At this point in the process, the separate U and Pu streams remain cross-contaminated (e.g., Pu in the U stream) as well as being contaminated with significant amounts of Np and fission products. The purpose of product purification is to remove these contaminants to acceptable levels.

7.1.3.1 Uranium Purification. The uranium is in the organic phase as it enters purification. It is then typically back extracted into dilute nitric acid and then subjected to one or two more cycles of TBP extraction and nitric acid back extraction to achieve the necessary purity. An aqueous solution of U may also be passed over a bed of silica gel for final purification. The purity requirements are higher if the uranium is being recycled for isotopic re-enrichment, as opposed to being simply used as feed material to be enriched with Pu.

7.1.3.2 Plutonium Purification. The plutonium is in the aqueous phase as it enters purification. It is typically subjected to one more cycle of TBP extraction and nitric acid back extraction. The final purification step consists of passing a nitric acid solution of the Pu through a column of anion-exchange resin to remove the residual contaminants.

7.1.4 Product Conversion The two product streams resulting from purification of U and Pu are aqueous acid solutions of the respective nitrates. The final forms of these products are generally UO_2 or UF_6 and PuO_2, respectively. Such conversion is usually done relatively promptly because the liquids are more vulnerable to leakage, criticality, and radiation effects and are expensive to store.

7.1.4.1 Uranium Conversion. The conversion of uranium nitrate solution to UO_2 generally proceeds as described in Sec. 2.2. Briefly, the uranium is precipitated as ammonium diuranate, which is then calcined to yield UO_2. This can be mixed with other fissile elements such as Pu to make mixed-oxide fuel, which can then be fabricated as described earlier and recycled to a reactor. Alternatively, the UO_2 can be further converted to UF_6 for re-enrichment, as described in Sec. 2.3.

7.1.4.2 Plutonium Conversion. The approaches used to convert plutonium nitrate to PuO_2, which is the only useful form in power production systems, are somewhat more diverse than for uranium. The plutonium can be precipitated with oxalic acid as plutonium oxalate, which is then filtered, dried, and calcined to PuO_2. The addition of hydrogen peroxide to the plutonium nitrate solution directly precipitates PuO_2, which can then be recovered through filtration and dried. Finally, there is some experience with direct evaporation and calcination of the nitrate solution to yield PuO_2, although this has not been used commercially.

7.1.4.3 Coconversion. Techniques have been developed and tested that form mixed $(U,Pu)O_2$ directly from a mixed-nitrate solution. These are called *coconversion processes*. They can involve direct calcination of the nitrate mixture to yield UO_3 and PuO_2, followed by hydrogen reduction to the mixed dioxide. Alternatively, the U and Pu can be coprecipitated and then calcined to the dioxide.

7.2 Reprocessing Variations

Numerous variations of reprocessing technology have been developed, and many have been deployed. Some of these variations represent the normal evolutionary improvement of any technology. Others include features necessary to produce somewhat different products or handle various types of spent fuel. Finally, fundamentally different approaches can be used for a specific fuel type.

7.2.1 Purex Variations A number of specific variations in the implementation of the Purex process are embodied in Sec. 7.1, and many more (primarily regarding chemical conditions in the processes and equipment differences) are possible, depending on cost estimates and the objectives of the Purex plant designer.

The only major variation of Purex that has been seriously considered (but not deployed) is to operate the process without the partitioning and purification operations (American Nuclear Society 1978). This yields a mixed U-Pu product that is contaminated with significant amounts of radioactive fission products for the purpose of making the material less desirable for diversion to undesirable uses. Such a material could only be recycled by designing facilities and equipment to carry out all steps of the fuel cycle with fully remote operations.

7.2.2 Aqueous Reprocessing Variations A number of aqueous reprocessing technologies other than Purex have been developed since the 1940s, when large-scale nuclear technology was born. Most of the early processes (e.g., bismuth phosphate precipitation, REDOX, Trigly, Butex) were displaced by the superior Purex process and others developed after Purex did not appear to offer enough advantages to justify the cost and risk of development. As a consequence, the Purex process continues to dominate the processing of uranium-based fuels to the exclusion of other aqueous processes.

Other aqueous processes are used in the processing of fuels that are not uranium based. The best known of these processes is *Thorex*, which is used for thorium-based fuels in which ^{233}U is produced by neutron capture. Thorex is similar to Purex in many respects, and the reader is referred to Sec. 7.1 for the operational sequence of the process. The primary difference in Thorex is that Th does not dissolve easily in nitric acid, and it is necessary to add HF to the dissolver solution to obtain an acceptable dissolution rate. However, the HF causes additional problems in the process, principally unacceptably high corrosion of metals. As a consequence, aluminum nitrate is added to the dissolver to complex the fluoride ion and keep corrosion to an acceptable level. The fluorides and aluminum report to the high-level waste and may result in problems or additional cost in its management. So far, Thorex has not been applied commercially.

7.2.3 Nonaqueous Reprocessing Variations Two major classes of nonaqueous processes have been developed: pyroprocesses and fluoride volatility. The potential advantages of these processes are that first, unlike organic solvents, radiation damage to the reagents does not create deleterious effects in the process, and second, the fundamentally different nature of the reagents offers unique possibilities concerning what is readily separated and what is not. The waste streams from these processes differ markedly from aqueous process wastes.

7.2.3.1 Pyroprocesses. *Pyroprocesses* are defined by the use of high-temperature (>500 °C) molten metals and salts as the reprocessing reagents. The feed material must typically be in the form of metal, and oxide fuels must be reduced to the metal (typically with Ca) before processing. Numerous pyroprocesses have been investigated over the last few decades, including volatilization, fractional crystallization, extraction with liquid metals, liquid extraction from fused salts, electrolysis, partial oxidation, skull reclamation, and salt transport. Most of these have not been developed to any appreciable extent because they manifested serious deficiencies compared to other processes, but those described below have been investigated to a significant extent.

A partial oxidation process (called *melt refining*) that involves melting uranium-based metallic spent fuel in a ZrO_2 crucible at 1400 °C has been applied to the recycle of fuel at the EBR-II test reactor in Idaho for almost 30 years. Many fission products are volatilized at this temperature, and other nonvolatile fission products that are more reactive than uranium and 5–10% of the feed uranium are oxidized by the ZrO_2 and form a separate layer (called a *skull*) in the crucible. The remaining metal is a mixture of fission products less reactive than uranium (e.g., Zr, Nb, Mo, Ru, Rh, Pd), which are collectively known as *fissium*, and uranium. This mixture is combined with fresh, enriched uranium metal, and the product is poured into glass molds to make recycle fuel. The fissium is highly radioactive, but its physical properties stabilize the uranium during irradiation in the reactor. The *skull reclamation* process uses a Mg-Zn alloy to reduce the valuable uranium in the skull selectively to the metal, which is soluble in the alloy. The Mg-Zn is then removed by distillation to recover the uranium.

An electrolysis process called *electrodeposition* is being investigated for processing metallic U-Pu fuels for advanced reactors cooled with liquid sodium. In this process, stainless-steel–clad fuel made of metallic U-Pu-Zr and a portion of the fission products are chopped and placed in a basket. The electrorefiner contains a bottom layer of molten Cd and a top layer of LiCl-KCl eutectic salt. The basket is lowered into the salt layer, and $CdCl_2$ is added to oxidize the alkali, alkaline-earth, and rare-earth metals in the spent fuel to their chlorides, which dissolve in the salt layer. Electrolysis occurs by making the basket and bottom Cd layer the anode. Two cathodes are immersed in the molten salt layer, with one part being steel and one part being molten Cd in a ceramic crucible. During electrolysis, U-Cd is deposited on the steel cathode, and a mix of U-Pu-Cd-lanthanides is deposited on the Cd cathode. The U-Pu product contains the other actinides heavier than U that were present in the spent fuel. Both products contain significant amounts of fission products and the Zr that was present in the initial fuel. When electrodeposition is complete, the two cathodes are removed to a retort where the Cd is volatilized. The remaining constituents are then removed to an injection melter, which melts the actinide products, adjusts the composition to the correct U-Pu-Zr proportions, and injects this mixture into fuel molds. The fuel is then recycled to the reactor.

7.2.3.2 Fluoride Volatility Processes. As might be evident from the section on uranium enrichment, fluorides of some elements are volatile at modest temperatures (a few hundred degrees Celsius or less). This property has been used as a basis for reprocessing spent fuel using a *fluoride volatility process*.

In this process, the fuel material is exposed by decladding operations much as in the Purex process. However, at this point, the fuel material is converted from the oxide to fluorides using a sequential combination of HF and F_2. Many of the fluorides are volatile but at varying temperatures. This permits a first separation of the U from other radionuclides by using simple distillation. The impure uranium stream from this operation is then further purified using techniques such as passing the gases through solid beds of NaF to remove undesirable elements by selective sorption of uranium. When this is used as a primary reprocessing technology, only the U is recovered, and the Pu follows the fission-product waste. As a consequence, this has been considered for only highly enriched uranium fuels where the Pu is mostly composed of ^{238}Pu, which is not worth recovering.

Fluoride volatility processes are capable of excellent decontamination from undesirable constituents and have been used to clean uranium feed to enrichment operations. A full-size reprocessing plant (Midwest Fuel Reprocessing Plant) in which the final cleanup operations were based on fluoride volatility processes was designed and built at Morris, Illinois, but never operated because of design inadequacies (especially inadequate surge capacity within the facility).

7.2.4 Continuous Reprocessing The reprocessing of spent fuel from an individual reactor, as described in Sec. 7.1, is performed intermittently on a group of discharged spent fuel assemblies sent to a separate facility. However, reactor systems have been developed and tested in which the fuel is circulated through a core region configured so that a nuclear chain reaction occurs and the fuel is heated. The fuel then flows to a heat exchanger, where the heat is removed by generating steam to make electricity in a turbine. The fuel (or a fraction thereof) is then circulated to a reprocessing operation that is an integral part of the fuel flow loop, where it is *continuously reprocessed* to remove deleterious fission products.

This concept has been tested in designs involving aqueous fuel [e.g., the Aqueous Homogeneous Reactor Experiment (Chapman *et al.*, 1963) and the Molten Salt Breeder Reactor (Weinberg *et al.*, 1970)]. In the aqueous case, reprocessing operations involve volatilization of the noble-gas fission products and use of the fact that actinide sulfates exhibit *retrograde solubility* (less soluble at higher temperatures) to precipitate them with some of the fission products and recover them with a cyclone. For the molten salt reactor, the reprocessing technology would be very similar to pyroprocessing as described in Sec. 7.2.3.1. These concepts have not been developed further than the test reactor phase, and there are no apparent plans to do so.

8. STORAGE AND TRANSPORTATION OF NUCLEAR MATERIALS

Because of economics of scale and other business factors, most facilities constituting the nuclear fuel cycle shown in Fig. 1 are generally not colocated. As a consequence, various radioactive product materials must be transported between facilities. This, in turn, dictates that the various facilities have significant capability for storing the feed and product materials in order to achieve economic transportation loads, to ensure uninterrupted facility operations, or to condition materials prior to processing.

Although there are radioactive materials transported between and stored at each of the facilities shown in Fig. 1, most of these operations are straightforward because the materials involved are only mildly radioactive. Considerations for transportation and storage of materials that have not been irradiated involve protecting them from dispersion and the natural elements (e.g., rain) and, in the case of precision-manufactured components such as fresh fuel assemblies, protecting them from physical damage during transport. These considerations, and the transportation and storage methods employed, are very similar to those used for mildly toxic industrial chemicals and other high-precision equipment and will not be detailed here. One exception is storage and transportation of highly enriched fissile material, which requires special considerations to provide adequate protection from illicit diversion and criticality control.

On the other hand, spent fuel and the high-level waste from the primary decontamination operation of fuel reprocessing are highly radioactive, emitting significant amounts of heat and penetrating radiation. The considerations in their transport and storage are unique and are described in some detail below.

8.1 Storage

8.1.1 Water Pools Spent fuel is most commonly stored in deep-water pools, which are usually rectangular and placed in a large open room with a high-capacity overhead crane. They are present at reactor plants, which typically have the discharged spent fuel from many years of operations stored in the pool since disposal facilities have not yet been built in any country. They are also present at fuel reprocessing plants and constitute the centerpiece of stand-alone facilities designed for long-term spent-fuel storage. Experience has shown that fuels clad in Zircaloy and stainless steel can be stored under water for decades with no significant degradation.

The pools have varying surface areas depending on the capacity of the facility. They are normally quite deep: 3–6 m plus the height of a fuel assembly. The water layer above the top of the fuel assemblies provides radiation shielding to the workers (e.g., crane operators) located around and above the pool, and one fuel-assembly height is required for storage. A portion of the pool is normally deeper yet by about an extra fuel-assembly length plus 1–2 m to accommodate a large, thick-walled vessel used to transport the fuel between sites (see Sec. 8.2 for details).

The pool is built with a grid structure of metal racks to hold the spent fuel in place in a configuration that eliminates the possibility of a critical reaction. The pools have a high mass and typically a high center of gravity, and extensive provisions are made to ensure integrity during potential seismic events. The water in the pool is circulated to maintain it at extremely high purity levels and to remove the decay heat from the spent fuel. Fuel assemblies in which the cladding of one or more elements has been penetrated are normally sealed in a metal can before being stored.

Other materials having significant radioactivity are often stored in the pools. Examples are contaminated or irradiated reactor components and metal hardware from dismantled fuel assemblies. In a reprocessing plant pool, the high-level waste packages and cladding waste packages are typically stored in the pool.

8.1.2 Dry Storage Storage of some materials under water may not be possible or desirable on the basis of technical or economic grounds. This may be the case because water will adversely affect the integrity of the fuel (e.g., fuels clad in Al and Mg or made of graphite), an existing pool is full and expansion is not possible, or the fuel characteristics are such that it is more economical to store it under dry conditions.

There are two common technologies for dry storage. One is to store the fuel in a container called a *storage cask* that is so massive that it provides adequate radiation protection. This cask is simply loaded with spent fuel or waste, sealed, and then placed outside on a concrete pad where heat is removed via conduction through the package and natural convection. This container is very similar to those used for transporting the spent fuel except that it may not be certified for off-site transportation. It is described in detail in Sec. 8.2.

The second common dry-storage technology is *dry wells*. These are typically an array of individual cells made of reinforced concrete and sized so that a fuel assembly can be lowered into them and a plug providing radiation shielding inserted into the top of the well. The wells are not normally ventilated, and heat removal occurs via conduction through the walls and then convection in a moving air stream. If the wells are ventilated and actively cooled, the gas stream must be purified before release. This type of design is also used in reprocessing plants for storage of high-level and other highly radioactive wastes.

8.2 Transportation

Spent fuel is transported between facilities via trucks, railroads, and ships in containers called *shipping casks* or *shipping packages*. This operation is challenging because the cask must simultaneously provide for radiation protection, heat removal, criticality protection, and barriers to the release of radionuclides from the spent fuel in the case of accidents.

8.2.1 Regulations Standards that casks must meet have been established by international organizations (IAEA, 1992) and national regulatory authorities and are remarkably uniform throughout the world. This is necessary because of the international nature of the nuclear fuel cycle and the need to move nuclear material between nations. The manner in which a particular designer meets these standards is flexible, depending on the specific characteristics of the fuel being transported. When a new shipping cask is to be built, or an existing cask significantly modified, it must be shown to meet the standards by actual testing, typically with a scale model, or by rigorous engineering analysis. A cask is subjected to the following tests in sequence:

1. a 9-m drop onto a flat, horizontal, unyielding surface so that it strikes in its most damaging orientation (typically an edge);
2. a 1-m drop onto a 0.15-m-diameter steel bar at least 0.2 m long, at its most vulnerable part;
3. a fire test in which the cask is totally engulfed in a 800 °C thermal environment for 30 min;
4. water immersion in which the cask is submerged under at least 0.9 m of water for 8 h, and a separate cask is completely immersed under 15 m of water for 8 h. In addition, for casks carrying over 1 MCi of radioactivity, the International Atomic Energy Agency requires that the immersion depth be increased to 200 m (a pressure chamber is used to simulate this depth).

To be acceptable, the cask must remain leaktight after this test sequence.

Myriad additional regulations are often imposed on the transportation operation *per se*. These include how the cask is fastened to the transport vehicle, radiation level limits, shipping documentation, labeling, driver qualifications, emergency response, and routing.

8.2.2 Shipping Casks The above requirements, when coupled with the need for a significant payload and removal of significant amounts of decay heat from the spent fuel, result in the cask having to be made almost exclusively of metal components. A typical schematic of a spent-fuel shipping cask is shown in Fig. 11. The cask has an inner and outer shell usually made of stainless steel. Between these shells is a very thick layer of denser metal to provide shielding from penetrating photon radiation. Iron, lead, and uranium are often used to provide this

shielding. In addition, if the spent fuel emits a significant amount of neutron radiation, there is often a layer of hydrogenous material (e.g, polyethylene) that contains a good neutron absorber (e.g., boron). Casks typically weigh between 25 and 100 Mg.

A grid called a *basket* that is appropriately sized for the spent fuel being transported is inserted into the hollow cavity in the middle of the cask. The basket holds the fuel in place to prevent damage during normal transport and minimize damage during accident conditions. It is also important in assuring that the array of fuel assemblies will remain subcritical during transport.

The cask is typically loaded by removing its lid and immersing it in the pool with the open end upward. The fuel is then loaded into the cask with a crane, the lid placed on the cask (to provide radiation shielding), and the cask removed from the pool. Water is drained from the cask interior, the lid bolted down, the inside dried with a vacuum pump, the cask leak tested, and the interior filled with an inert gas (typically nitrogen). The outside of the cask is decontaminated to remove the trace radioactivity present from the pool water, loaded onto the transport vehicle (trailer or rail car), tied down, and then transported to its destination, where the process is reversed to unload the fuel. The cask is cooled by conducting the heat through the walls; no active cooling measures are employed, although fins are often used to enhance convective heat transfer on the outer surface.

9. BENEFICIAL USE OF RADIOISOTOPES

The preceding sections of this article have been concerned primarily with the beneficial use of a very limited number of radioisotopes: ^{232}Th/^{233}U and ^{235,238}U/$^{239-242}$Pu, with the latter halves of the pairs being created during fuel irradiation. Thorium and ^{235,238}U occur naturally, although the latter often requires enrichment to achieve usable concentrations of ^{235}U. However, a large number of other radioisotopes have found beneficial uses in smaller, but nevertheless extremely important, applications. The purpose of this section is to describe the production and uses of radioisotopes other than those used in the manufacture of power reactor fuels.

9.1 Production and Recovery of Radioisotopes

Radioisotopes other than those that occur naturally are produced by two methods: irradiation of a target by nuclear particles and decay of other radioisotopes.

9.1.1 Production by Irradiation Radioisotope production by irradiation can be accomplished using nuclear reactors or particle accelerators (see NUCLEAR ENERGY: FISSION; ACCELERATORS, LINEAR). In the case of reactors, neutrons irradiate the target material and are captured or induce fission as a result. In the case of accelerators, the target is irradiated by high-energy charged particles such as protons, deuterons, or alpha particles. This results in the ejection of photons and/or other nuclear particles. In both cases, the target material, irradiating particle intensity, irradiation duration, and particle energy spectrum are selected to maximize the yield of the desired radioisotope or minimize contamination by undesirable isotopes.

Very often, the target material is a stable material enriched in a specific isotope (see Sec. 3.2.5) to maximize the yield and purity of the desired radioisotope. The targets are always small (micrograms to grams) in the case of accelerator irradiation, and in cases where expensive, enriched stable isotopes are used as targets in reactors. Targets are also small (ranging from 100 g for initial isotopes to micrograms for targets of the heaviest elements) when long-lived radioisotopes (the transuranic actinides in particular) are irradiated in reactors to produce heavier actinides. When the desired radioisotope is a fission product, the target may be nuclear fuel, which can be a relatively large assembly as described previously, or a target consisting of a few grams of enriched uranium.

9.1.2 Production by Decay In a few cases, very pure radioisotopes can be recovered by decay. Specifically, a pure, relatively long-lived isotope is isolated and allowed to decay. Periodically, its decay product is separated (or *milked*) from the parent for a particular use. This production method is significantly dependent upon serendipity, requiring the ability to isolate a suitable long-lived parent that does not produce competing decay products and that produces the desired product at an adequate rate. This method is used, for example, in the preparation of ^{99m}Tc from decay of fission product ^{99}Mo.

9.1.3 Recovery of Radioisotopes In general terms, radioisotopes are recovered by dissolving the target and applying appropriate chemical or physical processes to isolate a relatively pure product. When production is by decay, the parent is often maintained in dissolved form to facilitate separation. In the case of fission products, the feed material is most often the high-level waste produced after the primary decontamination operation in reprocessing. In other cases, the target may be dissolved in any of a number of reagents and the separation effected using a variety of techniques (e.g., solvent extraction, precipitation, ion exchange, vaporization). These techniques are specific to the nature of the target and product, as well as the product purity specifications. In most cases, the processing also involves recovery of the residual target material, which is often very valuable. The recovery operations take place in facilities ranging from standard ventilated laboratory hoods to elaborate cells with thick radiation shielding, depending on the characteristics and amount of the radioisotopes being processed. In very special cases, a few atoms of exotic radioisotopes such as some of the very heavy elements are separated by recoil from thin films that are bombarded with particles from accelerators.

9.2 Useful Radioisotopes and Their Applications

A wide variety of radioisotopes are regularly used in the modern world. Some of these applications are very specialized and esoteric, relating only to the frontiers of knowledge (e.g., the very heavy synthetic elements). Other applications occur every day in familiar settings and affect the lives of many people (e.g., medical diagnostics/treatment and the use of radioisotopes in smoke detectors). The following provides a framework of the applications of radioisotopes that is used here for the purposes of more detailed discussions: medical diagnostics and treatment, industrial applications, basic research in the physical sciences, radiotracer applications, power production, and military applications.

9.2.1 Medical Diagnostics and Treatment By far the most rapidly growing use of radioisotopes is in the medical community (see NUCLEAR MEDICINE). Within this community, radioisotopes are used for diagnosis (determining the cause of symptoms) and treatment (curing the problem that causes the symptoms). Approximately 300 radiopharmaceuticals are presently available, and this number is growing rapidly.

9.2.1.1 Diagnosis. The chemical properties of many isotopes result in their concentrating in particular organs when introduced into the body. The radioactive emanations from the decay of these isotopes can then be detected, providing an indication of the activity of the organ or even an image of the organ that can achieve remarkable clarity through computer enhancement. Although a wide variety of radioisotopes are used for this purpose (e.g., ^{131}I, ^{201}Tl, ^{47}Sc), the most commonly used is ^{99m}Tc, which is produced by decay from its longer-lived ^{99}Mo parent. By incorporating the ^{99m}Tc into various chemical compounds, it can be caused to concentrate in almost any organ of the human body. It is estimated that ^{99m}Tc is used in about 30 000 medical procedures per day.

9.2.1.2 Treatment. After a problem is diagnosed, radioisotopes are often used to effect a cure. In general, this involves use of the radioactive emanations of a radioisotope to destroy specific tissues such as tumors. For example, gamma rays from ^{131}I are often used in the treatment of the thyroid gland by introducing it into the body, and ^{60}Co is used as an external gamma-ray source for treating a variety of tumors. Californium-252 decays in part by the emission of neutrons and has been found to be effective in treating cancer of the cervix and prostate.

9.2.2 Industrial Applications

9.2.2.1 Sterilization. The quest to improve the quality of health and foodstuffs has resulted in an increasing need for sterilization. Regarding the former, sterilization of a wide variety of medical equipment is required. Because much of this material is now made of plastics and polymers, the previous practice of using high temperatures is unacceptable. Sterilization of foodstuffs is increasingly desirable to prevent spoilage while retaining the full nutritional content and taste, and, again, this is not possible by using high-temperature or drying technologies.

It has been found that irradiating the equipment or food with massive amounts of gamma radiation is very effective in sterilization without impairing other characteristics or making the target material radioactive. The medical equipment can be sterilized after being sealed in impermeable packages, and sterilized food can last for months without refrigeration. Although any radioisotope that emits high-energy gamma rays can be used in this application, by far the most common are ^{60}Co (produced by neutron irradiation of natural ^{59}Co), ^{192}Ir (produced by neutron irradiation of natural ^{191}Ir), and ^{137}Cs (a fission product). Gamma ray sterilization has also been tested on sewage sludges, although application has been very limited.

9.2.2.2 Radiation-Induced Reactions. Gamma rays (typically from the same sources as described immediately above) have also found use in creating desirable chemical reactions. One of the most common is the use of gamma rays to induce the polymerization of a monomer (e.g., linking ethylene monomer to form polyethylene). Gamma rays from radioisotopes can also be used to break chemical bonds when required, and this has been used to control the molecular weight of Teflon®.

9.2.2.3 Measurement and Testing. Radioactive emanations from radioisotopes can be used in a number of ways related to industrial measurement and testing.

1. A gamma-ray source and a number of detectors can determine the level or density of liquid in a tank as a means of process control.
2. Beta particles (e.g., from ^{90}Sr) can be used to measure the thickness of thin layers on a substrate such as metal plating or paint as a means of process or quality control.
3. Neutron and gamma radiation are used in petroleum exploration to determine the characteristics of the surrounding rock down-hole, which is called *well logging*.
4. Neutron and gamma radiation are used to radiograph industrial equipment to detect imbedded flaws (similar to an x ray of the human body).
5. Radioisotopes are used to make self-luminous materials (e.g., watch dials, egress lighting).
6. Americium-241 is used in many home smoke detectors, where the difference between radiation-induced ionization of the smoke and clean air results in activation of the alarm.

9.2.3 Basic Research in the Physical Sciences The properties of radioisotopes have made them very useful in research concerning the physical sciences. In some instances, the radioisotope is the subject of study. For example, the heavy actinide isotopes (e.g., einsteinium, fermium) are studied to learn more about the structure of the nucleus and the laws that govern it, as well as the chemical properties of these exotic elements. In most other cases, the properties of the radioisotope emanations are used as a tool to learn more about a specific phenomenon or object. One of the most common examples is *activation analysis*, in which an object is briefly exposed to neutrons and the induced radioactivity measured as a means to determine nondestructively the atomic composition of the object. Applications of activation analysis range from industry to criminology. The use of radioisotopes to determine the age of an object (e.g., ^{14}C dating) is also quite common in the archaeological and geological sciences.

9.2.4 Radiotracer Applications A *radiotracer* is a radioisotope that is used to follow the movement or reaction path of a material. For example, a biological compound into which radioactive tritium has been introduced can be used to study the behavior of the compound in the human body. Radiotracers are widely used in many applications described above, including medicine (e.g., examining blood circulation patterns), industry (e.g., tracking the movement of process fluids and leak detection), and the sciences (e.g., monitoring the movement of groundwater around waste-disposal sites). Radiotracers may be natural (e.g., ^{14}C, ^{226}Ra) or artificial (i.e., manufactured and introduced into the system being studied).

9.2.5 Power Production Some radioisotopes are used indirectly in the production of nuclear power. For example, a neutron source is needed to initiate the chain reaction in a nuclear reactor, especially a new reactor containing only unirradiated fuel. These sources are often made of an alpha-emitting radioisotope (e.g., ^{210}Po) and an element that releases neutrons when an energetic alpha particle is absorbed (e.g., beryllium) or of a radioisotope such as ^{252}Cf that decays in part by *spontaneous fission* and consequent neutron emission.

A much more common use of radioisotopes is as a source of power for specialized applications. Medium-lived radioisotopes such as ^{90}Sr, ^{238}Pu, and ^{244}Cm have been and continue to be used for this purpose. The heat from the radioisotope may be used without conversion (i.e., as a source of space or process heating). However, the heat is typically converted to electricity directly by using the heat to create a flow of electrons in a thermoelectric generator or indirectly by vaporizing a fluid which drives a turbine that turns an electric generator.

The major attribute of such power sources is a high power output per unit weight combined with a very long useful lifetime. The cost of radioisotopes makes their use as a power source impractical for normal applications. However, they have found extensive use in specialized applications such as powering equipment (e.g., military outposts, buoys, communications) where refueling would be more expensive, powering the instrumentation aboard spacecraft (especially interplanetary probes), and in early artificial hearts.

9.2.6 Military Applications There are specialized military applications for specific radioisotopes. One of the most common is the use of tritium in nuclear weapons, which can greatly increase the explosive power of the device. This occurs when the fissioning of the uranium or plutonium primary system provides sufficient energy to initiate a reaction in which two tritium nuclei are fused, with the resulting release of considerable additional energy. Other radioisotopes such as ^{252}Cf and ^{244}Pu have found use in diagnosing the sequence of events that occurs in underground nuclear weapons tests. Californium-252 is also used to radiograph intact military aircraft for flight-induced structural damage, an approach that has proven to be less costly than disassembling the aircraft and using more conventional radiographic techniques.

GLOSSARY

Activation Analysis: Analysis of the elemental content of a material by briefly irradiating it with neutrons and measuring the radioactive emissions from the resultant short-lived radioactive products.

Activation Product: The radioactive product of neutron capture by a material originally composed of nonradioactive isotopes.

Atomic Vapor Laser Isotope Separation: A physical method of uranium enrichment based on the selective adsorption of laser light by vaporized ^{235}U atoms to produce charged atoms (ions).

Burnup: A measure of fuel consumption (and power production) in a nuclear reactor. In the strict sense, burnup is the depletion of fissile material through fission or other processes and is expressed as a percentage. In this sense, fuel could have 75% burnup (in which case 75% of the initial ^{235}U nuclei have fissioned or been converted to another isotope). Burnup is more commonly used to express the amount of energy produced per metric ton of uranium metal (MWd/t). This is more a measure of the total number of fissions that occur, because heat is produced by fissioning of initial ^{235}U nuclei, fissioning of Pu produced in the reactor, and other nuclear processes. While it would be more correct to use the term "exposure" in this context, "burnup" continues in popular usage. Commercial power reactors attempt to maximize the amount of energy produced (i.e., fuel consumed) and thus typically have high burnups (greater than 10 000 MWd/t). "Production reactors" are operated to maximize production of weapons-grade ^{239}Pu. This is typically limited by the generation of ^{240}Pu that occurs at higher burnups. Production reactors thus typically have burnups of much less than 10 000 MWd/t.

Calutron: An electromagnetic isotope separation device used to enrich uranium during World War II and subsequently to produce a variety of enriched stable isotopes for research and medical applications.

Cascade: Isotope separation devices (gaseous diffusion or centrifuge) connected so as to multiply the amount of enrichment and/or depletion achievable by a single device.

Centrifugal Contactor: A solvent extraction device that mixes two immiscible liquids of differing density and then forces their rapid separation with the use of centrifugal force.

Cladding: The protective surrounding of reactor fuel materials to prevent their corrosion or erosion by the reactor coolant, to increase the strength of the fuel material, and to contain fission products that would contaminate the coolant.

Cladding Hulls: Pieces of nuclear fuel cladding remaining after fuel dissolution.

Coconversion: A process wherein uranium and plutonium concurrently and together undergo conversion from nitrate salts to oxide.

Continuous Recycle: A nuclear fuel cycle in which the fuel is dissolved or suspended in a liquid such as water, molten salts, or molten metals and continuously circulated through a loop involving fission, heat removal, waste product removal, and fuel renewal.

Continuous Reprocessing: Reprocessing technology used in continuous (as opposed to a discrete fuel batch) recycle, which involves on-line reprocessing of nuclear fuel.

Conversion: Changing the chemical form of uranium or plutonium to one desirable as feed to a subsequent step of the nuclear fuel cycle [e.g., yellowcake to UF_6, U/Pu nitrates to $(U,Pu)O_2$, UF_6 to UO_2].

Core: The power-producing heart of a nuclear reactor, containing the nuclear fuel that undergoes fission and releases energy. The core contains the fuel, the moderator (if required), and the control rods. The core is often surrounded by a reflecting material (e.g., beryllium) that bounces stray neutrons back into the fuel.

Dissolution: Immersion of fuel rod pieces resulting from segmentation in solvents, typically hot nitric acid, to dissolve the fuel.

Dry Well: A storage area containing air surrounded by thick radiation shielding in which spent fuel or nuclear waste is stored while being cooled by conduction of heat to an air stream outside the cell walls.

Electromagnetic Isotope Separation: An isotope separation or enrichment process that capitalizes on the different radii of the circular paths in a magnetic field of ions having different atomic masses.

Enrich: Increase the relative abundance of an isotope of an element, for example, to increase the ^{235}U concentration from its natural value of 0.72% to 3–5% for use in civilian power reactors.

Fertile Material: A material that is not fissionable by thermal (low-energy) neutrons, but that can be converted into a fissile material through neutron capture by irradiation in a reactor. There are two basic types of fertile materials: ^{238}U and ^{232}Th. When these fertile materials capture neutrons, they are converted into fissile ^{239}Pu and ^{233}U, respectively.

Fissile Isotope: An isotope that can fission by absorbing a thermal neutron and can support a thermal neutron chain reaction as well. Examples are ^{239}Pu and ^{235}U.

Fission Products: The complex mixture of elements produced as a result of nuclear fission. Fission products decay and form additional products, which may be radioactive or stable. The mixture of fission products so formed contains about 200 different isotopes of over 30 elements.

Fissionable Isotope: An isotope that can be fissioned by only high-energy neutrons.

Fluoride Volatility Process: A reprocessing technology based on the low-temperature volatility of fluorides of key elements (such as uranium).

Fuel Assembly: A number of fuel rods held in a fixed geometric array.

Fuel Fabrication: Processing of unirradiated nuclear and structural materials into a chemical and physical form and configuration that are appropriate for the fuel of a specific reactor design.

Fuel Refabrication: Processing of nuclear materials recovered from spent (irradiated) fuels and structural materials into a form and configuration that are appropriate for the fuel of a specific reactor design.

Fuel Rod (or Fuel Element): A container of nuclear fuel, usually a metal tube, suitable for insertion in the core of a reactor.

Gas Centrifuge: A device for enriching uranium (and other isotopes) in which gaseous UF_6 is contained in a hollow cylindrical rotor that is spun at high speed. The heavier $^{238}UF_6$ molecules tend to move closer to the rotor wall than the lighter $^{235}UF_6$ molecules, thus allowing enrichment to occur.

Gaseous Diffusion: A process for enriching uranium that uses gaseous UF_6 as the working fluid. The lighter $^{235}UF_6$ molecules flow through a porous barrier slightly faster than the heavier $^{238}UF_6$ molecules, thus allowing enrichment to occur.

Grid Spacers: Metal component of a fuel assembly used to hold fuel rods in place laterally.

Head End: The initial step of reprocessing, which includes spent fuel segmentation and dissolution.

High-Level Waste: The highly radioactive waste remaining after reprocessing.

Ion Exchange: A solid or liquid material with replaceable ions that can exchange with other ions in the surrounding solution.

Isotope: A nuclear species that is unique because of the number of neutrons and protons it contains. Most elements are composed of a mixture of isotopes, each with the same number of protons but differing in the number of neutrons. Isotopes may be nonradioactive or radioactive.

Isotope Enrichment: A process to increase the relative abundance of selected isotopes of an element.

Laser Isotope Separation: An enrichment process in which a selected isotope is excited by a laser beam tuned to a specific frequency (color). The excited isotope can then be removed by, for example, electromagnetic or chemical means. Important examples include Atomic Vapor Laser Isotope Separation (AVLIS) and Molecular Laser Isotope Separation (MLIS).

Metric Ton (t): 1000 kilograms or 1 Mg. Also written as tonne. Equal to 2200 pounds.

Milk: Periodically separate a desirable decay product being continuously produced by a long-lived radioactive parent.

Mixer-Settler: A solvent extraction device that mixes two immiscible liquids of differing densities and allows them to settle under normal gravitational force to effect the separation of components.

Molecular Laser Isotope Separation (MLIS): Laser isotope separation in which the feed is a uranium compound, typically UF_6.

Neutron Capture: A process in which an isotope absorbs a neutron but does not fission, thereby creating a heavier isotope of the same element.

Nuclear Fuel: The nuclear material that sustains a chain reaction in a nuclear reactor.

Nuclear Fuel Cycle: The sequence of operations involved in supplying fuel for nuclear power generation: irradiating the fuel in a nuclear reactor, handling and treating the fuel elements following discharge from the reactor, and disposing of the radioactive wastes. If spent fuel is to be reprocessed, the fuel cycle is called a "closed" cycle. If the fuel is not to be reprocessed, it is a "once-through" cycle.

Off Gas: Gases evolved during reprocessing of spent fuel.

Once-Through Nuclear Fuel Cycle: A nuclear fuel cycle in which the fuel constituents are not recovered for reuse, and the spent fuel is managed intact.

Penetrating Radiation: Particle or electromagnetic emissions, resulting from the decay of radioactive isotopes or devices such as an x-ray machine, that can penetrate significant thicknesses of solid materials.

Pulse Column: A vertical pipe in which a dissolved material (e.g., plutonium) can be extracted or exchanged by the contracting of two immiscible solutions of differing densities. The lighter solution is usually fed into the bottom of the column, while the heavier solution is fed near the top. The process is enhanced by filling the column with suitable materials to produce droplets of one solution (e.g., perforated horizontal plates) and periodically pulsing the flow.

Purex: A reprocessing technology involving aqueous nitric acid dissolution of spent fuel and recovery and separation of uranium and plutonium using solvent extraction from nitric acid solutions using tributyl phosphate.

Pyroprocessing: A reprocessing technology that employs high temperatures and typically uses molten metals and salts as the reprocessing reagents.

Radiation Dose: A measure of the radiation energy absorbed in materials, especially living organisms.

Radionuclide: Same as a radioactive isotope.

Radiotracer: A radioactive isotope used to follow the movement or reaction path of a material.

Recycle: Reuse of the fissile and fertile products from reprocessing. Recycle involves reprocessing and refabrication.

Reprocessing: Chemical processing of spent nuclear fuel to recover desired constituents, typically uranium and plutonium.

Reprocessing and Recycle: A nuclear fuel cycle in which fuel constituents are recovered for reuse.

Segmentation: A process used to reduce fuel rods to short pieces that are open at the ends, thus exposing the spent fuel.

Separation Factor: The ratio of isotopic concentration in the product (enriched) stream to the concentration in the waste (tails) stream of a single stage of an enrichment process.

Shipping Cask (or Shipping Package): A container with thick walls of radiation-absorbing material used to transport spent fuel while providing protection from radiation and preventing the release of nuclear material during an accident.

Solvent Extraction: Contacting two immiscible liquids to selectively move a dissolved constituent of one liquid to the other.

Spent Fuel: Fuel that has been removed from a nuclear reactor because it has reached the end of its useful life.

Spontaneous Fission: A mode of radioactive decay in which a nucleus fissions without being struck by a neutron. Observed only in heavy actinide isotopes.

Stable Isotopes: Nonradioactive isotopes of an element.

Stage: A single step in an isotope separation or chemical separation process. In an isotope enrichment cascade, a single stage consists of all those separators that receive feed material of the same enrichment. The number of stages in a cascade primarily depends on the desired cascade product enrichment and waste stream assays and on the separation factor of the process. The definition is the same for chemical separation, but stages are not necessarily physically distinct units as is common in isotope enrichment.

Tails: Material from isotope enrichment that is depleted in the isotopes of interest.

Thorex: A variant of the Purex process that is used to recover thorium and uranium from thorium-based fuels.

Tonne (abbreviation t): A metric ton, 1000 kg.

Tributyl Phosphate (TBP): A water-immiscible liquid used in reprocessing. It is used to extract uranium and plutonium from an acidic aqueous solution. TBP is usually diluted with an organic solvent such as kerosene.

Uranium Concentrates: The product of a uranium ore concentration plant. Uranium concentrates typically contain 65 to 85% uranium, expressed as U_3O_8. Concentrates are usually in the form of UO_3, U_3O_8, or yellowcake.

Uranium Milling: Concentration and purification of uranium in ores.

Yellowcake: Ammonium or sodium diuranate, chemical forms of uranium concentrates.

INTRODUCTION

Nuclear medicine makes use of the fact that certain radioisotopes emit γ rays with sufficient energy that the γ rays can be detected outside of the body. These radioisotopes are attached to biologically active compounds, called radiopharmaceuticals, which either localize in certain bodily tissues or follow a particular biochemical pathway. Modern nuclear medicine encompasses many disciplines, including the use of *in vitro* and *in vivo* techniques. However, the following discussion will concentrate on the uses of radioactive substances for the diagnosis or therapeutic treatment of human disease.

1. HISTORICAL BACKGROUND

Nuclear medicine (NM) has its origins in the pioneering work of the Hungarian doctor G. Hevesy, who, in 1924, used radioactive isotopes of lead as tracers in bone studies. Shortly thereafter, R. H. Stevens made intravenous injections of radium chloride to study malignant lymphomas (1926).

However, it was not until the discovery of artificially produced radioactive isotopes that the number of available species suitable for use as tracers began to increase. The 1931 invention, by Ernest Lawrence, of the cyclotron made it possible to produce radioactive isotopes of a number of biologically important elements.

The use of these artificially produced radiotracers continued with J. G. Hamilton and R. Stone using radioactive sodium clinically in 1937. In 1938, S. Hertz, A. Roberts, and R. D. Evans used radioactive iodine in the study of thyroid physiology, followed, in 1939, by J. H. Lawrence, K. G. Scott, and L. W. Tuttle studying leukemia with radioactive phosphorus. By 1940, J. G. Hamilton and M. H. Soley were performing studies in iodine metabolism by the thyroid gland *in situ* by use of radioiodine in normal subjects and in patients with various types of goiters.

In 1941, the first medical cyclotron was installed at Washington University, St. Louis, Missouri, where radioactive isotopes of phosphorus, iron, arsenic, and sulfur were produced. With the development of the fission process, during the second World War, most radioisotopes of medical interest began to be

produced in nuclear reactors. After World War II, the wide use of radioactive materials in medicine established the new field of what was then called atomic medicine, and only later became known as nuclear medicine. Radioactive carbon, tritium, iodine, iron, and chromium found increasing use in the study of disease processes.

In the 1950s, B. Cassen developed the concept of the rectilinear scanner, which opened the way to obtaining in a short amount of time the distribution of radioactivity in a subject. This development was followed by production of the first γ camera by H. Anger in 1953 (see BIOMEDICAL ENGINEERING). The original design was modified later in the decade to what is now known as the Anger scintillation camera, thus heralding the modern era of γ cameras whose principles are still in use today.

D. Kuhl and colleagues introduced the concept of transaxial tomogram using a transverse imaging device. Extensions of this work led to almost exact tomographic sections. Hounsfield introduced the x-ray–transmission computed tomography by application of the reconstruction techniques used in radio astronomy. Its extension to emission computed tomography (ECT) is the basis of single-photon–emission tomography (SPECT) and positron-emission tomography (PET).

P. Richards was instrumental in the development of the ^{99}Mo/^{99m}Tc generator system following its invention at Brookhaven National Laboratory in 1966. Technetium-99*m* produced via this generator system has become the most widely used radionuclide in nuclear medicine today, accounting for as much as 85% of all *in vivo* diagnostic procedures.

The modern era of nuclear medicine may become known as molecular medicine as the field translates advances in molecular biology and biochemistry into treatment of humans and the diagnosis of disease and anatomical abnormalities.

2. RADIOISOTOPES; RADIONUCLIDE PRODUCTION

Radionuclide production is indeed true alchemy, that is, converting the atoms of one element into those of another. This conversion involves the altering of the number of protons and/or neutrons in the nucleus (target). If a neutron is added without the emission of particles, then the resulting nuclide will have the same chemical properties as the target nuclide. If, however, the target nucleus is bombarded by a charged particle, for example, a proton, the resulting nucleus will usually be that of a different element. The exact types of nuclear reactions a target undergoes depend on a number of parameters, including the type of bombarding particle and the energy of these projectiles.

The binding energy of nucleons in the nucleus is of the order of 8 MeV, on average. Therefore, if the incoming projectile has more than this amount of energy, the resulting reaction may cause other particles to be ejected from the target nucleus. By carefully selecting the target nucleus, the bombarding particle, and its energy, it is possible to produce a specific radionuclide.

Specific activity is a measure of the number of radioactive species (atoms or molecules) as compared with the total number of species present in the sample. The specific activity is usually expressed in terms of radiation units per mass unit. The traditional units have been Ci/mole (Ci/g) or fraction thereof. If the only atoms of the labeled element present in the sample are those of the radionuclide, then the sample is referred to as *carrier free*. For example, a compound labeled with ^{99m}Tc will be carrier free, since there are no stable isotopes of technetium. However, in most cases, there are small quantities of unlabeled compounds that have a similar chemical behavior and can act as *pseudocarrier*. The specific activity of an isotope or radiopharmaceutical is important in determining the chemical or biological effect the substance may have on the system under investigation.

As an example of specific activity, assume that glucose has been labeled with 10 mCi of ^{11}C with a half-life of 20.3 min in such a way that one of the glucose carbon atoms is the radioactive label and the remaining five carbons are natural nonradioactive carbon. Its carrier free specific activity (SA) would be as follows: atoms of $^{11}\mathrm{C} = N = dN/\lambda dT = 10 \times 3.7 \times 10^7/0.693(20.3 \times 60) = 6.5 \times 10^{11}$. For every radioactive carbon atom, there is one glucose molecule, and, using Avogadro's number, the number of moles is then 1.08×10^{-12}, and the SA $= 9.3 \times 10^9$ Ci/mol.

If the radionuclide had been ^{14}C with its 5730-yr half-life, following the same process but using the λ for ^{14}C, the SA would be 62 Ci/mole. If the radiolabeled glucose had been prepared in a plant, the naturally occurring glucose would have lowered the SA because of the nonradioactive glucose molecules. Therefore, it is easy to see that the short lived radioisotopes potentially have a much higher specific activity.

The use of nuclear reactors for the production of radioisotopes relies on the fact that during the fission process in a reactor, there are large numbers of neutrons produced and thermalized by the surrounding media, usually water or graphite. These neutrons are ideal for initiating (n,γ) reactions. In some reactors, the higher-energy neutrons are used to produce radioisotopes via other reactions, for example, (n,p) or (n,α) reactions. Table 1 illustrates some neutron-induced reactions.

The fission process is a source of several widely used radioisotopes. For example, ^{90}Sr, ^{99}Mo, ^{131}I, and ^{133}Xe are all produced in reactors by fission and can be separated from the uranium fuel cells or from targets of enriched ^{235}U placed in the reactor for radioisotope production directly. The major drawback of using fission-produced materials is the production not only of isotopes of the desired species, but of large quantities of both radioactive waste material and other radionuclides as well. In producing ^{131}I from fission, the isotopes ^{127}I and ^{129}I also are formed, thus reducing the specific activity.

It is ironic that the first radionuclides artificially produced were produced on Lawrence's cyclotrons, but it was another 30 years before accelerator-produced radionuclides began to play a major role in the production of medically important radiopharmaceuticals. The principal advantage of accelerator-produced radioisotopes is the high specific activities that can be obtained. Another not insignificant advantage is that a smaller amount of radioactive waste is generated from charged-particle reactions, especially at low (30 MeV) bombarding energy.

Table 1. Reactor produced radionuclides.

$^{14}N(n,p)^{14}C$
$^{31}P(n,\gamma)^{32}P$
$^{32}S(n,p)^{32}P$
$^{50}Cr(n,\gamma)^{51}Cr$
$^{124}Xe(n,\gamma)^{125}Xe \rightarrow {}^{125}I$

Cyclotrons designed for producing medical radioisotopes were initially capable of accelerating protons, deuterons, $^{3}He^{+2}$, and α particles. However, the primary radioisotopes used in medical applications can all be produced by protons, and the simplicity of design for proton-only cyclotrons has resulted in cyclotrons that accelerate H^{-} ions capable of two or more simultaneous beams of varying energies and intensities. The modern cyclotron is completely computer controlled and is capable of running for many days with minimal attention.

The production mode of the radionuclides used for diagnostic and therapeutic purposes uses both cyclotrons and reactors, as shown in Table 2. Table 3 shows the quantities produced for the common commercially available radionuclides and the change in demand over the last decade.

As can be seen from Table 4, the PET radionuclides are produced from either proton or deuteron reactions. Since most early PET research was performed at major research laboratories having accelerators capable of proton or deuteron production, these reactions were the standard. However, in the early 1980s, small, compact, proton-only cyclotrons became available, and cyclotrons specifically designed for producing PET radionuclides were installed in many hospitals. The major drawback of these proton-only cyclotrons is that, in some cases, an enriched target material must be used for sufficient product to be generated.

The success of the small low-energy cyclotron encouraged research into the design of even lower-energy accelerators, i.e., linear accelerators and cyclotrons of a few MeV extracted energy. To date, these accelerators are in the developmental stage, but there could be a proliferation of these devices in most medical centers if they prove inexpensive to purchase and operate.

The equation for the rate of production is

$$R = I\sigma t, \tag{1}$$

where R is the number of nuclei formed per second, I is the flux of bombarding particles per second, σ is the cross section (probability of the reaction occurring) in cm^2, and t is the target thickness expressed as the number of

Table 2. The production modes of some radionuclides widely used for diagnostic or therapeutic purposes. The principal mode of decay is given, along with the major γ-ray energies and their intensities (I) in percent of total decay rate.

Nuclide	Principal decay mode	E(I) keV (%)	Reaction
^{67}Ga	EC	93 (37) 185 (20)	^{68}Zn(p,2n)
^{99}Mo/^{99m}Tc	IT	140 (98)	^{98}Mo(n,γ), fission product
^{111}In	EC	171 (90)	^{112}Cd(p,2n)
^{123}I	EC	159 (83)	^{124}Xe(p,2n)^{123}Cs → ^{123}Xe →
^{131}I	β^-	364 (81)	^{130}Te(n,γ)^{131}Te →
^{127}Xe	EC	203 (68)	^{133}Cs(p,spall)
^{133}Xe	β^-	81 (36)	Fission product
^{201}Tl	EC	167 (11)	^{203}Tl(p,3n)^{201}Pb →

nuclei per cm^2 (n/cm^2). It is of historical interest to note that the unit for cross section is the barn, which is defined as 10^{-24} cm^2. The expression barn comes from the fact that the probability of a neutron interacting with a target is proportional to the area of the nucleus, which, compared to the size of the neutron, is as big as a barn.

The rate of production is, of course, affected by the fact that the resulting nuclide is radioactive and, thus, undergoes radioactive decay. For short-lived nuclides, the competing reaction rates, production and decay, will come to equilibrium at sufficiently long bombardment times, since the rate of decay is proportional to the number of radionuclei present. The point where equilibrium has been reached is called saturation, meaning that, no matter how much longer the irradiation occurs, the production rate is equal to the rate of decay, and no additional product will be formed. At shorter irradiation times, the fraction of product produced is related to the saturation factor given by $1 - e^{-\lambda t}$, where λ is the decay constant of the decaying nuclide, and to the bombardment time t. It is evident that an irradiation equivalent to one half-life would result in 50% of saturation. For practical reasons, an irradiation rarely exceeds three half-lives (90% of saturation), except for the shortest-lived radioisotopes.

For long-lived species, the quantity produced is usually expressed in terms of integrated dose or total beam flux (μA-h). For example, with a long-lived radionuclide such as ^{82}Sr ($t_{1/2}$ = 25 d), the amount produced will be essentially the same whether it is produced from 100 μA in 1 h or 50 μA in 2 h (both represent 100 μA-h of beam).

Finally, the other source of radionuclides used in medicine is the generator. A radioactive generator takes advantage of the cases where one longer-lived (parent) radionuclide decays, usually by β^- emission, to a shorter-lived (daughter) radionuclide. The chemical differences in the two elements are exploited to separate the daughter product from the parent. The parent radionuclide is produced by one of the methods described above and then attached to an inert substance from which the desired product can be eluted. The product can be used directly, as in the case of ^{82}Rb$^+$ from the Sr/Rb generator, or after undergoing a chemical reaction, as in the case

Table 3. Some of the principal commercially available radionuclides and the quantities, in curies, used over the last decade. Note the rate of growth for ^{123}I and ^{201}Tl.

Nuclide	$t_{1/2}$	Retail consumption (1982)	Retail consumption (1987)	Retail consumption (1990)
^{67}Ga	78.3 d	800	800	820
^{99}Mo/^{99m}Tc	66 h/6 h	100 000 (^{99}Mo)	120 000	150 000
^{111}In	68 h	150	160	185
^{123}I	13.2 h	75	1250	3100
^{131}I	8.0 d	10 000	10 000	14 000
^{127}Xe	36.4 d	100	100	100
^{133}Xe	5.2 d	25 000	25 000	45 000
^{201}Tl	73 h	500	2500	6000

Table 4. The most commonly used positron emitters and typical reactions for their production; chemical forms of precursors for labeling more complex chemical species and typical radiopharmaceuticals.

Nuclide	$t_{1/2}$ (min)	Reaction	Precursor	Radiopharmaceutical
^{11}C	20.3	^{14}N(p,α)	CO$_2$, CH$_3$I	Many
^{13}N	9.97	^{16}O(p,α)	NH$_3$, NO$_3^-$	NH$_3$
^{15}O	2.03	^{14}N(d,n) ^{15}N(p,n)	O$_2$, H$_2$O, CO	same as precursor
^{18}F	109.7	^{18}O(p,n) ^{20}Ne(d,α)	F$^-$, F$_2$	Fluorodeoxyglucose Fluorodopa

of ^{99m}Tc from the Mo/Tc generator (see below).

The equilibrium equations (Sorenson and Phelps, 1987) that reflect the relative radioactivity of parent and daughter are given by the general equation

$$A_d(t) = A_p(0)[\lambda_d/(\lambda_d - \lambda_p)] \times (e^{-\lambda_p t} - \mathrm{e}^{\lambda_d t}) + A_d(0)e^{-\lambda_d t}, \qquad (2)$$

where A is the radioactivity for daughter (d) and parent (p), respectively. The initial radioactivity present is expressed as $A(0)$ for both parent and daughter. The first term in Eq. (2) accounts for the growth of the daughter as a function of the decay of the parent and the disappearance of the daughter due to its decay, and the last term accounts for the presence of any daughter nuclei at zero time.

All generator systems used routinely in nuclear medicine form equilibrium between parent and daughter. For the situation where the parent has a half-life much longer than the daughter, for example, with ^{68}Ge/^{68}Ga and ^{82}Sr/^{82}Rb, the change in the amount of the parent during the time for steady state to be reached will be negligible; that is, $\lambda_p \ll \lambda_d$ and $e^{-\lambda_p t} \approx 1$. Thus, by using Eq. (2), the quantity of daughter radioactivity at any time can be expressed by

$$A_d(t) = A_p(0)\,(1 - e^{-\lambda_d t}). \qquad (3)$$

Thus, after a very long time when $e^{-\lambda_d t} \approx 0$, the daughter and parent radioactivities are approximately equal. The steady-state condition is referred to as secular equilibrium.

In the case of the ^{99}Mo/^{99m}Tc generator, the parent (^{99}Mo) decays at a rate ($t_{1/2}$ = 66 h, where $t_{1/2} = \ln 2/\lambda$) long in comparison to its daughter (^{99m}Tc $t_{1/2}$ = 6 h), such that $\lambda_p < \lambda_d$, so that $e^{-\lambda_d t}$ is negligible in comparison to $e^{-\lambda_p t}$ when t is sufficiently long. Under these conditions, Eq. (2) can be solved so that the ratio of the daughter radioactivity to that of the parent is given by

$$A_d/A_p = T_p/(T_p - T_d), \qquad (4)$$

where T is the half-life for each species, respectively. This condition is referred to as transient equilibrium, even though, in the strict sense, it is a steady state and not a true equilibrium.

3. RADIOACTIVE TRACERS

The term radiotracers refers to a radioactive species that is used to follow (trace) the uptake into or function of an organ system in a living plant or animal. Initially, the radiotracers used were radioactive isotopes of naturally occurring elements or chemical congeners of these elements, as in the case where de Hevesy used Pb to trace bone activity (see above). Other early uses of simple elements as radiotracers were the use of radioiodine to monitor iodine uptake in the thyroid and the use of radioactive phosphorus to monitor metabolism.

The characteristics of an ideal tracer include the following:

1. The behavior of the tracer should be identical or related in a known manner to the substance to be traced; and
2. the quantity of tracer used should not have an effect on the process to be studied.

Inherent in the first of these characteristics is that there should be negligible effects due to the different isotopes present, as in the case of ^{131}I substituted for the natural isotope of iodine, ^{127}I. The rates of movement of atoms or molecules vary inversely as the square roots of their masses. Thus, for very light nuclei, e.g., isotopes of hydrogen, there can be a 73% difference between the diffusion rates of ^{1}H and ^{3}H. The difference in the diffusion rates for more massive isotopes is much less, as in the case of the iodine isotopes, where the difference is about 1.5%. Fortunately, this effect is generally of no consequence in nuclear medicine.

Radioactive isotopes of the elements of sodium and potassium (^{24}Na, ^{42}K) have been used to measure the sodium and potassium content of the body, employing the *isotope dilution* technique. Analysis by isotope dilution involves adding a known mass and specific activity of a substance to a mixture containing an unknown quantity of the substance and taking an aliquot of the mixture and determining the new specific activity of the substance under investigation. It can be shown that the mass of the substance of interest in the unknown mixture can be expressed as

$$M_u = M_1(S_1/S_2 - 1), \tag{5}$$

where M_u is the mass of the substance in the system under investigation, S_1 and S_2 are the specific activities of the tracer before and after its addition to the system, respectively, and M_1 is the mass of the labeled substance added.

4. RADIOPHARMACEUTICALS

The term radiopharmaceutical is derived from the fact that a radionuclide has been attached to a biologically active compound and is used for the diagnosis or the therapeutic treatment of human diseases. Radiopharmaceuticals differ in one major aspect from regular pharmaceuticals in that they are given in such small concentrations that they do not elicit any pharmacologic response. Because of this difference, there have been several attempts to change the name used to describe these substances. Present-day radiopharmaceuticals are used for diagnostic purposes in about 95% of the cases, and the remainder are used in therapy. The therapeutic effect is in response to the radioactivity associated with the radiopharmaceutical and not to the chemical nature of the compound, which is administered in very small concentrations.

In order for a radiotracer (radiopharmaceutical) to be used in humans safely, it must meet quality standards that include chemical and radiochemical purity, that it be sterile and free from pyrogenic material. The ideal radiopharmaceutical should

1. be readily available at a low cost;
2. be a pure γ emitter, that is, have no emission of particles such as α's and β's that contribute radiation dose to the patient but do not provide any diagnostic information (see Sec. 8);
3. have a short biological and physical half-life so that it is eliminated from the body as quickly as possible;
4. have a high target to nontarget ratio so that the resulting image has a high contrast; that is, the background does not blur the image; and
5. possess the proper metabolic activity in that it follows or is trapped in the metabolic process of interest.

The ability to measure regional biochemical function requires a careful design process with these principles in mind. However, it is not possible in reality to meet all of these criteria. For example, all decay processes involve the emission of particles, as in the case of the pure γ emitters, which have Auger electrons emitted during some fraction of the decays. Thus, it is necessary to address the following steps (Eckelman, 1991) in the development of a biochemical probe:

1. develop a radiotracer that binds preferentially to a specific site;
2. determine the sensitivity of the radiotracer to a change in biochemistry; and
3. find a biochemical change as a function of a specific disease that matches that sensitivity.

Figure 1 illustrates the ability to image different functional systems using the same radionuclide by varying the compound to which it is attached.

A large number of radiotracers have been synthesized to probe metabolic turnover such as oxygen consumption, glucose utilization, and amino-acid synthesis. Enzymatic activity, neurotransmission, receptor density, and occupancy have all been measured via appropriately designed radiotracers. It should be pointed out that the development of radiotracers for PET fundamentally violates rule number 2 for the ideal tracer, since, by na-

FIG. 1. Dependence of distribution of radioactivity on the radiopharmaceutical used. Left to right: the skeleton imaged by ^{99m}Tc-methylene diphosphonate, the liver and spleen with ^{99m}Tc sulfur colloid, the lungs with ^{99m}Tc albumin microspheres, and the kidney-ureter-bladder system with ^{99m}Tc DTPA (diethylenetriaminepenta-acetic acid). (Used with permission of J. S. Robertson, Mayo Clinic.)

ture, the PET radioisotopes emit β^+ particles. However, the resulting coincident γ rays from the β^+ annihilation form the basis for the technique, which will be described below.

In addition to these principles, the synthetic chemist must plan on how to insert the radioisotope into the molecule at a point in the synthesis so that there is minimal handling, and late enough in the synthesis process to minimize loss due to chemical yield and radioactive decay. For these reasons, the preparation of radiopharmaceuticals requires planning and techniques not encountered by traditional synthetic chemistry.

5. RADIOIMMUNOASSAYS

On the basis of the radioisotope techniques developed earlier in the 1950s, S. Berson and R. Yalow published in 1959 the first use of radioimmunoassay (RIA) to measure the concentration of insulin in unextracted human plasma. The RIA principle is simple and is illustrated by the schematic in Fig. 2.

The concentration of an unknown amount of unlabeled antigen can be determined by comparing its inhibitory effect on the binding of radioactively labeled antigen to specific antibody with the inhibitory effect of

FIG. 2. Schematic representation of the reactions used in radioimmunoassay.

known standards (Yalow, 1978). Because of the use of radioactive tracers, the method is highly sensitive for detecting very small quantities. Concentrations of less than 1 p*M* can be determined for some species. The technique involves the separation of the labeled antigen of interest into bound and unbound fractions after its interaction with an antibody in the presence of an unknown amount of unlabeled antigen. The ratio of the bound to free fractions of the labeled antigen is compared to the binding of known standards.

In order to use this method to measure the concentration of a substance, the antigen in the samples to be tested and the antigen in standard samples must have identical immunologic behavior. Therefore, it is not necessary for the unknown and the standards to be chemically identical or to have identical biological behavior. The original technique has been modified by making use of a variety of radiotracers (Harbert and da Roche, 1984) to measure concentrations of vitamins, enzymes, peptides, serum proteins, hormones, viruses, drugs, and tumor antigens, as shown in Table 5.

Commercially available *kits* provide the materials for performing RIA for most of these substances. A typical kit would consist of a series of standard samples, each containing a specific amount of an unlabeled antigen, a vial of labeled antigen, a vial of antibody solution, and a substance used to precipitate the antigen-antibody complex. In most cases, ^{125}I is the radioactive isotope employed.

6. IMAGING TECHNIQUES

The following sections describe the techniques used to obtain *in vivo* functional images following the injection of radiotracers. The underlying basis for the techniques is that the radioisotopes employed must emit photons of sufficient energy that they penetrate the body so that they may be detected. All modern nuclear-medicine imaging devices make use of a scintillator coupled to a device that converts the emitted light into an electrical pulse. The following sections describe the more common methods presently in use.

6.1 Planar Imaging

By far the most common imaging device in nuclear medicine is the planar camera or Anger camera, named after its inventor, H. Anger. The basic components of the camera include a thin crystal of NaI scintillator coupled to a cluster of photomultiplier tubes and an (x, y) positioning circuit, and a readout device that may be an oscilloscope or film. In between the radioactive source and the detector is a collimator constructed of lead metal. The collimator has one or more holes drilled through it to allow the γ rays through. Since γ rays cannot be bent or focused, the collimator's function is to absorb those γ rays that do not pass through the openings.

In its simplest form, the collimator has a single pinhole and acts like a camera lens. Other collimators are constructed with the holes converging, diverging, or parallel to the imaginary line connecting the object to be imaged and the camera face. The converging collimator has the effect of magnifying the imaged object, while the diverging collimator reduces the image. The parallel collimator is used for high resolution. Regardless of which collimator is used, they all absorb a large fraction of the photons emitted by the radiotracer in the patient.

Table 5. A few examples of the application of radioimmunoassay.

Test	Substrate	Radioisotope	Applications
Schilling test	Vitamin B_{12}	^{57}Co	Indication of absorption of vitamin B_{12} as in pernicious anemia.
Blood volume	Serum albumin	^{131}I	Determination of blood volume in pre- and postoperative patients
Red blood cell survival	Red cells	^{51}Cr	Hemolytic anemia patients have a very short red cell survival time.
Plasma iron turnover	Ferrous citrate	^{59}Fe	Hematologic disorders have abnormal iron turnover rates

The NaI scintillator has been designed to minimize multiple interactions with the incident γ rays so that the position of interaction can be accurately determined. Typical scintillation cameras have detectors 25–45 cm in diameter with thicknesses in the range of 0.64–1.27 cm.

The (x, y) positioning circuit relies on the light output from the many (19–91) photomultiplier tubes (PM tubes) mounted on the back of the scintillator. The photomultiplier tube closest to the position of the γ ray's interaction will receive the maximum amount of light, while the other PM tubes will receive light in proportion to the solid angle subtended by the tube at the point of interaction. The positioning circuit sums the output of the PM tubes and produces x and y pulses proportional to the (x, y) coordinates of the γ-ray interaction.

A more detailed discussion of the Anger camera can be found in BIOMEDICAL ENGINEERING.

6.2 Positron-Emission Tomography

Positron-emission tomography (PET) makes use of the unique characteristics of the radionuclides that decay by emitting positrons. When these positrons lose energy through their interactions with the electrons of the surrounding matter, each positron will annihilate with an electron, giving rise to two photons, or γ rays, which radiate at 180° from each other. This conversion of matter into energy is an example of the energy–mass relationship described by Einstein. With an appropriate array of detectors, these coincident annihilation γ rays can be detected. Thus, the annihilation event is self-collimating; that is, the back-to-back photons define the line of response between two detectors. By mathematically back-projecting the lines of response, it is possible to reconstruct a density map for the location of the radioactivity. If the positron radionuclide is attached to a biologically active compound (radiopharmaceutical), then the spatial and temporal distribution in an organ or a functional system can be determined.

The spatial resolution of a PET system is determined by the ability to measure the origin of the two annihilation photons. The theoretical limits arise from the range of the positrons in tissue and the lack of true collinearity of the emitted photons. The first limit is determined by the kinetic energy of the positron, which for the typical PET radionuclides have a range of 2–20 mm in tissue. The second limiting factor arises from the fact that the annihilation event occurs when the positron-electron pair still have a small amount of kinetic energy, and, in order to conserve momentum, the two photons are emitted at an angle slightly different from the 180° for the at-rest situation. The effect of this lack of collinearity depends on the detector separation, which means the larger the diameter of the tomograph, the greater the effect. Thus, the best resolution that can be expected for a PET scanner is of the order of 2 mm. Because positrons are emitted from the decaying nucleus over an energy spectrum and only a very small fraction have the maximum range, the broadening associated with positron range amounts to only a fraction of a millimeter for ^{18}F and ^{11}C, the two most widely used positron-emitting nuclides.

Initially, PET scanners were constructed with a single ring of detectors. However, the limited axial field of view made it difficult to perform meaningful studies. Subsequent designs employed multiple rings of detectors, separated by lead or tungsten septa to collimate the γ rays into planes or slices. Thus, the tomographs could acquire data over an extended field of view, and reconstructed images could be displayed in three dimensions.

The design of the detector system has the constraints of high efficiency to minimize the radioactive dose given to the patient and a small detector for finer resolution with the added complication and expense of more detectors and the associated electronics. The modern tomograph designers have solved this problem by using a block detector, which has many small detectors sharing a smaller subset of photomultiplier tubes (PMT); for example, a block of detector material is cut into an 8×8 array sharing four PMTs. Using Anger logic, the location (which crystal segment) of the incident photon can be accurately determined.

The strength of PET is the ability to determine the amount of attenuation caused by the surrounding material, e.g., the torso in a cardiac scan, by using an external positron source, usually ^{68}Ga in equilibrium with its parent ^{68}Ge. Since the count rate is determined by the coincidence rate, only those γ

rays that are not absorbed by the intervening material are registered. Thus, by comparing the count rate with and without the attenuating material (the patient), it is possible to correct for the attenuation that the γ rays originating internally will experience.

The sequence of measurements in a PET scan include a blank scan with a positron source without the patient, followed by the same measurement with the patient in place. This determines the attenuation factors. This is followed by removal of the external source and the injection of the PET radiotracer, and a third scan. The reconstructed image of this last measurement is corrected for attenuation.

The other factors affecting the quality of a PET scan are the amount of scatter of the γ rays and the number of random coincidences. Scatter is caused by one, or both, of the coincident γ rays scattering from the subject or from other material in the scanner, giving rise to an incorrectly encoded line of response. The γ rays are detected by different pairs of detectors than if they had not been scattered, which results in the blurring of the image. Scatter is corrected for by determining the scatter function at the edge of the field of view and extrapolating a profile across the field of view. The correction is applied before attenuation corrections and reconstruction are performed.

Random coincidences arise from the limitations of the detector design, which requires a finite timing window to allow the two γ rays to be registered in the opposing detectors and their electronics. The coincidence window for modern tomographs is usually set at between a couple of nanoseconds and 20 ns. The random rate is determined by

$$r = \tau N_1 N_2, \qquad (6)$$

where τ is the coincidence resolving time and N_1 and N_2 are the count rates in the opposing detectors, respectively. Obviously, the shorter the resolving time, the lower the random coincidence rate; and conversely, the higher the individual detector counting rates, the higher the random coincidence rate. Because the random events have no directional character, the effect is to add noise uniformly throughout the image. Corrections for random events are made either by determining the single rates directly and applying Eq. (6) or, alternatively, by the use of a separate circuit with time delay to measure the random rate.

Another important factor in PET is that the radionuclides that decay by positron emission are the light elements associated with biological systems—carbon, oxygen, and nitrogen. Fluorine's atomic size makes it a suitable substitute for hydrogen. Thus, it is possible, in principle, to construct nearly any compound found in a biological system with a positron emitter. When using ^{18}F as the label, the resulting analog often has similar properties to the natural compound. The difficulty is, of course, the short half-lives of these isotopes, which makes the job of synthesizing them extremely difficult. The basic strategy is to insert the label as near the end of the synthesis as possible. There have been hundreds of compounds labeled with positron-emitting isotopes. However, simply having a labeled compound does not make it useful. What is required is a complete understanding of the metabolic processes the compound undergoes and how the label follows that process, because the PET image detects the location of the radionuclide, not its chemical form. Thus, modeling of a PET radiopharmaceutical is an important component in PET. Nevertheless, even with the complexity of synthesizing PET radiopharmaceuticals and the modeling required to understand the images, PET has proved to be an important tool in understanding basic *in vivo* biochemistry. There are a small number of compounds that are beginning to see use in clinical medicine and are mentioned in the relevant sections below. In particular, 2-[^{18}]F-fluoro-2-deoxyglucose (FDG) has been used to assess myocardium viability, as well as to detect hypermetabolic tissue associated with tumor growth.

6.3 Single-Photon–Emission Computed Tomography

As with PET, single-photon–emission computed tomography (SPECT) acquires views of the emitted photons from many different angles and reprojects these views to reconstruct the image or distribution of radioactivity in the object or patient. In SPECT, the radiopharmaceuticals used contain radioisotopes such as ^{99m}Tc that emit single photons (ones that are not in timed coincidence with one another). Directional information is achieved by collimating the photons incident on the detector. The collimator thus reduces the sensitivity of the camera, because all of the photons not parallel to the holes in the collimator are prevented from reaching the detector surface.

Since the reconstructed image contains the three-dimensional information on the distribution of radioactivity, SPECT also has the potential for quantification. The factors affecting this capability are similar to those in PET, for example, system sensitivity, dead time, spatial resolution, sampling interval, reconstruction filters, and the size of the object being imaged. Also, as in PET, the photons emerging from the subject are attenuated by the amount of matter between their origin and the detector and, of course, have a definite probability of being scattered along their path. These last two nonlinear effects are the most significant and difficult to correct for.

Because of the inherently lower energies (100–150 keV) of the photons emitted by radionuclides used in SPECT, the effect of attenuation can be quite dramatic, with reductions as great as a factor of 5 or more. Thus, with single-photon emitters, it is nearly impossible to determine whether data reflect a weak source near the surface or a stronger source located at some greater depth. In addition, the amount of scattering is strongly dependent on the energy of the photons, with the photons from ^{201}Tl having a scattering fraction of as much as 40–50% depending on the depth of the source.

Whereas scintillation camera images show the distribution of the radiopharmaceutical in defined regions in planar view, they suffer from the superimposition of organs and background contributions to the areas of interest. It is because of these shortcomings in planar imaging that SPECT has a major role to play in diagnostic imaging, regardless of whether SPECT can achieve the difficult task of providing quantitative information. The ability to view the distribution in three dimensions greatly affects the interpretation of the images. Figures 4 and 6 illustrate this point.

7. FUNCTIONAL IMAGING

Nuclear-medicine imaging differs from other radiological imaging in that the radiotracers used in nuclear medicine relate to the function of an organ system or metabolic pathway, and, thus, the tracing of these agents reveals the integrity of these systems or pathways. This is the basis for the unique information that a nuclear-medicine scan provides, as indicated in the variety of agents used to monitor the systems indicated in Table 6 and described in the following sections for various scanning procedures for the various organ or functional systems of the body. The structures of some of the ^{99m}Tc compounds are shown in Fig. 3.

7.1 Central Nervous System

Unlike other body tissues, the nervous system is highly discriminatory as to which solutes are transported into its tissues. This selective permeability is called the blood–brain barrier. The ability to measure changes in the blood–brain barrier (BBB) with radiophar-

maceuticals provided a major impetus for the growth of nuclear medicine over the last 25 years (Swanson *et al.*, 1990). In more recent times, the other radiological imaging techniques, such as computed tomography (CT) and, more recently, magnetic resonance imaging (MRI), have all but eliminated the use of radioactive agents to measure brain lesions.

However, recent developments in ligands that cross the BBB intact have opened the possibility of measuring functional changes in the brain associated with regional perfusion, metabolism, and the distribution and concentration of receptors. While very few of these new radiopharmaceuticals have achieved widespread clinical usage, the potential applications clearly indicate that brain imaging will again become an important aspect of nuclear medicine.

The brain is divided into two hemispheres along a fissure that runs from the anterior to the posterior. Each hemisphere has four lobes called the frontal, temporal, parietal, and occipital. The brain consumes up to 25% of the blood's oxygen supply and receives about 20% of all the blood that comes from the heart. The nervous system is bathed in a colorless fluid known as the cerebrospinal fluid.

The outer layer of the brain is composed of gray matter, which forms the cortex. Below this layer is the interconnecting tissue, made up of white matter interspersed with gray-matter areas. The gray matter is made up of neuronal endings, while the color of white matter is due to the myelin sheathes covering the axons.

Normal brain capillaries differ anatomically from capillaries found elsewhere in the body by their closed endothelial clefts and close approximation and continuity of the endothelial cells with the covering membrane. Molecules of glucose, water, and electrolytes apparently pass freely into the vascular space by passive diffusion and then into the brain cells themselves by active transport across its membrane, utilizing high-energy processes produced from the metabolism of glucose (the primary energy source of the brain).

Larger molecules are normally stopped at the endothelial lining, but, in disease, they may pass by pore filtration through the endothelial clefts widened by the disease process. These lesions that disturb the brain's integrity unselectively allow radiopharmaceuticals to permeate the nervous tissue.

Cerebral imaging normally consists of two phases (Harbert and da Roche, 1984), as follows:

1. a dynamic or angiographic study comprised of the arrival of the radioactive bolus in the cerebral hemisphere, which essentially constitutes a qualitative measure of brain perfusion, and
2. static images obtained approximately 1 h after the dynamic study, which provide a record of the distribution of the radiopharmaceutical in cerebral regions.

Scans at even later times can help delineate suspected lesions. The most commonly used agent for permeability studies is $^{99m}TcO_4^-$, pertechnetate, though the more expensive ^{99m}Tc-DTPA, diethylenetriamine-penta-acetic acid, is preferred because it clears more rapidly from the blood and does not accumulate in the blood vessels of the lateral ventricles (fluid-filled spaces in the brain), as does ^{99m}Tc-pertechnetate, resulting in a *hot spot* in the brain scan.

Single-photon–emission computed tomography (SPECT, see above) is gaining favor for three-dimensional perfusion studies of the brain. HM-PAO and ECD labeled with ^{99m}Tc are the agents of choice, hexamethylpropylene amine oxime and ethyl cysteinate dimer, respectively. These two compounds take advantage of the *p*H shift that occurs between the blood and the brain tissue (Saha, 1992). At the *p*H of blood (*p*H = 7.4), the agent is neutral and lipid soluble and can rapidly penetrate the intact blood-brain barrier. When it encounters the more acidic brain tissue (*p*H = 7.0), the agent acquires a charge, and, as an ion, it is incapable of reverse diffusion. Figure 4 depicts a blood flow image using SPECT and HM-PAO. A number of radioiodinated lipophilic agents, including IMP (isopropyl-*p*-iodoamphetamine) and HIPDM (*N*,*N*,*N*′-trimethyl-*N*-[2-hydroxy-3-methyl-5-iodobenzyl]-1,3-propanediamine), have shown promise but have been replaced by the technetium agents.

Although the concept of using positron emitters for biomedical investigations had been around since the 1951, positron-emission tomography (PET) did not become practical until the mid 1970s, based on the confluence of the PET scanner by Ter-Pogossian,

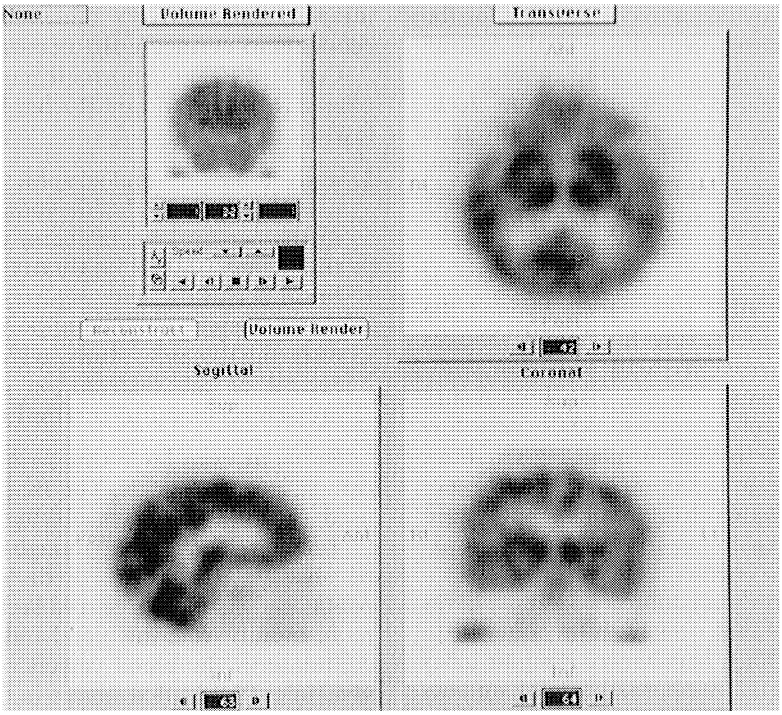

FIG. 4. SPECT image of the brain using ^{99m}Tc-HM-PAO, hexamethylpropylene amine oxime. The image is shown in a volume-rendered form, in the upper left, and three slice configurations: transverse, sagittal, and coronal. The abreviations are as follows: Ant—anterior (front); Post—posterior (back); Rt—right; Lt—left; Sup—superior (top); and Inf—inferior (bottom). (Courtesy I. Szaz, University Hospital, UBC Site.)

Phelps, and Hoffman (Ter-Pogossian *et al.*, 1975) in St. Louis and the development of the glucose analog ^{18}F-fluoro-deoxy-D-glucose (FDG) by Wolf and colleagues at Brookhaven National Laboratory (Reivich *et al.*, 1979). FDG is transported by plasma and crosses the BBB, where it is phosphorylated in a similar manner to glucose. The resulting FDG-6-phosphate is not a substrate for the other enzymes that are involved with glucose metabolism; thus, the labeled species is metabolically trapped. Once the relationship between FDG and glucose transport and uptake is taken into account, it is possible to obtain a quantitative measure of glucose metabolism on a region-specific basis. Mathematically, this relationship is achieved by determining the steady-state ratio of the net extraction of FDG to that of glucose at constant plasma levels of FDG and glucose and is referred to as the *lumped constant*. The FDG technique with PET has been used extensively in fundamental research of the functioning human brain to understand a number of normal brain functions, as well as disease processes. The clinical utility of this method has been employed to monitor tumor treatment and to locate the foci of epileptic seizures.

Oxygen consumption, blood flow, and blood volume have been measured using the ^{15}O-labeled molecules of O_2, H_2O, and CO, respectively. Neurotransmission and receptor density have also been measured for a number of neurological disorders, such as Parkinson's disease and schizophrenia. Figure 5 compares the uptake of ^{18}F-6-fluorodopa, FDOPA, in a normal subject and one affected by Parkinson's disease. The images in FDOPA scans reflect the uptake and conversion of fluorodopa to fluorodopamine and thus monitor the efficacy of the enzymatic systems involved in those processes. Research using PET is aimed not only at diagnosing disease but at an understanding of the disease process, as well as monitoring possible treatments.

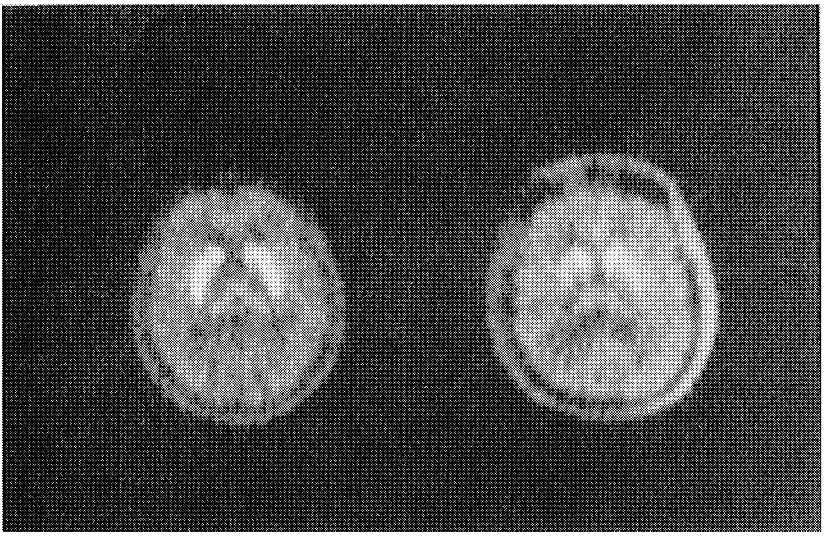

FIG. 5. PET image of ^{18}F-fluorodopa (FDOPA) uptake in (left) a normal patient and (right) a patient with Parkinson's Disease. Note the diminished uptake of FDOPA in the lower portion of the striatal region in the right image. (Courtesy UBC/TRIUMF PET Program.)

7.2 Cardiac Imaging

In general, nuclear medicine studies of the heart can be divided according to the clinical information sought (Swanson *et al.*, 1990). These studies include those that monitor the myocardium directly, such as perfusion assessment of metabolic activity, and determining whether the myocardium is healthy or infarcted. The imaging agents for perfusion use either potassium analogs or agents that are trapped in the myocardium in proportion to flow. The new technetium agents are included in the latter.

Among the perfusion agents, ^{201}Tl is the most widely used. Monovalent thallium has an ionic radius that is equivalent to that of K^+; thus, its uptake follows the active transport system for sodium and potassium. As much as 4% of the injected dose is taken up by the myocardial tissue, reaching its maximum in about 10–30 min after injection. The blood is cleared rapidly, with about 5% of the injected dose remaining in the blood pool after about 5 min.

^{201}Tl continuously redistributes between intracellular and interstitial compartments with differing rates for healthy and infarcted tissue. This behavior is typical for alkaline-like, singly charged cations. Thus, the equilibrium that is established upon redistribution can be used to distinguish between infarcted and ischemic tissue. In the case of ischemia, the diminished uptake disappears with redistribution, while persistent defects remain.

While the physiological behavior of ^{201}Tl is highly suited for perfusion imaging, its imaging characteristics are less than ideal. Principally, the energy of the emitted photons is extremely low (69–80 keV), which results in their being scattered, resulting in a loss in spatial resolution. Also, the half-life of ^{201}Tl (73 h) adds to the radiation burden for the patient. This radionuclide is cyclotron produced, making it expensive. Because of these negative attributes, there have been active attempts to find a ^{99m}Tc-based replacement.

Within the last decade, a series of ^{99m}Tc-labeled compounds have been proposed for myocardial perfusion studies (Saha, 1992). The

^{99m}Tc isonitriles are chemical complexes consisting of six monodentate CN*R* ligands surrounding a positively charged Tc^+ ion in the center, resulting in a stable cationic complex $Tc(CNR)_6{}^+$, where *R* represents one of the three functional groups tested thus far, tertiary butyl, carboxyisopropyl, and *hexakis*-2-methoxy-2-isobutyl groups. Of these agents, ^{99m}Tc-sestamibi (MIBI, where the complex is carboxyisopropyl isonitrile) has received the widest clinical usage. The myocardial uptake of this agent is proportional to regional myocardial blood flow. It does not redistribute with time, and, thus, a second injection must be performed the following day if a stress/rest protocol is desired. Figure 6 shows cardiac images acquired using ^{99m}Tc-MIBI.

Another class of technetium agents has been developed, consisting of boronic acid adducts of technetium dioxime (BATO). Unlike the isonitriles, the BATO complexes are neutral with respect to charge and are highly lipophilic. Lipid solubility is the uptake mechanism. ^{99m}Tc-teboroxime has undergone clinical trials. It consists of seven coordinate bonds coming from three dioxime molecules and one chlorine atom. ^{99m}Tc-teboroxime also does not redistribute and, thus, requires a second injection. BATO has a higher uptake in the myocardium than the isonitriles but does not clear as rapidly from the blood as does sestamibi and therefore does not have as high an image contrast.

$^{82}Rb^+$, as supplied from the ^{82}Sr generator, is the PET analog of K^+. Between 65 and 75% of the $^{82}Rb^+$ is extracted from plasma by the myocardium in the first pass at normal blood flow. Ammonia and water labeled with ^{13}N and ^{15}O, respectively, have also been used clinically to monitor cardiac blood flow. The use of these compounds is restricted by the fact that their short half-lives (^{13}N, $t_{1/2}$ = 10 min; ^{15}O, $t_{1/2}$ = 2 min) dictates production to be at or very near the site of use by an accelerator.

The metabolic function of the heart muscle can be monitored by a number of iodinated fatty acids (see below) or with the glu-

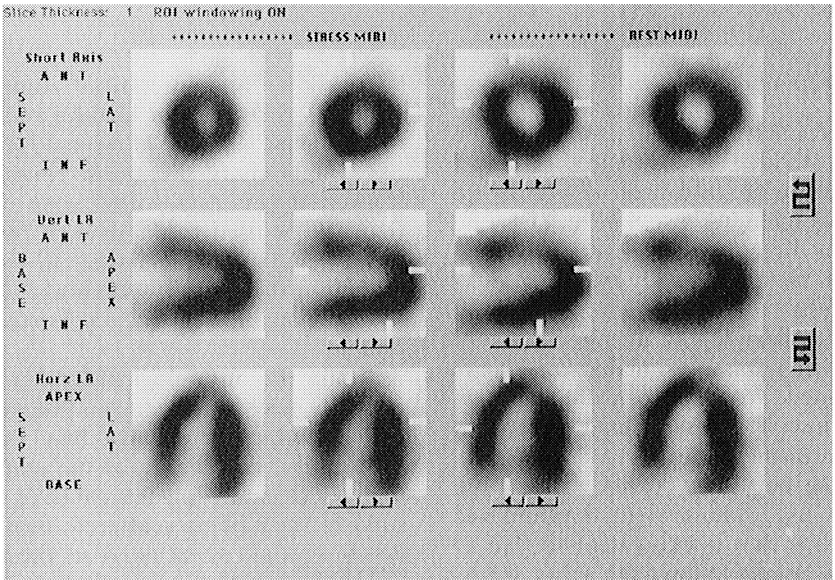

FIG. 6. SPECT image of the heart using ^{99m}Tc-MIBI, methoxy isobutyl isonitrile. The two columns on the left show the distribution in the heart at rest, and the two columns on the right show the distribution in the heart under stress. The top row has the images oriented in an oblique manner. This involves the reorientation of the heart images in such a way that slices at right angles to the long axis of the left ventricle become transverse or oblique images. The second row shows slices in a plane parallel to the long axis, from septum (the muscle that separates the the two chambers) to lateral wall (the thick outside wall of the heart), which are referred to as oblique/sagittal (Obl/Sag). The bottom row has the plane at right angles to oblique/sagittal and is the oblique/coronal (Obl/Cor). The abbreviations refer to ANT, anterior; INF, inferior; SEPT, septum; LAT, lateral; Base, base of the heart; APEX, the apex of the heart. (Courtesy I. Szaz, University Hospital, UBC Site.)

cose analog 2-fluoro(^{18}F)-2-deoxyglucose (FDG). FDG in conjunction with PET has the potential to measure the metabolic capacity of the myocardium quantitatively. Just as in the case for the brain, the metabolism of FDG essentially stops after phosphorylation, trapping the labeled analog in the cells.

The combination of ^{18}F-FDG and ^{13}N-ammonia with PET has received considerable interest in assessing the viability of the myocardium. Figure 7 compares a normal heart image with those that indicate ischemia. The ammonia scan measures blood flow and can detect obstructions in the blood supply to the myocardium, as shown in the figure. The FDG scan, however, indicates that the muscle is still capable of utilizing glucose and thus may return to normal function if reperfused via heart bypass surgery.

While FDG is an excellent compound for monitoring cardiac metabolism, its widespread use is hindered by the fact that these studies require a PET scanner, and, even though PET scanning is becoming more available, it is still only found in about 100 centers as of 1993. The primary energy source of the heart muscle under fasting conditions and rest is free fatty acids. A number of fatty acids have been labeled with ^{123}I. The most promising of these is ^{123}I-labeled *p*-iodophenylpentadecanoic acid (IPPA). The iodine atom is more strongly bound to aromatic carbons than to aliphatic carbons, thus minimizing the loss of the ^{123}I *in vivo*. With the favorable characteristics of ^{123}I and the rapid blood clearance of the fatty acids, IPPA holds promise for use in monitoring cardiac metabolism in the clinical setting, although the usefulness of such measurements has not been established.

Ventricular function is measured with blood-pool agents. These studies are performed by gating the data collection to the cardiac cycle. In this method, the radiopharmaceutical must reside in the vascular compartment for a sufficiently long time and at constant levels for the data acquisition.

7.3 Bone Scans

Although bone mineral is mainly composed of calcium, phosphate, and hydroxyl ions, living bone is a dynamic and physiologically active organ. The large adsorptive surface of bone provides chemically reactive sites that can be labeled with a wide variety of radionuclidic substances (e.g., Sr^{+2}, Pb^{+2}, Ra^{+2}, and Mg^{+2} for Ca^{+2}; F^- for OH^-; CO_3^{-2}, citrate, phosphate esters, diphosphonates, and pyrophosphate for phosphate).

In the formation of bone, amorphous calcium phosphate (ACP) precipitates on the surfaces of collagen fibers, where it grows over days and weeks to form hydroxyapatite [HA; $Ca_{10}(OH)_2(PO_4)_6$] (Swanson *et al.*, 1990). It has been shown that ^{99m}Tc-diphosphonate binds

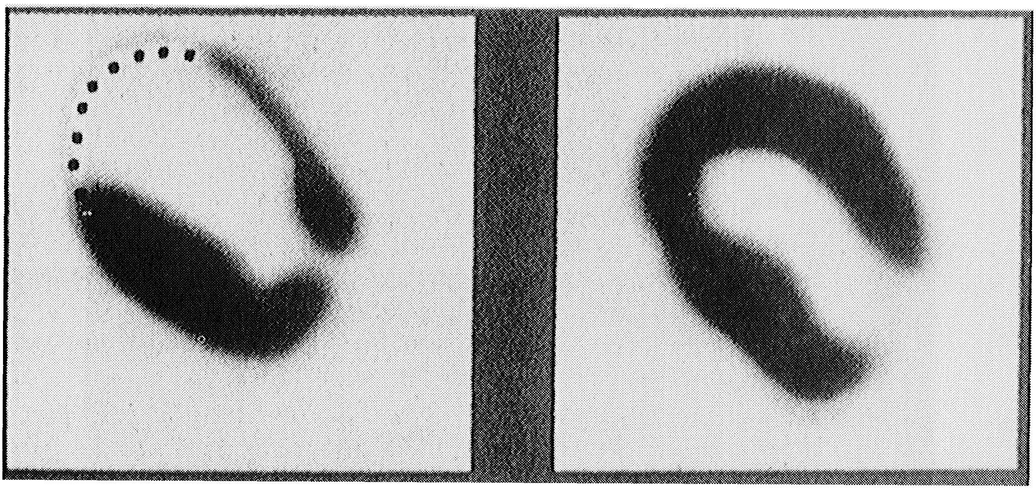

FIG. 7. PET image of the heart comparing blood flow with ^{13}N-ammonia on the left and metabolism with ^{18}F-FDG on the right. Note that there is a mismatch between flow and metabolism, indicating that the region of low flow is still capable of metabolizing glucose. (Courtesy M. Phelps, UCLA.)

to ACP to a higher degree than to crystalline HA. This selectivity forms the basis for detecting bone lesions, since areas of increased osteogenic activity contain higher concentrations of ACP than normal bone.

Shortly after its discovery in 1937, ^{18}F was discovered to have a high affinity for bone and teeth. This characteristic was exploited in the 1950s, when ^{18}F-fluoride was used extensively as a bone-scanning agent in nuclear medicine. With the advent of the ^{99m}Tc agents in the 1970s, the use of fluoride was replaced because of the better physical characteristics of half-life and photon energy, as well as the ease of delivery of ^{99m}Tc from a generator.

With the growing number of PET centers with their own cyclotrons, the interest in ^{18}F-fluoride as a bone-scanning agent has returned. The tomographic resolution and sensitivity for ^{18}F are superior to those of the single-photon systems. Thus, the resulting images can provide for accurate anatomical localization and improved lesion contrast. The first-pass extraction of fluoride from plasma is quantitative and in proportion to bone perfusion. Figure 8 illustrates the use of PET and whole-body ^{18}F-fluoride imaging.

7.4 Endocrine Systems

The endocrine systems regulate body functions through the secretion of various chemicals called hormones, from the Greek word meaning *arouse to activity*. The endocrine system includes the thyroid and parathyroid, pancreas, pituitary, gonads, and the adrenal glands. The thyroid gland helps control energy production, and the parathyroid provides for the distribution of calcium between the blood and bone. The adrenal glands regulate blood pressure, while the pancreas controls blood sugar levels. The pituitary controls growth, as well as regulating the activity of the gonads, the adrenal, and thyroid glands through the release of hormones. The gonads produce the germ cells of reproduction and a number of hormones related to the reproductive process.

The hormones generated by the thyroid that regulate the basal metabolic rate contain iodine. The iodine is accumulated in the thyroid from various food sources; thus, radioactive iodine becomes the simplest and nearly ideal tracer of metabolic function of the thyroid. With the production of ^{131}I from

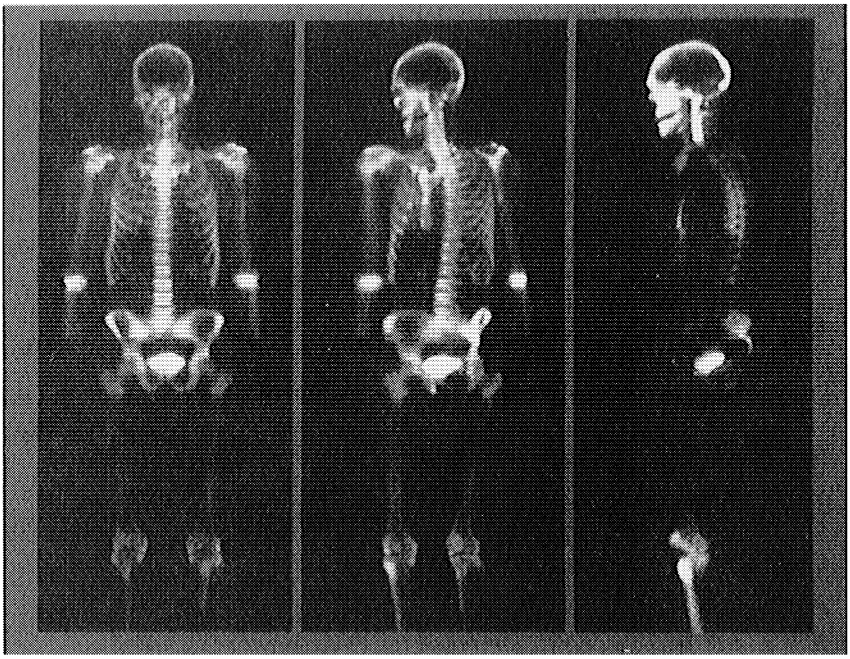

FIG. 8. Whole body PET scan of the skeleton using ^{18}F-fluoride in a normal male. The images from the left are the anterior projection, sagittal, and coronal images. (Courtesy C. Hoh, UCLA.)

reactors during and after the second World War, studies and treatment of thyroid diseases became widely available. There are a number of radioisotopes of iodine, but ^{123}I has the best physical properties for nuclear imaging, namely short half-life for low radiation exposure to patient, the energy of the principal γ ray matched to the present collimator systems on γ cameras, and no β-particle emission, which also reduces the dose to the patient in comparison to ^{131}I. Until recently, the production of ^{123}I required a high-energy accelerator. However, in the early 1980s, the use of a low-energy reaction on enriched ^{124}Xe to produce this radionuclide in high yield and extremely high purity increased the availability of this important radionuclide. The major drawback remains that its cost of production still makes the cheap and readily available ^{131}I competitive. As the reliability of ^{123}I becomes established, the universal acceptance of this radionuclide will be assured.

Radioiodine uptake studies utilizing sodium iodide are used to study hypothyroidism and hyperthyroidism, and to plan radioiodine treatment, the assessment of functional reserve, and the evaluation of thyroid gland autonomy. Radionuclide imaging of the thyroid is used to assess the size, position, and morphology of the thyroid gland, the detection of metastatic thyroid cancer and response to therapy, the evaluation of acute thyroid pain, the detection of accessory thyroid tissue, and the assessment of the functional status of nodules.

Because $^{99m}TcO_4^-$, pertechnetate, has a similar size and ionic characteristics to iodine (Swanson *et al.*, 1990), it is expected to be trapped in the thyroid. However, with the trapping, it is not incorporated into the functional hormonal system. Pertechnetate is used primarily for studying the morphologic structure of the thyroid.

Certain cells of the pancreas secrete enzymes that are used in the digestive system to react with proteins, carbohydrates, and lipids, while other cells secrete the hormones insulin and glucagon. Insulin controls the glucose level in blood. The amino acid methionine is incorporated in the digestive enzymes. Thus, an analog of methionine, selenomethionine, where the sulfur in methionine is replaced with radioactive ^{75}Se, has been used to image the pancreas to detect tumors, pancreatitis, and pseudocysts. However, because of high uptake in the liver and gastrointestinal areas, visualization of the pancreas is difficult.

The two adrenal glands positioned on top of the kidneys have two structures, an outer cortex and a central medulla. The adrenal cortical cells synthesize a number of steroid hormones from the circulating plasma cholesterol. Radioiodinated analogs of cholesterol, 19-iodocholesterol and 6β-iodomethyl-19-norcholesterol, have been used to image the cortical rim of the adrenal glands. Tumors and hyperfunction, Cushing's syndrome, can be diagnosed with increased uptake of these compounds.

7.5 Kidney

The urinary system is composed of the two kidneys, which are connected to the bladder via the ureters, and the bladder contents are discharged through the urethra. Just as in the case of the adrenal glands, morphologically the kidneys have an outer rim called the cortex and an inner area called the medulla. The nephron is the functional unit of the kidney and consists of tubules and ducts intermixed with the capillary bed of the blood. The nephrons perform three functions: the filtration of blood plasma, selective absorption of the materials the body requires, and the secretion of waste materials to the urine. The kidneys receive about 25% of the blood supply in each cycle, so that the entire blood volume passes through the kidneys every few minutes (Saha, 1992).

As part of the secretion process, there are two independent pathways for organic ions, and one for anions and one for cations. The pathway for anions has been exploited for imaging in nuclear medicine by the use of *o*-iodohippuric acid (OIHA), initially labeled with ^{131}I and more recently with ^{123}I. A new agent that is replacing OIHA is ^{99m}Tc-mertiatide or MAG3, a chelating agent based upon amide nitrogen and thiolate sulfur groups. Since the excretion rate of a drug by the kidneys depends on the molecular size, lipid solubility, and pK_a of the drug, and the volume of distribution of the drug in the body as well as the rate of transport through the renal tubules, it is possible to quantify renal function.

After injection of ^{99m}Tc-MAG3, dynamic images are acquired, followed by a delay to allow for plasma clearance, and a static image is then obtained. Renograms, or a display of the uptake and flow in the kidney, are obtained by placing a region of interest (ROI) on the temporal images of the kidneys and displaying the radioactivity present in the ROIs as a function of time.

^{99m}Tc-DTPA is often used to monitor the morphologic structure of the kidneys by acquiring a static image 30–60 minutes after injection (see Fig. 1).

7.6 Pulmonary System

The pulmonary system is imaged by the demonstration of pulmonary perfusion employing limited capillary blockade, as well as ventilation assessment with inspired inert gases, such as the noble gas xenon.

The airway of the respiratory system consists of the trachea, which divides into right and left main-stem bronchi, and these in turn divide to form lobar bronchi. The lobar divisions on the right are upper-, middle-, and lower-lobe bronchi, while, on the left, only upper- and lower-lobe bronchi exist. These lobes further divide into segments terminating in alveoli. In the adult, there are approximately 250 to 300 million alveoli, with an average diameter of 150 μm per alveolus. In addition to the direct pathway to the alveoli, there are pores and canals that interconnect them to allow collateral ventilation in the peripheral lung.

In the xenon ventilation studies, the patient breathes in the radioactive gas and holds his or her breath while the lungs are ventilated. Then the patient breathes while the air and xenon reach equilibrium, and, finally, the patient breathes in fresh air to wash out the xenon. Images are acquired in all three conditions. The ventilation studies can be used to determine if there is any airway obstruction, bronchitis, or emphysema.

For ventilation studies, ^{133}Xe is the most widely used noble gas, even though ^{127}Xe has better physical properties (higher photon yield, higher photon energy). The difference in availability has dictated the relative usage of these two isotopes of xenon (see Tables 2 and 3). Xenon-127 requires a high-energy accelerator to be produced, and the only accelerators producing ^{127}Xe at the present time are those associated with basic physics programs, thus making production and delivery unstable. Efforts to use the ^{126}Xe(n,γ) reaction may alter this in the future.

Perfusion studies employ the limited capillary blockade through the use of particles that become lodged in the capillary beds of the lung. The capillaries that surround the alveoli are between 7 and 10 μm in diameter. Thus, to achieve highest extraction efficiency, the ideal size for the particles is in the range of 10–20 μm. Macroaggregates (MAA) and human albumin microspheres (HAM) labeled with ^{99m}Tc have been used for 20 years to measure perfusion. More than 90% of the particles from either agent are extracted from the blood pool in the first passage through the lungs. Distribution in the lung is expected to be uniform, and, thus, the image appears "hot." Where blood flow is occluded or restricted because of emboli or vessel constriction, the particles will be prevented from passing these points of obstruction. The image thus appears with "cold spots" at these locations. Perfusion studies are used to diagnose obstructions caused by pulmonary embolism, tumor, infection, and tuberculosis.

7.7 The Liver, Spleen, and Bile

The lobules of the liver consist of two basic type of cells: hepatocytes and endothelial cells (Kupffer's cells). The hepatocytes make up about 85% of the cell population in the liver and are responsible for the major metabolic functions, while the endothelial cells make up the remaining 15% of all liver cells and serve to cleanse the blood. Each lobule consists of a central vein surrounded by a number of sinusoids, like spokes around the hub of a wheel. Sinusoids are vessels that transport blood from the portal vein to the central veins that eventually deliver blood to the hepatic vein (Saha, 1992).

The liver serves to metabolize the sugars and simple amino acids from digestion and to store the resulting peptides and proteins, as well as for the detoxification of harmful substances through methylation and conjugation. The liver excretes bile into the intestines through the hepatic duct.

The spleen consists of two main compartments. They are the white pulp, consisting of small lymphocytes and plasma cells, and red pulp, a swampy mass of vascular spaces whose supporting structure contains blood-cleansing cells. The two main functions of the spleen are antibody production in the white pulp and particle filtration in the red pulp. Blood entering the spleen through the splenic arterioles empties first into the white pulp, where plasma skimming occurs to remove soluble antigens. Passing through the white pulp, the blood enters the red pulp through an open meshwork of large oval cells at the junction of these two cell types. This cellular maze serves to remove abnormal cells and allows normal cells to proceed unhindered.

Labeled colloids are used to evaluate the blood-cleansing function of both the liver and the spleen. The most widely accepted agent today is ^{99m}Tc-sulfur colloid. After administering the ^{99m}Tc-sulfur colloid, the majority of the particles (0.3–1.0 μm) are accumulated by the reticuloendothelial cells of the liver (80–90%) and spleen (5–10%), and the remainder go to the bone marrow. In principle, the correlation between particle size and organ avidity for the colloid would have the spleen removing the larger particles, the smaller particles going to the liver and the smallest particles to the bone marrow. In the normal liver, a homogeneous distribution of radioactivity throughout the organ is expected. Any localized, space-occupying process in the liver may present as a focal area of decreased uptake referred to as a defect. Lesions as small as 8 mm in size may be identified, while those that are 20–25 mm in diameter are routinely imaged. Colloid scans are used to diagnose cirrhosis of the liver, abscesses, tumors, metastatic lesions, and hepatitis.

To evaluate the functional integrity of the hepatocytes, ^{99m}Tc-IDA has been developed. The ^{99m}Tc-IDA is given to fasting patients, where it rapidly appears in the liver and then progressively clears from the liver via the biliary tree, where major hepatic ducts and the gall bladder are able to be visualized.

7.8 Tumor and Inflammatory Processes

Although the precise mechanism by which tumor cells proliferate is not known, there are some common factors that can be exploited for imaging. With the increased metabolic activity and blood flow, along with high vascular permeability, agents that mark these events can be used to identify this change in function as compared to normal tissue. Tumors also have antigens associated with them that can be used to target a radiopharmaceutical specifically to all of the locations of the particular tumor.

The radiopharmaceuticals in routine clinical use are, in general, nonspecific with respect to tumor type and primarily reflect the altered functional state. In fact, ionic ^{67}Ga as gallium citrate was accidentally found to accumulate in soft-tissue tumors. It was quickly learned that ^{67}Ga localized in many nonmalignant areas, such as inflammatory lesions. It has thus become a common mode for evaluating patients with suspected infectious processes. Although the mechanism by which ^{67}Ga accumulates in these tissues is not understood, it is known that gallium quickly binds to transferrin in the blood and that this protein binding may be part of the process.

More recently, ^{111}In-labeled leukocytes have been used to detect abscesses in various parts of the body. Whereas ^{67}Ga is eliminated slowly through the gut, the labeled leukocytes are not excreted through the bowel and kidney. Thus, the abdominal background in this region is lower. The difficulty in labeling the leukocytes, however, is a major shortcoming.

As referred to in other sections, a number of other agents are used to monitor tumors associated with particular organs or functional systems. As the understanding of the use of monoclonal antibodies increases, the variety and specificity of these agents will increase their use.

8. RADIATION DOSIMETRY

The γ rays and particle emissions associated with the radionuclides used in nuclear medicine cause ionization to occur as they pass through matter. If the material these photons and particles are passing through is human tissue, these ionizations can break chemical bonds or kill cells if sufficient energy is deposited in these structures. Fortunately, in the case of nuclear-medicine imaging, the repair mechanisms of the human body usually prevent long-lasting damage from occurring. The restorative function in certain organs is more sensitive than others; thus, it becomes important to monitor the amount of energy deposited per unit mass in the various parts of the body by the decay of radioactive species. The energy absorbed from the ionizing radiation per unit mass of material is referred to as the absorbed dose. The *Système Internationale* (SI) unit for absorbed dose is the *gray* (Gy) and is equivalent to 1 J/kg. In spite of the efforts to make SI units the standard, the traditional units for radiation exposure and absorbed dose are commonly used. The term rad is used to express absorbed dose, and its relationship to the Gy is such that 100 rad = 1 Gy. The dose-equivalent unit (rem) was developed to account for the differences in the effects which various types of radiation have in causing biological damage. In radiation protection, the rem is defined as

$$\text{No. rems} = \text{No. rads} \times \text{QF} \times N$$

where QF is the quality factor and N the modifying factor of the radiation in question. The term QF is related to the amount of energy transfer to the surrounding medium the radiation traverses. The quality factor for photons is 1, while protons and neutrons have the value of 10 and heavy ions (α and other larger ions) have the value of 20, reflecting the greater loss of energy per unit length in matter for the heavier species. For practical purposes, the term N is assumed to be unity. The dose equivalent in SI units is the sievert (Sv), where 1 Sv is equal to 100 rem. Since it is difficult to determine the actual absorbed dose that radiation workers receive, it is common to refer to their radiation exposure in sieverts or rems and fractions thereof. However, for nuclear-medicine procedures, an effort is made to determine the patients' actual radiation exposure expressed in grays.

In order to estimate the absorbed dose due to a nuclear-medicine procedure, a method has been developed whereby dose estimates are calculated. These calculations require the knowledge of the biological distribution data and the physical properties of the radionuclide. The absorbed-dose method allows one to calculate the dose delivered to the tissue of interest, referred to as the target organ, from the radioactivity accumulated in a source organ, which may or may not be a number of sites within the body. The source organ can also be a target organ, which is generally the case when dealing with low-energy photons or particle emissions.

The actual process of calculating the dose (Loevinger *et al.*, 1988) includes the following steps:

1. The time integral of the amount of radioactivity (accumulated activity) that is in a source organ is determined by following the time course of radioactivity in the organ of interest.
2. The total amount of energy associated with the emissions of the radioactive species in the source organ is calculated. This is usually tabulated according to the type of radiation (penetrating or nonpenetrating), energy, and intensity (the frequency of the particular emission).
3. The fraction of the energy that is absorbed by the target organ is determined. The amount of energy absorbed depends on the type and energy of the emissions, as well as the physical relationship between the source and target organs, that is, the relative size, shape, and distance apart.

There are obvious difficulties in determining these quantities, especially in each human subject. Therefore, estimates and certain assumptions are made to simplify the calculations.

To calculate the cumulative activity A, the sum of all of the nuclear transitions in an organ is determined for the time interval of interest. Cumulative activity defines the time integral of the activity, which is proportional to the sum of all the nuclear transitions during a given time interval.

The rate of disappearance of the radioactive species from the body or organ within the body is due to the radioactive decay, which is dictated by the physical half-life of the radionuclide in question, and the biological processes that accumulate or eliminate the species. This latter process is measured as the biological half-life. Thus, the clearance from a source organ is measured by the effective half-life, a combination of the radioactive decay and biological elimination. Mathematically, this is represented by the sum of the decay constants for the physical and biological half-lives:

$$\lambda_e = \lambda_p + \lambda_b, \tag{7}$$

where the respective decay constants are equal to $(\ln 2)/t_{1/2}$ for each process, physical and biological. Residence time defines the average time that the administered radioactivity spends in the source organ. The residence time of a radiopharmaceutical in any particular organ is related to the fraction of the injected dose reaching the organ and to the chemical and biological processes that the radiopharmaceutical experiences.

Figure 1 illustrates how the distribution of different radiopharmaceuticals can affect the absorbed dose, not only to specific organs but also to the whole body. The compounds used in the figure are labeled with the same radionuclide, but the chemical form dramatically alters where they deposit in the body. The ^{99m}Tc-diphosphonate binds to the hydroxyapatite of bones and is distributed throughout the skeleton, while the spleen and liver have a high uptake of ^{99m}Tc-sulfur colloid. The lungs are clearly visible with ^{99m}Tc-albumin microspheres, and the kidney-ureter-bladder system concentrates the ^{99m}Tc-DTPA complex.

The distribution of the radiopharmaceutical will, of course, be dependent upon the functional integrity of the organ or functional system, which could be radically different in health and disease. Thus, to have as accurate an estimate of dose as possible, the actual distribution in the subject must be determined. Otherwise, the values used will only be population averages.

The data on the physical characteristics for the decay of the radionuclides used in nuclear medicine have, for the most part, been determined accurately. For a given radionuclide, each emission is characterized as to its energy and relative frequency. The product of these two values is the energy imparted per decay of the nuclide and referred to as the equilibrium absorbed-dose constant, symbolized by Δ. The value for this term in traditional units is g-rad/μCi-h, and Gy-kg/Bq-s in SI units.

The emissions associated with radioactive decay can be classified into two types of radiation, nonpenetrating and penetrating radiation. Nonpenetrating radiations are those particles emitted by the source that contribute a negligible dose to organs other than the source organ. These emissions include all of the particulate emissions, as well as very low-energy photons. Penetrating radiations are those particles emitted by the source that contribute a significant dose to organs other than the source organ. All of the emissions that can be detected outside of the body, as in the case for imaging, are obviously in this category.

The absorbed fraction is the fraction of energy emitted by the source organ that is absorbed by the target organ, and is given the symbol ϕ. The value of the absorbed fraction depends on the size, shape, and composition of the source organ, the attenuation factors between the two organs (distance and composition) of the intervening matter, along with the energy of the emission and its type. In the special case of nonpenetrating radiation (α and β particles, conversion and Auger electrons, and low-energy x rays or γ rays), where the source and target organs are one and the same, the value of ϕ is 1, and, for all other organs, ϕ equals 0. That is, all of the energy is absorbed in the source organ, while no energy is imparted to surrounding tissue.

Mathematical models have been derived to calculate the values of ϕ as a function of photon energy for pairs of organs in a standard adult of 70 kg. As an example, the fraction of absorbed energy in the heart (target organ) from a uniformly distributed source of 100-keV photons in the liver (source organ) equals 0.067. In establishing the values for ϕ, the reciprocity theorem has been used, which states that it does not matter which organ is the source and which the target, the relationship is the same. The energy absorbed per gram is the same for radiation traveling from organ A to organ B as it is in traveling from B to A.

To aid in the calculation of dose, a single parameter has been tabulated that is the product of the equilibrium absorbed-dose constant and the absorbed fraction per unit mass, and has been given the symbol S:

$$S = \Sigma \Delta \phi, \tag{8}$$

where $\Delta\phi$ is summed (Σ) over all emissions from the radionuclide.

The Medical Internal Radiation Dose Committee of the U.S. Society of Nuclear Medicine (MIRD Committee) has compiled tables of S values for organ pairs and all commonly used radionuclides in nuclear medicine. Thus, once the cumulated activity for a particular radiopharmaceutical is known for each organ, then the dose is determined from the product as in

$$D = AS, \tag{9}$$

for each organ in the body.

The *S* values are tabulated for about 20 organs acting both as source and target organs. The compiled values of the *S* are for a standard 70-kg man; therefore, in applying these values to other persons of differing size, the *S* values may not be correct.

Recently, the International Commission on Radiological Protection (ICRP) has adapted the concept of *effective dose equivalent* H_E for use in calculating dose to patients receiving radiopharmaceuticals (ICRP, 1988). The advantage of this approach is that a single figure can be used to express the radiation risk to patients undergoing different diagnostic procedures. The calculation is performed by summing the doses to the different organs in the body, weighted by a factor determined to reflect the relative sensitivity of that organ to radiation. For example, the weighting factors for gonads, red bone marrow, and skin are 0.20, 0.12, and 0.01, respectively. Tables of the effective dose per unit administered activity have been compiled by the ICRP for the standard radiopharmaceuticals. Table 7 gives some of these values. With this approach, it can be seen how the various procedures can be compared and, in the case of the same radiopharmaceutical, how the different radioisotopes affect the dose.

The calculation of absorbed dose is obviously a complex undertaking, but, as described here, a number of simplifications and assumptions have been made, so that useful values of estimated dose can be determined.

9. RADIOTHERAPY

The use of radionuclides for therapeutic purposes makes use of the modes of radioactive decay involving particulate emission. These modes include α and β decay (both positron and negatron), as well as any mode resulting in Auger electron and/or Coster–Kronig electron emission. The emission of γ rays may or may not accompany these particle emissions.

The use of particles emanating from the nucleus relies on the fact that these particles are stopped within a short distance. Alpha-emitting radionuclides are especially attractive in that α particles with 5–8 MeV energy have a range in tissue of about 40–80 μm. Figure 9 schematically illustrates the range of particles in tissue, along with a relative scale of tissue sizes to reflect the range along which the energy of the particles would be deposited. In choosing a therapeutic radionuclide, the precise site of localization of the radiopharmaceutical carrier in the tumor governs this choice. Thus, the Auger emitters must be transported to the nucleus if not incorporated into the DNA itself if *cell kill* is to be achieved. Table 8 gives some radionuclides that are considered to be candidates for use in radiotherapy.

Alpha particles with their high linear energy transfer (LET, the energy deposited per unit length by radiation as it passes through matter) are potentially lethal for cells if deposited on the cell surface or into the cytoplasm. There are very few acceptable α-emitting radionuclides because of the complex decay schemes associated with these isotopes. However, there are two candidates that have received special attention, ^{211}At and ^{212}Bi, both of which are cyclotron produced and have relatively short half-lives, which severely restrict their availability.

In addition to the types of particles emitted in their decay, there are a number of other considerations in assessing the suitability of radioisotopes for use in therapy. The physical half-life of a radionuclide used in therapy

Table 7. Radiation exposure due to selected radiopharmaceuticals. Note the factor of 100 difference between ^{123}I and ^{131}I in the thyroid uptake studies. This difference is due to the longer half-life of ^{131}I.

Radionuclide	Substance	*E* (mSv/MBq)
^{15}O	Oxygen gas, single breath, 20 s hold	4.2×10^{-4}
^{18}F	FDG	2.0×10^{-2}
^{99m}Tc	Tc-DPTA	5.2×10^{-3}.
^{99m}Tc	Pertechnetate	1.2×10^{-2}
^{123}I	Iodide (thyroid uptake 35%)	2.2×10^{-1}
^{131}I	Iodide (thyroid uptake 35%)	2.4×10^{1}
^{201}Tl	Thallium chloride	2.3×10^{-1}

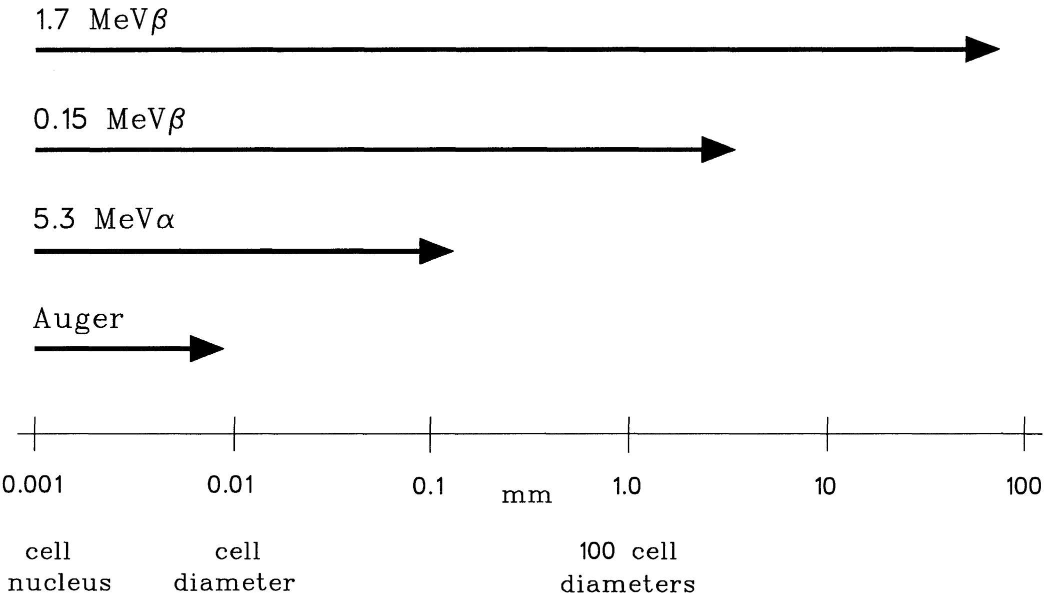

FIG. 9. Schematic representation of the ranges of particles in tissue in comparison to relative size of the cell structure.

must be long enough to allow the labeled species to clear the blood pool and concentrate in the region of interest but short enough to prevent the radionuclide from becoming a radiation burden to the rest of the body through metabolism of the primary agent. The physical half-life should be closely associated with the biological half-life of the radiopharmaceutical in the tumor. In this way, the bulk of the decays occur in the region where their damaging effects will be directed to the tumorous tissue and not to normal tissue.

One of the major difficulties in using pure β-emitting nuclides for therapy is the inability to detect their location accurately from outside of the body. However, a low-abundance γ ray with an energy of 100–200 keV can be used in imaging to assess localization and estimate delivered dose. Thus, the accompanying γ ray(s) should be in low abundance to remove radiation burden from surrounding healthy tissue.

The availability of a radionuclide and its associated chemistry determine its practical utility as far as receiving widespread clinical use is concerned. Just as in the case of the α emitters, even with their nearly ideal particulate energies, the difficulties in producing them have not only restricted the availability for clinical assessment but also basic research. The chemical form of the radionuclide has ramifications in determining how the radionuclide will be delivered to the site of interest. In this regard, ^{131}I has been con-

Table 8. Radionuclides with potential use as radiotoxic agents. The half-life of the radionuclide is included along with the particle emitted and its energy and the principal γ ray with its intensity (I) in percent.

Radionuclide	$t_{1/2}$	Particle	$E_{\max}$ (MeV)	E_γ (MeV) (I)
^{90}Y	64 h	β^-	2.3	None
^{111}In	2.83 d	Auger e^-	···	0.17 (90)
^{125}I	60.1 d	Auger e^-	···	0.035 (6)
^{131}I	8.1 d	β^-	0.6	0.36 (81)
^{153}Sm	46.7 h	β^-	0.81	0.103 (28)
^{186}Re	90.6 h	β^-	1.07	0.14 (9)
^{211}At	7.2 h	α	5.87 (7.45 from ^{211}Po)	0.69 (0.2)

sidered the nearly ideal radiotherapeutic agent for thyroid carcinoma because of the high natural uptake of iodine by the thyroid.

Radionuclides that are used in therapy are made in three different manners (see Sec. 2). The most common is from neutron capture, since neutron-rich radionuclides decay by β^- emission. The high fluxes of neutrons associated with nuclear reactors make it possible to produce large quantities of neutron-rich radionuclides by this method. However, the specific activity of reactor-produced radionuclides is generally low. An alternative source that is available indirectly from a reactor is from generators. Accelerator-produced radionuclides, as mentioned above, can, in principle, produce radionuclides with very high specific activity.

The interest in therapy with radionuclides has increased during the last decade, not only with the prospect of labeling site-specific compounds with these radiotoxic substances but also as palliative agents for treating metastatic tumors. Post-mortem studies indicate that a large majority of carcinomas develop bone metastases. While the exact mechanisms for causing pain in skeletal metastases are unknown, their management has been directed toward palliation. The use of targeted radionuclide therapy for this treatment is gaining favor. High specific uptake in bone lesions with rapid clearance from other tissue is an important consideration here, as in all tumor treatments using radiotoxic nuclides. Of the bone agents in use, ^{32}P orthophosphate and ionic ^{89}Sr have been used most extensively. More recently, ^{153}Sm-EDTMP (ethylenediaminetetramethylenephosphonic acid) and ^{186}Re-HEDP (1-hydroxymethylidene diphosphonate) show promise to be even more effective at rapid symptom relief.

The use of antibodies for direct treatment of tumors without damaging normal tissues has been of interest for at least a century. However, it was not until recently that the ability to isolate and label antibodies has made this approach possible on a large scale. Although a number of antibodies had been labeled with ^{131}I in the 1950s and 1960s, it was not until the mid 1970s, when the techniques for producing monoclonal antibodies were developed, that advances in radioimmunotherapy (RIT) became a reality.

There are five factors that determine the potential utility of radiolabeled antibodies for radioimmunotherapy:

1. the absolute quantity of radiopharmaceutical delivered to the tumor (target);
2. the amount of radioactivity in other organs (nontarget);
3. the radiosensitivity of the tumor;
4. the radiation dose delivery rate; and
5. the types and energies of radiations emitted.

There is still some dispute as to whether monoclonal antibodies are more efficacious than polyclonals for achieving an acceptable target to nontarget ratio. The isotopes ^{111}In, ^{90}Y, ^{125}I, and ^{186}Re have all been incorporated into antibodies and are the subject of clinical trials. While the results are promising, it is still too early to know in which direction the results will lead.

^{131}I is still widely accepted, even though its physical characteristics are less favorable than those of other radiotoxic nuclides. For example, its half-life of 8 d is, in general, longer than the biological half-life of most carriers. Also, its β energy ($E_{\max} = 0.6$ MeV) is considered less than optimum for large tumors, as is the large number of γ rays that accompany the β decay. What remains attractive about this isotope is the wide variety of compounds into which iodine can be chemically inserted.

What is still a big question mark in the use of targeted radionuclide therapy is a complete understanding of the dose delivered, not only to the tumor but to surrounding healthy tissue. Dosimetric treatments that encompass situations where the microdosimetry on the cellular level is combined with biologic data could lead to more realistic dose estimates. This is especially true for the Auger emitters. When the decay of an Auger electron emitter occurs in the vicinity of DNA, the dose to microscopic volumes within the DNA may prove to be even more meaningful than the dose to the whole cell. The time-dependent distribution of the radiotoxic substance is required to gain a fuller understanding of the relationship between dose and effect.

10. FUTURE ASPECTS OF NUCLEAR MEDICINE

Probably the biggest advances in nuclear medicine in the future will be in the area of therapy. As the ability to deliver radionuclides to specific sites becomes a reality through research in monoclonal antibodies and their fragments, the use of therapy with radionuclides will become increasingly possible. As such, the rhenium isotopes ^{188}Re, from the ^{188}W/Re generator system, and ^{186}Re will be attractive choices because of rhenium's similar chemistry to ^{99m}Tc. Also, most experts feel that the growth area for PET will be in oncology for both diagnosis and treatment assessment. The ability to acquire quantitative metabolic and receptor density images throughout the whole body will provide a needed tool in the fight against cancer.

As the present-day PET tomographs approach theoretical spatial resolution, the remaining technological advances will be made in volume imaging, where the sensitivity of the tomograph is maximized by the removal of interplane septa. Work in this area has already begun with extremely promising results, not only in the increased sensitivity but in spatial sampling.

There is increasing interest in monitoring the effect on the neuronal system of the heart as a function of ischemia and infarction. One candidate is *m*-iodobenzylguanidine (MIBG), a norepinephrine analog. MIBG could monitor the depletion of the catecholamine stores of the heart in disease. Imaging of the muscarinic acetylcholine receptors in the heart using radioiodinated 3-quinuclidinyl-4-iodobenzylate (QNB) has been proposed. A ^{11}C-labeled QNB has also been proposed for use with PET. The availability of SPECT imaging has been a driving force in the development of ^{123}I-labeled compounds that are analogs of receptor antagonist used in PET. A number of these are undergoing clinical trials.

As the chemistry for attaching technetium becomes even more sophisticated, there will be more attempts at incorporating ^{99m}Tc into agents that have receptor sensitivity, so that receptor imaging will no longer be associated solely with PET radiopharmaceuticals or their iodinated analogs. However, in the meantime, more radiopharmaceuticals labeled with ^{123}I will find their way into widespread clinical use as they are validated in the assessment of disease and the availability of ^{123}I at a reasonable cost becomes assured.

There will be continuing efforts toward improving SPECT cameras as well as the software for correcting for scatter and attenuation in SPECT. To take advantage of the new radiopharmaceuticals for brain and heart, improved collimators will be designed.

Since radiopharmaceuticals generally are used to monitor function, there will be increasing use of these techniques to monitor treatment, for example, in determining the effectiveness of organ transplants. As an example of PET volume imaging, Fig. 10 illustrates the functional integrity following fetal

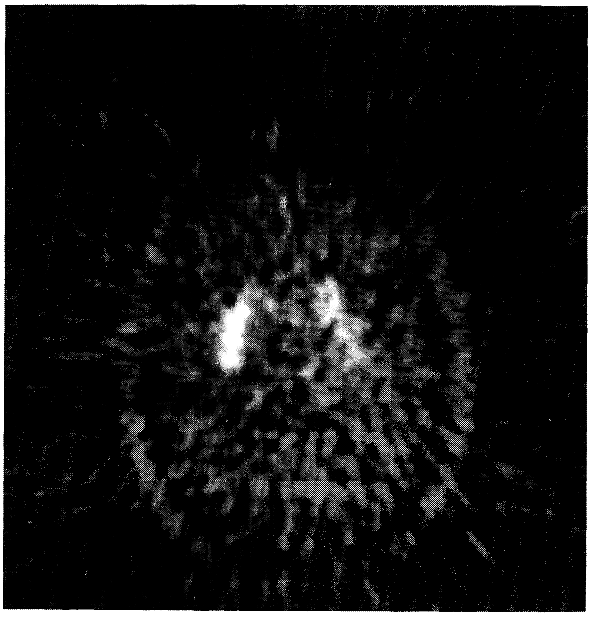

FIG. 10. PET image of ^{18}F-fluorodopa uptake in a patient who has received a fetal cell transplant. The arrows point to the four "hot spots" corresponding to the four surgical implants, indicating that the implanted cells are metabolically active with respect to the dopaminergic pathway. (Courtesy UBC/TRIUMF PET Program.)

cell transplantation. It can be expected that neuropsychiatric treatment will also be monitored by nuclear imaging processes as we gain a better understanding of the biochemistry of mental function.

As one of the pioneers of nuclear medicine, H. Wagner, recently said at the 1992 Annual Society of Nuclear Medicine meeting, nuclear medicine has begun the transformation of the art of diagnostic and therapeutic decision making into a quantitative science.

GLOSSARY

Alpha Decay: The mode of radioactive decay when the nucleus emits an α particle (the nucleus of ^{4}He), the product being two protons and two neutrons less.

Annihilation Radiation: The two 511-keV γ rays resulting from the annihilation of the β^+ with an electron in matter.

Antibody: A protein produced in the body in response to and as a counteragent to antigens.

Antigen: A substance that can induce the production of an antibody and bind with it specifically.

Auger Electron: The emission of an electron as an alternative to x-ray emission in an excited atom; thus, no x ray is emitted.

Becquerel: The SI unit of radioactivity, equivalent to one disintegration per second.

Beta Decay: The mode of radioactive decay when the nucleus emits an electron. In β^- decay, the atomic number increases by one, and, in β^+, decay the atomic number decreases by one.

Biological Half-Life: The time during which one-half of the amount of a substance is eliminated by a biological process such as urinary excretion.

Carrier Free: A term used in radiopharmaceutical sciences to indicate the absence of any stable atoms in a radionuclide sample. The term *no carrier added* is used to indicate the absence of purposely added nonradioactive atoms of the same element.

Curie: A measure of radioactivity equivalent to 3.7×10^{10} disintegrations per second.

ECD: The abbreviation for 1,1-ethylcysteinate dimer, which is used to monitor cerebral blood flow when labeled with ^{99m}Tc.

Electron Capture: The mode of radioactive decay when the nucleus captures an orbiting electron to convert a proton into a neutron; equivalent product to positron decay.

Electron Volt (eV): The kinetic energy required to move an electron through a potential difference of 1 V.

Half-Life ($t_{1/2}$): The time during which one-half the number of radioactive species decays. Same as physical half-life.

HIPDM: The abbreviation for *N*,*N*,*N*′-trimethyl-*N*-[2-hydroxy-3-methyl-5-iodobenzyl]-1,3-propanediamine, used as a blood-flow agent.

HM-PAO: The abbreviation for hexamethylpropylene amine oxime, which when labeled with ^{99m}Tc is used in cerebral blood-flow measurements.

IMP: The abbreviation for *N*-isopropyl-*p*-iodoamphetamine, which is used in assessing cerebral blood flow.

Infarct: An area of dead tissue resulting from a complete lack of blood circulation.

IPPA: The abbreviation for iodophenylpentadecanoic acid, a fatty acid used to monitor cardiac metabolism.

Ischemia: A condition where a tissue region has a deficiency in blood supply.

Kit: A package of the chemicals required to prepare a radiotracer.

Lumped Constant: The collection of mathematical terms used to express the relationship between the biological behavior of glucose and fluoro-deoxy-glucose.

MAG3: The abbreviation for triamidemonothiol-(N3M) complex ^{99m}Tc-mercaptoacetylglycylglycylglycine, which is used to monitor renal function.

MeV: Mega electron volts, a measure of energy equivalent to 1.6×10^{-19} joules.

RBC: The abbreviation for red blood cells.

Rectilinear Scanner: An imaging device whose detector is scanned mechanically in a rasterlike pattern over the area of interest.

Specific Activity: The measure of the amount of radioactivity per mass of sample.

Tritium: The only radioactive isotope of hydrogen, with 2 neutrons; it has a half-life of 12.3 years.

WBC: The abbreviation for white blood cells.

2.1
Introduction

With the collision of two nuclei, a nuclear reaction can take place and, as in the case of a chemical reaction, the final products can be different from the initial ones. This process occurs when a target is bombarded by particles coming from an accelerator or a radioactive substance. It was in the latter way that Rutherford observed, in 1919, the first nuclear reaction produced in the laboratory,

$$\alpha + {}^{14}_{7}\mathrm{N} \rightarrow {}^{17}_{8}\mathrm{O} + \mathrm{p} \tag{2.1}$$

using α-particles from a ^{214}Bi sample.

As in Eq. (2.1), other reactions were induced using α-particles, the only projectile available initially. With the development of accelerators around 1930, the possibilities multiplied by changing the energy and mass of the projectile. At present, it is possible to bombard a target with protons of energy greater than 1 TeV ($1\ \mathrm{TeV} = 10^{12}\ \mathrm{eV} = 1.602 \times 10^{-7}$ J), and beams of particles as heavy as uranium are available for study of reactions with heavy ions.

Sometimes we can have more than two final products in a reaction, as in

$$\begin{aligned} \mathrm{p} + {}^{14}\mathrm{N} &\rightarrow {}^{7}\mathrm{Be} + 2\alpha, \\ \mathrm{p} + {}^{23}\mathrm{Na} &\rightarrow {}^{22}\mathrm{Ne} + \mathrm{p} + \mathrm{n} \end{aligned} \tag{2.2}$$

or just one, as in the capture reaction $\mathrm{p} + {}^{27}\mathrm{Al} \rightarrow {}^{28}\mathrm{Si}^*$, where the asterisk indicates an excited state that usually decays, emitting γ-radiation. Under special circumstances, more than two reactants are possible. Thus, for example, the reaction $\alpha + \alpha + \alpha \rightarrow {}^{12}\mathrm{C}$ can take place in the overheated plasma of stellar interiors.

The initial and final products can also be identical. This case characterizes a process that can be elastic, as in $\mathrm{p} + {}^{16}\mathrm{O} \rightarrow \mathrm{p} + {}^{16}\mathrm{O}$ where there is only transfer of kinetic energy between the projectile and the target, or inelastic, as in $\mathrm{n} + {}^{16}\mathrm{O} \rightarrow \mathrm{n} + {}^{16}\mathrm{O}^*$, where part of the kinetic energy of the system is used in the excitation of ^{16}O.

Naturally, nuclear reactions are not limited to nuclei. They could involve any type of particle and also radiation. Thus, the reactions

$$\begin{aligned} \gamma + {}^{63}\mathrm{Cu} &\rightarrow {}^{62}\mathrm{Ni} + \mathrm{p}, \\ \gamma + {}^{233}\mathrm{U} &\rightarrow {}^{90}\mathrm{Rb} + {}^{141}\mathrm{Cs} + 2\mathrm{n} \end{aligned} \tag{2.3}$$

are examples of nuclear processes induced by γ-radiation. In the first case a γ-ray knocks a proton off ^{63}Cu and in the second it induces nuclear fission of ^{233}U, with the production of two fragments and emission of two neutrons.

Unlike a chemical reaction, the resulting products of a nuclear reaction are not

Encyclopedia of Nuclear Physics and its Applications, First Edition. Edited by Reinhard Stock.

determined univocally: starting from two or more reactants there can exist dozens of final products with an unlimited number of available quantum states. As an example, the collision of a deuteron with ^{238}U can result in, among others, the following reactions:

$$\begin{aligned} d + {}^{238}\mathrm{U} &\rightarrow {}^{240}\mathrm{Np} + \gamma, \\ &\rightarrow {}^{239}\mathrm{Np} + \mathrm{n}, \\ &\rightarrow {}^{239}\mathrm{U} + \mathrm{p}, \\ &\rightarrow {}^{237}\mathrm{U} + \mathrm{t} \end{aligned} \tag{2.4}$$

In the first one, the deuteron is absorbed by uranium, forming an excited nucleus of ^{240}Np that de-excites by emitting a γ-ray. The second and third are examples of *stripping reactions*, in which a nucleon is transferred from the projectile to the target. The last one exemplifies the inverse process: the deuteron captures a neutron from the target and emerges as ^{3}H (tritium). This is denoted as a *pickup reaction*. Another possibility would be, in the first reaction, that ^{240}Np fissions instead of emitting a γ-ray, contributing with dozens of possible final products for the reaction.

Each reaction branch, with well-defined quantum states of the participants, is known as a *channel*. In Eq. (2.4), for the *entrance channel* d + ^{238}U, there are four possible *exit channels*. Note that a different exit channel would be reached if some of the final products were in the excited state. The probability that a nuclear reaction takes place through a certain exit channel depends on the energy of the incident particle and is measured by the *cross section* of that channel.

Nuclear reactions proceed through many possible distinct mechanisms. For instance, in *direct reactions*, the projectile and the target have an interaction of short duration, with possible exchange of energy or particles between them. Another mechanism involves the *fusion* of the projectile with the target, the available energy being distributed among all nucleons, forming a highly excited *compound nucleus*. The decay of the compound nucleus leads to the final products of the reaction.

In high-energy collisions, the nuclei fragment and particles that were not initially present are produced (for instance, pions, kaons, etc.). The reactions proceed through an intermediate phase in which the nuclear matter is compressed. At very high energies, the quarks and gluons inside nucleons become ‘‘free’’ for a short time, forming the *quark–gluon plasma*. The study of high-energy reactions with nuclei is very important for a better understanding of what happens during spectacular stellar explosions (supernovae) and in the interior of compact stars, as for instance, neutron stars. The study of nuclear reactions at high energies allows to obtain information on the *equation of state* of nuclear matter.

2.2
Basic Principles

2.2.1
Conservation Laws

Several conservation laws contribute to restrict the possible processes in a nuclear reaction.

1. *Baryonic number*. There is no experimental evidence of processes in which nucleons are created or destroyed without the creation or destruction of corresponding antinucleons. The application of this principle to low-energy reactions is still more restrictive. Below the threshold

for the production of mesons (∼140 MeV), no process related to the nuclear forces is capable of transforming a proton into a neutron and vice versa, and processes governed by the weak force (responsible for the β-emission of nuclei) are very slow in relation to the times involved in nuclear reactions ($\sim 10^{-22}$–10^{-16} s). In this way, we can speak separately of proton and neutron conservation; this should show up with same amounts in both sides of a nuclear reaction.

2. *Charge*. This is a general conservation principle in physics, valid in any circumstance. In purely nuclear reactions, it is computed making the sum of the atomic numbers, which should be identical, on both sides of the reaction.
3. *Energy and linear momentum*. These are two of the most applied principles in the study of the kinematics of reactions. Using them, angles and velocities are related to the initial parameters of the problem.
4. *Total angular momentum*. It is always a constant of motion. In the reaction

$$^{10}\mathrm{B} + {}^{4}\mathrm{He} \rightarrow {}^{1}\mathrm{H} + {}^{13}\mathrm{C} \qquad (2.5)$$

^{10}B has $I = 3$ in the ground state, whereas the α-particle has zero angular momentum. If it is captured in an s-wave ($l_i = 0$), the intermediate compound nucleus is in a state with $I_c = 3$. Both final products have intrinsic angular momenta equal to 1/2. Hence, their sum is 0 or 1. Therefore, the relative angular momentum of the final products will be $l_f = 2$, 3, or 4.

5. *Parity*. It is always conserved in reactions governed by nuclear interaction. In the previous example, ^{10}B, ^{4}He, and the proton have equal parities, while ^{13}C has odd parity. Therefore, if $l_i = 0$, we necessarily have $l_f = 3$. Thus, the orbital momentum of the final products of Eq. (2.5) is determined by the combined conservation of the total angular momentum and of the parity.
6. *Isospin*. This is an approximate conservation law that is applied to light nuclei, where the effect of the Coulomb force is small. A nuclear reaction involving these nuclei not only conserves the z-component of the isospin (a consequence of charge and baryonic number conservation) but also conserves the total isospin **T**. Reactions that populate excited states not conserving the value of **T** are strongly inhibited. An example is the reaction $\mathrm{d} + {}^{16}\mathrm{O} \rightarrow \alpha + {}^{14}\mathrm{N}$, where the excited state 0^+, with 2.31 MeV, of ^{14}N is about a 100 times more populated than the 1^+ ground state. Conservation of energy, angular momentum, and parity does not impose any prohibition for that channel, whose low occurrence can only be justified by isospin conservation: the ground states of the four participant nuclei in the reaction have all $\mathbf{T} = 0$ and the state 1^+ of ^{14}N has $\mathbf{T} = 1$.

2.2.2
Kinematics

We consider a typical reaction, in which the projectile a and the target A result in two products, b and B. This can also be expressed in the notation that we used so far, $\mathrm{a} + \mathrm{A} \rightarrow \mathrm{b} + \mathrm{B}$, or even in a more compact notation, A(a,b)B.

Often, a and b are light nuclei and A and B the heavy ones; the nucleus b is emitted

at an angle θ and its energy registered in the laboratory system. The recoiling nucleus B has usually a short range and cannot leave the target. It is convenient to introduce the *Q-value of the reaction*, which measures the energy gained (or lost) because of the difference between the initial and final masses:

$$Q = (m_a + m_A - m_b - m_B)c^2 \quad (2.6)$$

Using energy and momentum conservation in the reaction, one gets

$$Q = E_b\left(1 + \frac{m_b}{m_B}\right) - E_a\left(1 - \frac{m_a}{m_B}\right) - \frac{2}{m_B}\sqrt{m_a m_b E_a E_b}\cos\theta \quad (2.7)$$

From this relation, one concludes that, when Q is negative, the incident particle has an energy threshold, E_t, which is a function of the angle θ, below which nuclei b are not observed:

$$E_t = \frac{-Q m_B (m_B + m_b)}{m_a m_b \cos^2\theta + (m_B + m_b)(m_B - m_a)} \quad (2.8)$$

This example shows the power of conservation laws in the analysis of nuclear reactions. Similar to this example, very useful relations can be derived in the relativistic regime, using other conserved quantities.

2.2.3
Cross Sections

Figure 2.1 shows schematically a typical scattering experiment. In fact, this is the sketch of Rutherford's experiment

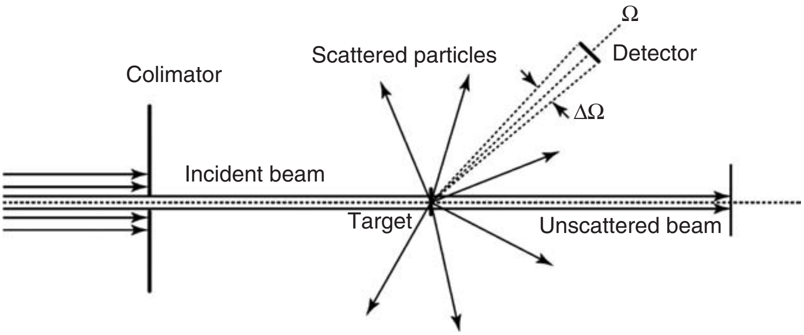

Figure 2.2 Schematic representation of a scattering experiment.

in 1910 [1]. Projectiles (here, α-particles) from a source pass through a collimator and collide with a target (gold foil). Some projectiles are scattered by the target and reach the detector (here, a fluorescent screen). Rutherford expected them to go straight through the target, with perhaps minor deflections. Most did go straight through, but, to his surprise, some particles bounced straight back! Rutherford hypothesized that the positive α- particles had hit a heavy mass of positive particles, which he called *the nucleus*.

Let us consider an experiment such as the one represented in Figure 2.2 that measures the count rate of events leading to the population of channel-α, $N_\alpha(\Omega,\ \Delta\Omega)$. Assuming that interactions between beam particles can be neglected, the count rate $N_\alpha(\Omega,\ \Delta\Omega)$ should be proportional to the incident flux J, to the fraction of solid angle $\Delta\Omega$, where the particles are scattered to, and to the number of target particles per unit volume. Hence, $N_\alpha(\Omega,\ \Delta\Omega)$ can then be written as $N_\alpha(\Omega,\ \Delta\Omega) = (\Delta\Omega \cdot n \cdot J)\ \mathrm{d}\sigma_\alpha(\Omega)/\mathrm{d}\Omega$. The constant of proportionality,

$$\frac{\mathrm{d}\sigma_\alpha(\Omega)}{\mathrm{d}\Omega} = \frac{N_\alpha(\Omega, \Delta\Omega)}{\Delta\Omega\ \cdot n\ \cdot J} \tag{2.9}$$

is called the *differential cross section* for channel-α. This quantity is very useful, as it does not depend on experimental details (detector size, incident flux, and target thickness). It depends exclusively on the physics of the projectile and the target particles.

One is often interested in the angle-integrated *total cross section* given by

$$\sigma_\alpha = \int \mathrm{d}\Omega \left[\frac{\mathrm{d}\sigma_\alpha(\Omega)}{\mathrm{d}\Omega}\right] \tag{2.10}$$

In nuclear physics, cross sections are usually measured in units of *barns*. One barn corresponds to an area of a circle of diameter approximately equal to 8 fm = 8×10^{-15} m. For comparison between theory and experiment, it is necessary to have cross sections in the same reference frame. Of course, the measured cross section is obtained in the laboratory frame, where the target is at rest. From the theoretical point of view, however, it is important to take advantage of the translational invariance of the projectile–target Hamiltonian, introducing the center of mass (CM) frame. The transformation is done using the laws of conservation of energy and momentum.

The Rutherford experiment has a simple classical description in which one assumes that the α-particles follow hyperbolic trajectories in the Coulomb field of the heavy target. Scattering at an angle θ can be easily calculated and with that one is able to calculate the Coulomb, or Rutherford cross section. The result is

$$\frac{d\sigma_R}{d\Omega} = \left(\frac{Z_P Z_T e^2}{4E}\right)^2 \operatorname{cosec}^4\left(\frac{\theta}{2}\right) \tag{2.11}$$

where Z_P (Z_T) is the projectile (target) charge number and E is the CM energy.

2.2.4
Elastic Scatteringa

When a beam of particles – represented in quantum mechanics by a plane wave – hits a nucleus, the wavefunction is modified by the presence of a scattering potential $V(r)$, responsible for the appearance of a phase in the outgoing part of the wave. Elastic scattering is just one of the channels along which the reaction can proceed and is known as *elastic channel*. Inelastic scattering and all the other channels are grouped in the *reaction channel*.

The occurrence of a nuclear reaction through a given reaction channel leads to a modification of the outgoing part of the wavefunction not only by a phase factor but also by a change in its magnitude, indicating that there is a loss of particles in the elastic channel. For a projectile with momentum $p = \hbar k$, this can be expressed by

$$\Psi \sim \frac{1}{2i}\sum_{l=0}^{\infty}(2l+1)i^l P_l(\cos\theta) \times \frac{\eta_l e^{i\left(\frac{kr-l\pi}{2}\right)} - e^{-i\left(\frac{kr-l\pi}{2}\right)}}{kr} \tag{2.12}$$

where the complex coefficient η_l is the factor mentioned above. If $\eta = 1$, the sum in Eq. (2.12) can be done analytically, leading to $\Psi \sim \exp(i\mathbf{k}.r)$, that is, a plane wave. But if $\eta_l = \exp[i\delta l]$, with δ_l real, the incoming and outgoing waves have the same magnitude, that is, the scattering is elastic.

The sum in Eq. (2.12) is known as the *partial wave expansion* of the scattering wave. The label $l = 0, 1, 2, \ldots =$ (s, p, d, … waves) denotes the contribution of a particular angular momentum (in units of $\hbar$) to the total wavefunction. Classically, the angular momentum of an incident particle is given by $l = kR$, where R is known as the *impact parameter*, which is the perpendicular distance to the target if the projectile were undeflected. In quantum mechanics l is not continuous, varying in steps of one.

We can rewrite Eq. (2.12) as a sum of a plane wave and a scattering outgoing wave in the form $\Psi \sim \exp(i\mathbf{k}.r) + f(\theta)e^{ikr}/r$, where $f(\theta)$ accounts for the distortion of the outgoing wave at the scattering angle θ. It is known as the *scattering amplitude*:

$$f(\theta) = \frac{1}{2ik}\sum_{l=0}^{\infty}(2l+1)(\eta_l - 1)P_l(\cos\theta) \tag{2.13}$$

One can now calculate the cross section by counting the number of particles that are scattered through an angle θ. This can be done by calculating the particle current associated with the wavefunction Ψ. One obtains the differential scattering cross section

$$\frac{d\sigma_e}{d\Omega} = |f(\theta)|^2 = \frac{1}{4k^2}\left|\sum_{l=0}^{\infty}(2l+1) \times (1-\eta_l)P_l(\cos\theta)\right|^2 \tag{2.14}$$

The total scattering cross section, Eq. (2.10), becomes

$$\sigma_e = \pi\lambda\!\!\!^{-}{}^2 \sum_{l=0}^{\infty}(2l+1)|1-\eta_l|^2 \tag{2.15}$$

with $\lambda\!\!\!^{-} = \lambda/2\pi = 1/k$.

2.2.5
Reaction Cross Sections

To calculate the reaction cross section, it is necessary to compute the number of particles that disappear from the elastic channel, which is measured by the flux of the probability vector current through a spherical surface of large radius centered at the target, calculated with the total wavefunction of Eq. (2.12). One finds

$$\sigma_r = \pi \lambda\!\!\!^{-2} \sum_{l=0}^{\infty}(2l+1)(1-|\eta_l|^2) \tag{2.16}$$

From Eqs. (2.15) and (2.16), when $|\eta_l| = 1$, the reaction cross section is zero and we have pure scattering. The contrary, however, cannot happen, as the vanishing of σ_e also implies the vanishing of σ_r. In general, there is a region of allowed values of η_l for which the two cross sections can coexist.

The maximum of σ_r happens for $\eta_l = 0$, which corresponds to total absorption. Let us suppose that the absorption potential is limited to the surface of a nucleus with radius $R \gg \lambda\!\!\!^{-}$, that is, that all the particles with impact parameter smaller than the radius R are absorbed. This is equivalent to saying that all particles are absorbed for $l \le R/\lambda\!\!\!^{-}$. In this case,

$$\sigma_r = \pi \lambda\!\!\!^{-2} \sum_{l=0}^{R/\lambda\!\!\!^{-}}(2l+1) = \pi(R+\lambda\!\!\!^{-})^2 \tag{2.17}$$

This is the value that would be intuitively adequate for the total cross section, that is, equal to the geometric cross section (the part $\lambda\!\!\!^{-}$ can be understood as an uncertainty in the position of the incident particle). However, we saw above that the presence of scattering is always obligatory. For $\eta_l = 0$, the scattering and reaction cross sections are identical, yielding the total cross section

$$\begin{aligned}\sigma &= \sigma_r + \sigma_e \\ &= \pi(R+\lambda\!\!\!^{-})^2 + \pi(R+\lambda\!\!\!^{-})^2 \\ &= 2\pi(R+\lambda\!\!\!^{-})^2\end{aligned} \tag{2.18}$$

that is twice the geometric cross section!

The presence of the scattering part, which gives an apparently unexpected result in Eq. (2.18), can be interpreted as the effect of diffraction of the plane waves at the nuclear surface. This effect leads to a ''shadow'' behind the nucleus, decreasing its apparent diameter so that, at a certain distance, the perturbation caused by the presence of the nucleus disappears and the plane wave is reconstructed. In this situation, we can say that the part of the beam that is diffracted has to be the same as the part that is absorbed, justifying the equality of σ_r and σ_e. The diffraction phenomenon appears clearly in the elastic scattering or inelastic angular distribution (differential cross section as a function of the scattering angle): Figure 2.3 exhibits angular distributions for the elastic scattering of 30 MeV protons on ^{40}Ca,^{120}Sn, and ^{208}Pb. The oscillations in the cross sections are characteristic of a *Fraunhofer diffraction*, similar to light scattering by an opaque disk. The angular distance $\Delta\theta$ between the diffraction minima closely follows the expression $\Delta\theta = \hbar/pR$, characteristic of diffraction phenomena.

2.2.6
Excitation Functions

When the projectile has a very low energy, $k \to 0$, and in particular, $l = kR \ll 1$. As an example consider the scattering of neutrons with $l = 0$ and ignore the spins of the neutron and of the target. In this case, the *Schrödinger equation* for the radial

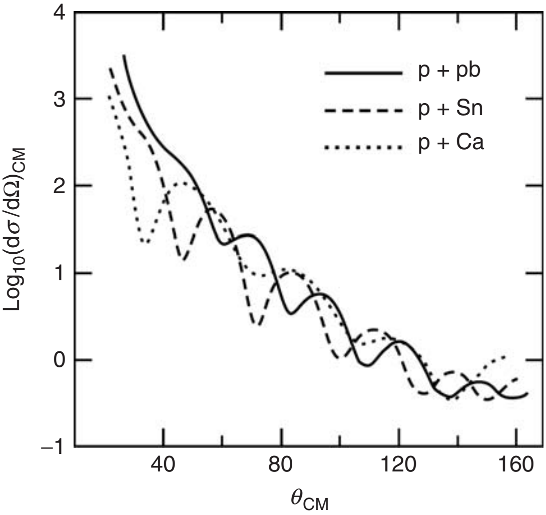

Figure 2.3 Elastic scattering angular distribution of protons of 30 MeV on Ca, Sn, and Pb. The curves are adjusted to the experimental data of Ref. 2

motion of the neutron with respect to the target is

$$\frac{d^2u_0}{dr^2} + k^2u_0 = 0 \quad (r \geq R) \qquad (2.19)$$

This is valid for the radial wavefunction u_0 at distances r larger than the *channel radius* $R = R_a + R_A$, with R_a and R_A being the radii of the projectile and the target, respectively. The solution of Eq. (2.19) is

$$u_0 = \eta_0 e^{ikr} - e^{-ikr} \quad (r \geq R) \qquad (2.20)$$

A radial wavefunction inside the nucleus should connect to the external function (2.20) with a continuous function and its derivative at $r = R$. That is, the function

$$f_l \equiv R\left[\frac{du_l/dr}{u_l}\right]_{r=R} \qquad (2.21)$$

must have identical values if calculated with the internal or the external function and this condition creates a relationship between f_l and η_l. Hence, the knowledge of f_l leads to the knowledge of the cross sections. For neutrons with $l = 0$, the application of Eq. (2.20) results in

$$f_0 = ikR\,\frac{\eta_0 + e^{-2ikR}}{\eta_0 - e^{-2ikR}} \qquad (2.22)$$

from which we extract

$$\eta_0 = \frac{f_0 + ikR}{f_0 - ikR}e^{-2ikR} \qquad (2.23)$$

If f_0 is a real number, then $|\eta_0|^2 = 1$. The reaction cross section, Eq. (2.16), will be zero and we have pure scattering.

Using Eq. (2.23), the scattering cross section, Eq. (2.15), can be written as

$$\sigma_{e,0} = \pi\lambda\!\!\!^{-2}|A_{\text{res}} + A_{\text{pot}}|^2 \qquad (2.24)$$

with $A_{\text{res}} = -2ikR/(f_0 - ikR)$ and $A_{\text{pot}} = \exp\,(2ikR) - 1$. The separation of the cross section in two parts has physical justification: A_{pot} does not contain f_0 and therefore does not depend on conditions inside the nucleus. It represents the situation where the projectile does not penetrate the nucleus as in the idealized situation where the nucleus is considered an impenetrable hard sphere. The wavefunction is zero inside the nucleus and u_0 vanishes at $r = R$, implying $f_0 \to \infty$ and $A_{\text{res}} \to 0$. Hence, A_{pot} is only responsible for scattering.

Substituting Eq. (2.23) in Eq. (2.16) and using

$$f_0 = f_R + \mathrm{i}f_I \tag{2.25}$$

we have

$$\sigma_{r,0} = \pi \bar{\lambda}^2 \frac{-4kRf_I}{f_R^2 + (f_I - kR)^2} \tag{2.26}$$

an equation that is useful when we study the presence of resonances in the *excitation function* (cross section as a function of the energy).

2.3
Statistical Reactions

2.3.1
Compound Nucleus

When a low-energy neutron (<50 MeV) enters the range of nuclear forces, it can be scattered or begin a series of collisions with the nucleons. The products of these collisions, including the incident particle, will continue in their course, leading to new collisions and new changes of energy. During this process, one or more particles can be emitted and they form, with the residual nucleus, the products of what is known as a *pre-equilibrium* reaction. At low energies, the largest probability is the continuation of the process so that the initial energy is distributed among all nucleons, with no emitted particle. The final nucleus with $A + 1$ nucleons has an excitation energy equal to the kinetic energy of the incident neutron plus the binding energy the neutron has in the new, highly unstable, nucleus [3]. It can, among other processes, emit a neutron with the same or smaller energy as that of the one absorbed. The de-excitation process is not necessarily immediate and the excited nucleus can live for a relatively long time. We say that there is, in this situation, the formation of a *compound nucleus* as intermediary stage of the reaction. In the final stage, the compound nucleus can evaporate one or more particles, fission, and so on. In our notation, for the most common situation in which two final products are formed (the evaporated particle plus the residual nucleus or two fission fragments, etc.) we write:

$$\mathrm{a} + \mathrm{A} \to \mathrm{C}^* \to \mathrm{B} + \mathrm{b}$$

the asterisk indicating that the compound nucleus C is in an excited state.

The compound nucleus lives long enough to "forget" how it was formed and the de-excitation to the final products b and B only depends on the energy, angular momentum, and parity of the quantum state of the compound nucleus. An interesting experimental verification was accomplished by Ghoshal in 1950 [4]. He studied two reactions that take to the same compound nucleus, ^{64}Zn*, and measured the cross sections of three different forms of decay, as shown below:

$$\begin{array}{ccccc} \mathrm{p} + {}^{63}\mathrm{Cu} \searrow & & \nearrow & {}^{63}\mathrm{Zn} + \mathrm{n} \\ & {}^{64}\mathrm{Zn}^* \to & & {}^{62}\mathrm{Cu} + \mathrm{n} + \mathrm{p} \\ \mathrm{a} + {}^{60}\mathrm{Ni} \nearrow & & \searrow & {}^{62}\mathrm{Zn} + 2\mathrm{n} \end{array} \tag{2.27}$$

If the idea of the compound nucleus is valid and if one chooses the energy of the proton and of the incident α-particle to produce the same excitation energy, then the cross section for each one of the three exit channels should be independent of

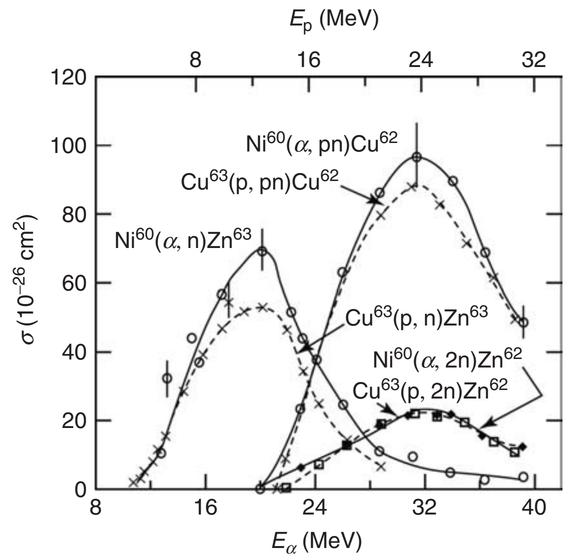

Figure 2.4 Cross sections for the reactions shown in Eq. (2.24). The scales of the upper axis (energy of the protons) and lower axis (energy of the α-particle) were adjusted to correspond to the same excitation energy of the compound nucleus [4].

the way the compound nucleus is formed. That is, the properties of the compound nucleus do not have any relationship with the nuclei that formed it. This is confirmed in Figure 2.4, where one sees clearly that the cross sections depend practically only on the exit channels.

The angular distribution of fragments, or evaporated particles, of a compound nucleus should be isotropic in the CM, and this is verified experimentally. However, the total angular momentum is conserved and cannot be ‘‘forgotten.’’ Reactions with large transfer of angular momentum, as when heavy ions are used as projectiles, can show a nonisotropic angular distribution in the CM system.

The occurrence of a nuclear reaction in two stages allows the cross section for a reaction A(a,b)B to be written as the product, $\sigma(\mathrm{a,b}) = \sigma_c(\mathrm{a,A})P(\mathrm{b})$, where $\sigma_c(\mathrm{a,A})$ is the cross section of formation of the compound nucleus starting from the projectile a and the target A and $P(\mathrm{b})$ is the probability that the compound nucleus emits a particle b leaving a residual nucleus B. If the quantum numbers of entrance and exit channels are well specified, that is, if the reaction begins at an entrance channel α and ends at an exit channel β, one can write

$$\sigma(\alpha, \beta) = \sigma_c(\alpha)P(\beta) \tag{2.28}$$

We can associate the probability $P(\beta)$ to the width Γ_β of the channel β and write

$$P(\beta) = \frac{\Gamma(\beta)}{\Gamma} \tag{2.29}$$

where Γ is the total width, that is, $\tau = \hbar/\Gamma$ is the half-life of disintegration of the compound nucleus. Equation (2.29) just expresses the fact that the decay probability through channel β is the decay rate through that channel divided by the total decay rate. In the competition between the several channels β, the nucleons have clear preference over the γ-radiation whenever there is available energy for their emission and, among the nucleons, the neutrons have preference as they do not have the

Coulomb barrier as an obstacle. Thus, in a reaction where there is no restriction for neutron emission, we can say that

$$\Gamma \cong \Gamma_n \tag{2.30}$$

where Γ_n includes the width for the emission of one or more neutrons.

The study of the function $P(\beta)$ is done in an evaporation model that leads to results in many aspects similar to the evaporation of molecules of a liquid, with the energy of the emitted neutrons having the form of a Maxwell–Boltzmann distribution (MB)

$$I(E) \propto E \exp\left(-\frac{E}{\theta}\right) \mathrm{d}E \tag{2.31}$$

with I measuring the amount of neutrons emitted with energy between E and $E + \mathrm{d}E$. The quantity θ, with dimension of energy, has the role of a *nuclear temperature*. It is related to the density of levels ω of the daughter nucleus B by

$$\frac{1}{\theta} = \frac{\mathrm{d}S}{\mathrm{d}E} \tag{2.32}$$

with

$$S = \ln \ \omega(E) \tag{2.33}$$

where $\mathrm{d}S/\mathrm{d}E$ is calculated for the daughter nucleus B at the maximum excitation energy that it can have after the emission of a neutron, that is, in the limit of emission of a neutron with zero kinetic energy.

The level density $\omega(E)$ is a measure of the number of available energy states for the decay of the compound nucleus in the interval $\mathrm{d}E$ around the energy E. In this sense, the relationship (2.33) is, neglecting the absence of the Boltzmann constant, identical to the thermodynamic relationship between the entropy S and the number of states available for the transformation of a system. Equation (2.32) is the well-known relation between the entropy and the temperature.

A simple expression for the energy dependence of the state density is provided by the equidistant spacing model, which assumes that the one-particle states are equally spaced with spacing d and that the total energy of the nucleus is simply obtained by adding the energies of the constituent nucleons. The solution of this problem can be obtained from statistical mechanics [6]:

$$\rho(E) \sim \exp\ (2\sqrt{aE})$$

Extensive analyzes of experimental data show that for nuclei far from the region of the magic nuclei, a varies linearly with A (or with N and Z), as shown in Figure 2.5:

$$a \cong \frac{A}{k}\ \mathrm{MeV}^{-1} \tag{2.34}$$

It is found that $k \cong 7.5 - 8$.

2.3.2
Energy Spectrum of Neutrons

The energy distribution of neutrons emitted by a compound nucleus has the aspect of the curve shown in Figure 2.6. Only the low-energy part obeys Eq. (2.31) and the reason is simple: the emission of a low-energy neutron leaves the residual nucleus with a large excitation energy, and the level density is very high. The large density of final states makes the problem tractable with the statistical model that leads to Eq. (2.31); in the opposite situation, it is the low-energy states of the residual nucleus. These isolated states appear as peaks in the tail of the distribution. When the emission is of a proton or of another charged particle, the form of Figure 2.6 is distorted, the part of low energy of the spectrum

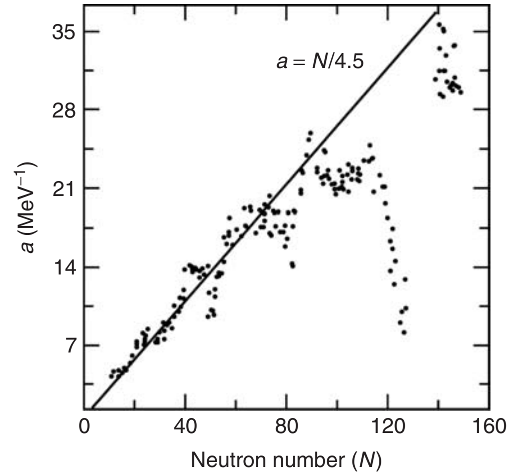

Figure 2.5 Values of the level density parameter a as a function of the neutron number. Far from magic regions, $a \approx N/4.5\ \text{MeV}^{-1}$, which approximately corresponds to $a = A/7.5\ \text{MeV}^{-1}$ [5].

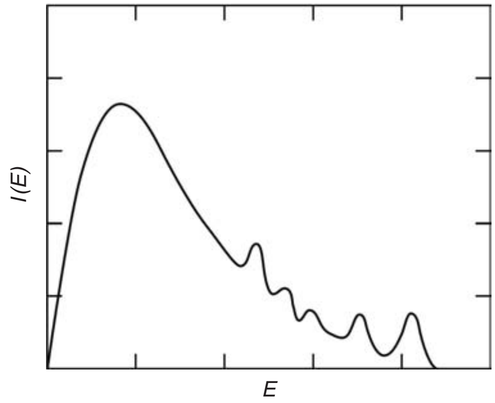

Figure 2.6 Energy spectrum of neutrons evaporated by a compound nucleus.

being suppressed partially by the Coulomb barrier.

Let us now assume that there is only elastic scattering or formation of a compound nucleus. We further assume that the elastic scattering is purely potential, without resonant elastic scattering. That is, there is no reemission of neutrons with energy equal to the incident projectile. This is equivalent to saying that the probability that the exit channel is the same as the entrance channel is very low. According to these assumptions, the cross section $\sigma_c(\alpha)$ of Eq. (2.28) is the reaction cross section of Eq. (2.16). We can still write the wavefunction inside the nucleus as just an incoming wave

$$u_0 \cong \exp(-\mathrm{i}Kr) \quad (r < R) \tag{2.35}$$

where $K = \sqrt{2m(E - V_0)}/\hbar$ is the wavenumber inside the nucleus, and it is assumed that the neutron with total energy E is subject to a negative potential V_0. Equation (2.35) is clearly a crude simplification when the incident neutron interacts in a complicated way with the other nucleons in the nucleus. It allows,

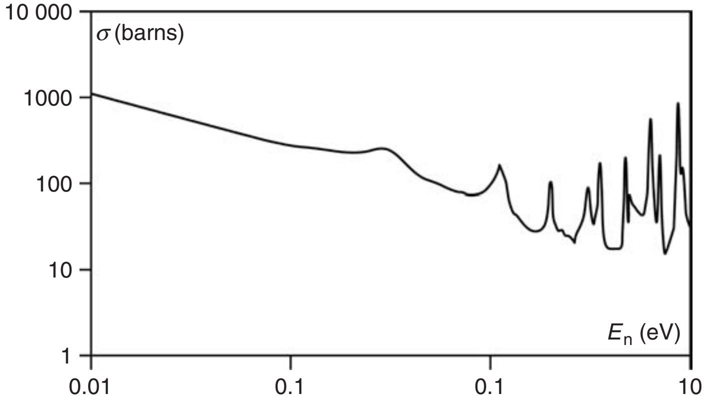

Figure 2.7 Total cross section for low-energy neutrons hitting ^{235}U.

however, to explain the average behavior of the cross sections for low energies. Starting with Eqs. (2.21) and (2.35), one determines the value of f_0:

$$f_0 = -\mathrm{i}KR \tag{2.36}$$

and from Eq. (2.26), we get

$$\sigma_c = \pi \lambdabar^2 \frac{4kK}{(k+K)^2} \tag{2.37}$$

for the cross section of compound nucleus formation for neutrons with $l = 0$. At low energies, $E|V_0|$, thus kK. Under these conditions, $\sigma_c = 4\pi/kK$, since $\lambdabar = k^{-1} \gg R$. Thus, σ_c varies with $1/k$. That is,

$$\sigma_c \propto \frac{1}{v} \tag{2.38}$$

where v is the velocity of the incident neutron. This is the well-known $1/v$ *law* that governs the behavior of the capture cross section of low-energy neutrons. Figure 2.7 exhibits the excitation function (cross section as function of the energy) for the reaction n+^{235}U. The cross section decays with $1/v$ up to 0.3 eV, where a series of resonances appear.

2.3.3
Resonances

To understand why there are resonances, we shall use again the simple model of a single particle subject to a square-well potential. We know that inside the well, the Schrödinger equation only admits solution for a discrete group of values of energy, $E_1, E_2, \ldots, E_n$. A particle is confined to the interior of the well by reflections that it has at the surface of the well. In these reflections, the wave that represents the particle should be in phase before and after the reflection and this only happens for a finite group of energies. Outside the well, the Schrödinger equation does not impose restrictions and the energy can have any value. But we know, from the study of the passage of a beam of particles through a potential step, that the discontinuity of the potential at the step provokes reflection even when the total energy of the particles is larger than the step, a situation where classically there would not be any difficulty for the passage of the particles. This reflection is partial and it becomes larger the closer the energy is to the height of the potential step. We can say that a particle with energy slightly positive is almost as confined as a particle inside the well. From this fact results the existence of almost bound states of positive energy known as *quasi-stationary states* or *resonances*. These resonances appear as peaks in the excitation function, a peak at a given energy meaning that the energy coincides with a given resonance of the nucleus.

The existence of resonances can also be inferred from the properties of the wavefunction. We consider only elastic scattering, with the other channels closed. The external and internal wavefunctions are both sine functions, the first with wavenumber $k = \sqrt{2mE}/\hbar$ and the second with $K = \sqrt{2m(E - V_0)}/\hbar$. If E is small and V_0 is about -35MeV, we have $K \gg k$. The internal and external parts should join at $r = R$ with continuous function and derivatives. As the internal frequency is much larger than the external one, the internal amplitude is quite reduced. There is a perfect matching between both and the internal amplitude is identical to the external one only at the proximity of the situation in which the derivative is zero. The energy for which this happens is exactly the energy of resonance.

Resonances appear in the excitation function at relatively low energies, where the number of open channels is not very large and it is possible to return to the entrance channel. To arrive at an expression of the cross section that describes a resonance, we rewrite Eq. (2.35) as,

$$u_l \sim \exp(-\mathrm{i}Kr) + b\exp(\mathrm{i}Kr)\ , \quad (r < R) \tag{2.39}$$

this time containing a second part, which takes into consideration the part of the wave that returns. This second part allows the existence of resonant scattering, where the incident particle is re-emitted with the same energy that it entered, after forming the compound nucleus. The complex amplitude b is always smaller than one, because there are no creation of particles in the region $< R$ in Eq. (2.26).

The second parenthesis in the denominator of Eq. (2.26) is never zero, since the numerator forces f_I to be always negative. If for f_R vanishes a certain energy, $\sigma_{r,0}$ passes by a maximum in that energy. We can tentatively identify these energies as being the energy of the resonances. Let us take the extreme case of a single resonance at the energy E_R, that is, $f_R = 0$ for $E = E_R$. We can expand f_R in a Taylor series in the neighborhood of a resonance, $f_R(E) = (E - E_R)(\mathrm{d}f_R/\mathrm{d}E)_{E=E_R} + \cdots$. Keeping just the first term of the expansion and using Eqs. (2.24) and (2.26), we get

$$\sigma_{e,0} = \pi \lambda\!\!\!^{-2} \left| \exp(2\mathrm{i}kR) - 1 + \frac{\mathrm{i}\Gamma_\alpha}{(E - E_R) + \mathrm{i}\frac{\Gamma}{2}} \right|^2 \tag{2.40}$$

$$\sigma_{r,0} = \pi \lambda\!\!\!^{-2} \frac{\Gamma_\alpha(\Gamma - \Gamma_\alpha)}{(E - E_R)^2 + \left(\frac{\Gamma}{2}\right)^2} \tag{2.41}$$

where we define

$$\Gamma_\alpha = -\frac{2kR}{(\mathrm{d}f_R/\mathrm{d}E)_{E=E_R}} \quad \text{and} \quad \Gamma = \frac{2kR - 2f_I}{(\mathrm{d}f_R/\mathrm{d}E)_{E=E_R}} \tag{2.42}$$

The energy Γ that appears in Eq. (2.40) is the total width of the resonance, $\Gamma = \Gamma_\alpha + \Gamma_\beta + \cdots$, that is, the sum of the widths for all the possible processes of decay of the nucleus, starting from the resonant state. Γ_α is the entrance channel width, and $\Gamma - \Gamma_\alpha$ is the sum of the widths of all the exit channels except α. If we

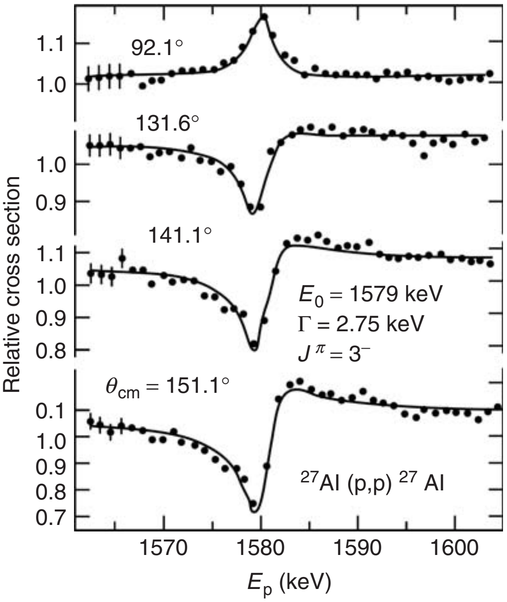

Figure 2.8 Differential cross section at four angles for the elastic scattering of protons off ^{27}Al, in units of the Rutherford cross section, in the neighborhood of the 1579 keV resonance. For larger angles, we have typical interference between the resonant scattering and the potential scattering [7].

restrict the exit channels to a single channel β, or we denote β as the group of exit channels except α, Eq. (2.41) is rewritten as

$$\sigma_{\alpha,\beta} = \pi \lambda\!\!\!^{-2} \frac{\Gamma_\alpha \Gamma_\beta}{(E - E_R)^2 + \left(\frac{\Gamma}{2}\right)^2} \tag{2.43}$$

which is the usual way of presenting the *Breit–Wigner formula*, which describes the form of the cross section close to a resonance. Let us recall that Eq. (2.43) refers to an incident particle of $l = 0$, without charge and without spin. If the spins of the incident and target particles are s_a and s_A, respectively, and the incident beam is described by a single partial wave $l \neq 0$, one can show that the cross section of Eq. (2.43) should be multiplied by the statistical factor $g = (2I + 1)/(2s_a + 1)(2s_A + 1)$, where I is the quantum number of the total angular momentum $I = \mathbf{s}_a + \mathbf{s}_A + \mathbf{l}$ of the compound nucleus. g reduces, naturally, to the unit in the case of zero intrinsic and orbital angular momenta.

If the exit channel is the same as the entrance channel α, the cross section should be obtained from Eq. (2.40) and its dependence in energy is more complicated because in addition to the resonant scattering there is the potential scattering, and the cross section from Eq. (2.40) will contain an interference term between both. The presence of interference results in a peculiar aspect of the scattering cross section, which differs from the simple form in Eq. (2.43) for the reaction cross section. This is seen in Figure 2.8 that shows the forms that a resonance can take in the scattering cross section.

The region of energy where resonances show up can extend to 10 MeV in light nuclei but it ends well before this in heavy nuclei. Starting from this limit, the increase in level density with energy implies that the average distance between levels is smaller than the width of the levels and individual resonances cannot be resolved experimentally. They form a continuum and this region is known as the *continuum region*. The cross section in this region fluctuates.

2.3.4
Statistical Theory of Nuclear Reactions

The fluctuating behavior of low-energy nuclear reactions is due to the interference of the reaction amplitudes corresponding to the excitation of each of the overlapping states, which vanish in the energy average of the cross section since these amplitudes are complex functions with random modulus and phase. Calling $\sigma_{\mathrm{CN}}(c)$ the cross section for the formation of a compound nucleus in the entrance channel c, and using the *reciprocity theorem*, which relates the cross section $\sigma_{cc'}$ to the cross section for the time-reversed process $c' \to c$, one gets

$$\sigma_{cc'}(E_{c'})\mathrm{d}E_{c'} = \sigma_{\mathrm{CN}}(c) \times \frac{(2I_{c'}+1)\mu_{c'}E_{c'}\;\sigma_{\mathrm{CN}}(c')\omega(U_{c'})\mathrm{d}U_{c'}}{\sum\limits_{c}\int_0^{E_c^{\max}}(2I_c+1)\mu_c E_c\;\sigma_{\mathrm{CN}}(c)\omega(U_c)\mathrm{d}U_c} \tag{2.44}$$

where I_c is the angular momentum and μ_c is the reduced mass in channel c. Ejectiles with energy in the range $E_{c'}$ to $E_{c'} + \mathrm{d}E_{c'}$ leave the residual nucleus with energy in the range $U_{c'}$ to $U_{c'} + \mathrm{d}U_{c'}$, where $U_{c'} = E_{\mathrm{CN}} - B_{c'} - E_{c'}$ and E_{CN} and $B_{c'}$ are, respectively, the compound nucleus energy and the binding energy of the ejectile in the compound nucleus. Equation (2.44) is the *Weisskopf–Ewing formula* for the angle-integrated cross sections [9]. To a good approximation, the level density $\omega(U) \propto \exp\,(U/T)$, so the ejectile spectrum given by the Weisskopf–Ewing theory is Maxwellian. It rises rapidly above the threshold energy, attains a maximum, and then falls exponentially.

The Weisskopf–Ewing theory is simple to use, but it has the disadvantage that it does not explicitly consider the conservation of angular momentum and does not give the angular distribution of the emitted particles. This is provided by the *Hauser–Feshbach theory* [10]. This theory takes into account the formation of the compound nucleus in states of different J and parity π. Let us consider the case of a reaction leading from the initial channel c to a final channel c'. If there is no *pre-equilibrium emission*, one may identify the compound nucleus formation cross section $\sigma_{\mathrm{CN}} = \sum_{J,\pi}\sigma_{\mathrm{CN}}^{J\pi}$ with the optical model reaction cross section $\sigma_R = \pi/k^2\sum_l(2l+1)T_l$, which, if the transmission coefficients $T_l = 1 - |S_l|^2$, do not depend on J. S_l is the average value of the scattering amplitude over several overlapping resonances.

Using the above assumptions, the reciprocity theorem, and following a similar derivation as with the Ewing–Weisskopf theory, the cross section for transition $c \to c'$ is given by the *Hauser–Feshbach* expression

$$\sigma_{cc'} = \frac{\pi}{k^2}\sum_J \frac{(2J+1)}{(2i_c+1)(2I_c+1)} \times \frac{\sum\limits_{s,l} T_l(c)\sum\limits_{s',l'} T_{l'}(c')}{\sum\limits_{c}\sum\limits_{s,l} T_l(c)} \tag{2.45}$$

The compound nucleus states may be both of positive and negative parity. Since parity is conserved, in evaluating the expression (2.45), one must take into account that the parity of compound nucleus states and the parity of the residual nucleus states may impose restrictions on the values of the emitted particle angular momentum. Thus, positive parity compound nucleus states decay to positive parity states of the residual only by even angular momenta and to negative parity residual nucleus states by odd angular momenta.

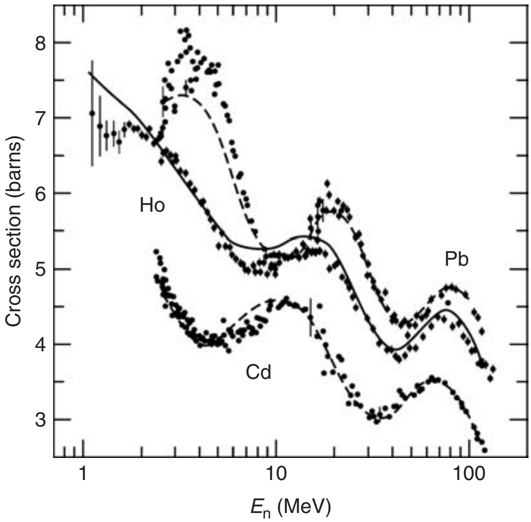

Figure 2.9 Total cross section for neutrons incident on cadmium, holmium, and lead, showing an oscillatory behavior. The curves for cadmium and lead are results of calculations with the optical model [8].

2.3.5
The Optical Model

Expression (2.18) shows that if a particle is always absorbed when it reaches the nucleus, the total cross section falls monotonically with the energy and grows linearly with $A^{\frac{1}{3}}$. In Figure 2.9, we see curves of total cross section of neutron scattering showing an oscillatory behavior for its energy dependence as well as for the mass dependence of the target. Their presence is mainly due to interference phenomena between the part of the incident beam that passes through the nucleus and the part that passes around it [11].

The basis of the *optical model* was established by Feshbach and collaborators in 1953 [12]. In this model, the interaction between the nuclei in a reaction is described by a potential $U(r)$, with r being the distance between the CM of the two nuclei. One replaces the complicated interaction that a nucleon has with the rest of the nucleus with a potential that acts on the nucleon. The potential $U(r)$ includes a complex part that takes into account the absorption effects, that is, the inelastic scattering. The nuclear scattering is treated in similar form as the scattering of light by a glass sphere and the name of the model is derived from this analogy.

In its most commonly used form, the optical potential is written as the sum

$$U(r) = U_R(r) + U_I(r) + U_D(r) + U_S(r) + U_C(r) \tag{2.46}$$

which contains parameters that can vary with energy and masses of the nuclei and that should be chosen by an adjustment to the experimental data. Obviously, the optical potential $U(r)$ will only make sense if these variations are small for neighboring masses or energies.

The first part of Eq. (2.46), $U_R(r) = -Vf(r, R, a)$, is real and represents a nuclear well with depth $-V$, being multiplied by a Woods–Saxon form factor $f(r, R, a) = [1 + \exp\{(r - R)/a\}]^{-1}$, where R is the radius of the nucleus and a measures the diffuseness of the potential, that is, the width of the region where the function f is sensibly different from 0 or

1. V, R, and a are treated as adjustable parameters.

The absorption effect or, alternatively, the disappearance of particles from the elastic channel is taken into account, including the two following imaginary parts $U_I(r) = -\mathrm{i}Wf(r, R_I, a_I)$ and $U_D(r) = 4\mathrm{i}a_I W_D \mathrm{d}f(r, R_I, a_I)/\mathrm{d}r$. An imaginary part produces absorption. It is easy to see this for the scattering problem of the square well: if an imaginary part is added to the well, $U(r) = -V_0 - \mathrm{i}W_0(r < r_0)$ and $U(r) = 0(r > r_0)$, it appears in the value of $K = [2m(E + V_0 + \mathrm{i}W_0)]^{1/2}/\hbar$. This will produce an exponentially decreasing internal wavefunction. Thus, it corresponds to an absorption of particles from the incident beam.

U_I is responsible for the absorption in the whole volume of the nucleus, but U_D, built from the derivative of the function f, acts specifically in the region close to the nuclear surface. These two parts have complementary goals: at low energies, there are no available unoccupied states for nucleons inside the nucleus and the interactions are essentially at the surface. In this situation, $U_D(r)$ is important and $U_I(r)$ can be ignored. On the other hand, at high energies, the incident particle has larger penetration and, in this case, the function $U_I(r)$ is important.

As with the shell model potential, used in nuclear structure, a spin–orbit interaction term is added to the optical potential. This term, which is the fourth part of Eq. (2.46), is usually written in the form

$$U_S(r) = \mathbf{s{\cdot}l}\ V_s\ \frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}f(r, R_S, a_S) \quad (2.47)$$

s is the spin operator and **l** the angular orbital momentum operator. As with $U_D(r)$, the part $U_S(r)$ is only important at the surface of the nucleus since it contains the derivative of the form factor f. The values of V_S, R_S, and a_S must be adjusted by experiment.

The presence of the term U_S is necessary to describe the effect of *polarization*. Through experiences of double scattering, it can be verified that proton or neutron beams suffer strong polarization at certain angles. This means that the quantity

$$P = \frac{N_\mathrm{c} - N_\mathrm{b}}{N_\mathrm{c} + N_\mathrm{b}} \quad (2.48)$$

where N_c is the number of nucleons in the beam with spin up and N_b with spin down, has a value significantly different from zero at these angles. With the inclusion of U_S, the optical model is able to reproduce in many cases the experimental values for the polarization given in Eq. (2.48).

Finally, a term corresponding to the Coulomb potential is added to Eq. (2.46) whenever the scattering involves charged particles. It has the form

$$U_C(r) = \frac{Z_1Z_2e^2}{2R_\mathrm{c}}\left(3 - \frac{r^2}{R_\mathrm{c}^2}\right)\ (r \le R_\mathrm{c}) \quad (2.49)$$

$$= \frac{Z_1Z_2e^2}{r}\ (r > R_\mathrm{c}) \quad (2.50)$$

where it is assumed that the nucleus is a homogeneously charged sphere of radius equal to the *Coulomb barrier radius* R_c, which separates the regions of nuclear and Coulomb forces.

Figure 2.10 exhibits the result of the application of Eq. (2.46) to the elastic scattering of 17 MeV protons on several light nuclei. The angular distribution is very well reproduced by the model, which also reproduces correctly the polarization given by Eq. (2.46) for copper as a function of the scattering angle.

The optical model has a limited set of adjustable parameters and is not capable to describe abrupt variations in the

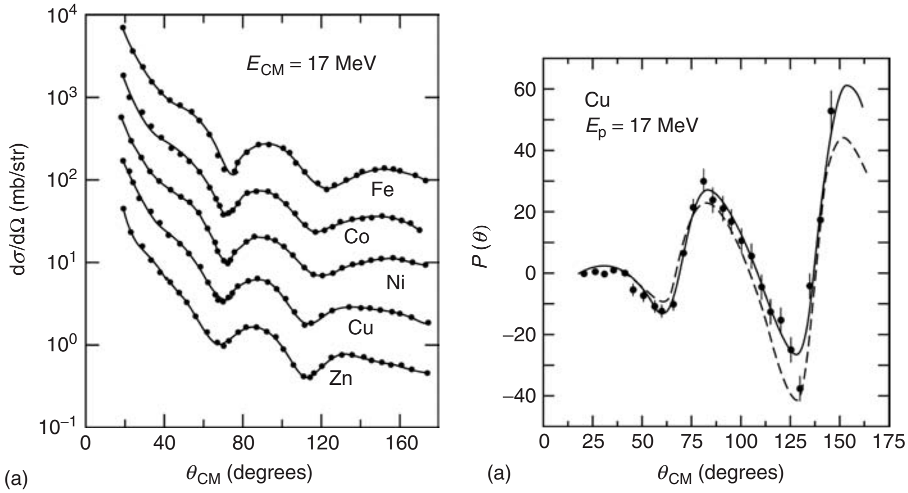

Figure 2.10 (a) Angular distribution of the elastic scattering of 17 MeV protons on nuclei in the region $Z = 26 - 30$. (b) The polarization value Eq. (2.48) in the scattering of 9.4 MeV protons on copper. The curves are, in both cases, obtained with fits from the optical model [13].

cross sections, as it happens for isolated resonances. However, it can provide a good description of the cross sections in the presence of the oscillations of large width in the continuous region, as it treats these as wave phenomena.

2.4
Direct Reactions

Direct reactions become more probable as one increases the energy of the incident particle: the wavelength associated with the particle decreases and localized areas of the nucleus can be "probed" by the projectile. In this context, peripheral reactions, where only a few nucleons of the surface participate, become important. Direct reactions happen during a time of the order of $10^{-22}\$$. Reactions with formation of compound nuclei can be up to six orders of magnitude slower. A reaction type at a given energy is not necessarily exclusive; the same final products can be obtained, part of the events in a direct manner, other parts through the formation and decay of a compound nucleus.

There are two characteristic types of direct reactions. In the first, the incident particle scatters inelastically and the transferred energy is used to excite a collective mode of the nucleus. Rotational and vibrational bands can be studied in this way. The second type involves a modification in the nuclear composition. Examples are transfer of nucleons, as *pickup* and *stripping* reactions. An important reaction of the latter kind is a *knockout* reaction where the incident particle knocks out a particle of the target nucleus and continues in its path, resulting in three reaction products. Reactions with nucleon exchange can also be used to excite collective states. An example is a pickup reaction where a projectile captures a neutron from a deformed target and the product nucleus is in an excited state belonging to a rotational band.

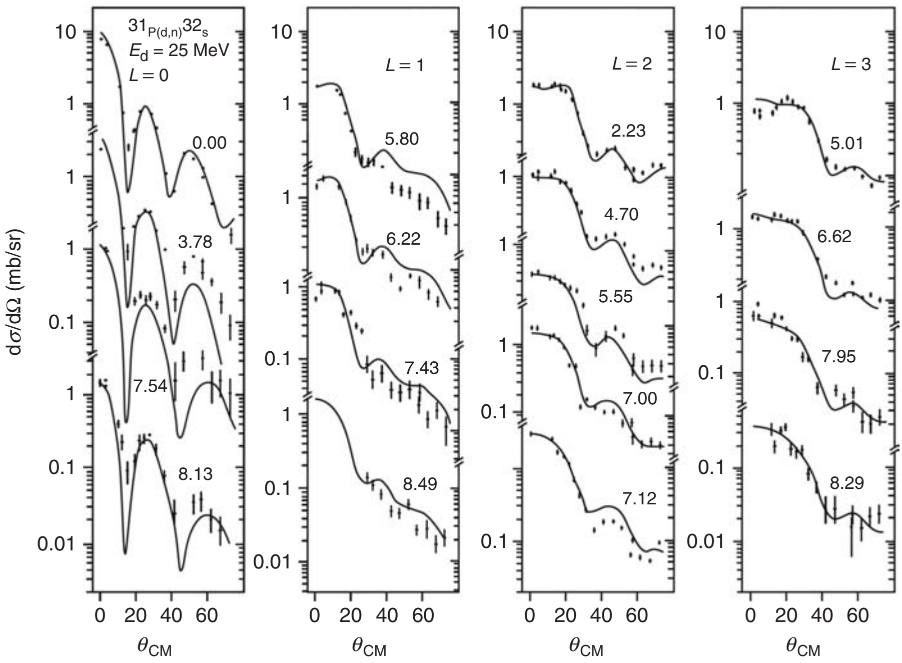

Figure 2.11 Angular distribution of the reaction $^{31}\mathrm{P}(d,n)^{32}\mathrm{S}$, with the transfer of a proton to several states of $^{32}\mathrm{S}$. The curves are results of DWBA calculations for the indicated l values [14].

Direct reactions exhibit a peculiar form of angular distribution, which allows us to extract information on the reaction mechanism with the employment of simple models. Typical examples are the stripping reactions (d,n) and (d,p), where the angular distribution of the remaining nucleon presents a forward prominent peak and smaller peaks at larger angles, with the characteristic aspect of a diffraction figure.

Figure 2.11 shows experimental results for the reaction $^{31}\mathrm{P}(d,n)^{32}\mathrm{S}$ [14]: angular distributions of the detected neutrons corresponding to each energy level of $^{32}\mathrm{S}$ are exhibited for several angular momenta. We see that the behavior of the cross sections is in agreement with qualitative predictions: the curves exhibit a first peak at a value of θ that grows with l. Other smaller peaks occur as θ increases. The increase of θ_l with l is an important characteristic that can be used to identify the value of the transferred momentum in a given angular distribution.

We consider an initial quantum state with particles of mass m_a hitting a target A of mass m_A. The final quantum state are particles of mass m_b moving away from nucleus B of mass m_B. The differential cross section for the process is given by

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{m_\mathrm{a} m_\mathrm{b} k_\mathrm{b}}{(2\pi\hbar^2)^2 k_\mathrm{a}} |V_\mathrm{fi}|^2 \tag{2.51}$$

involving the matrix element

$$V_\mathrm{fi} = \int \Psi_\mathrm{b}^* \Psi_\mathrm{B}^* \Psi_\beta(\mathbf{r}_\beta) V \Psi_\mathrm{a} \Psi_\mathrm{A} \Psi_\alpha(\mathbf{r}_\alpha) \mathrm{d}\tau \tag{2.52}$$

$\Psi_a, \Psi_b, \Psi_A,$ and Ψ_B are the internal wavefunctions of the nuclei a, b, A, and B. Ψ_α, Ψ_β are the wavefunctions of the relative motion in the entrance channel α and in the exit channel β. The integration volume $d\tau$ spans the coordinates of all particles. V is the perturbation potential that causes the ''transition'' from the entrance to the exit channel.

The use of plane waves for Ψ_α and Ψ_β in Eq. (2.52) is known as the *first Born approximation*. With it, we can arrive at an approximate expression for the behavior of the differential cross section. As the nuclear forces are of short range, one can restrict the integral Eq. (2.52) to regions where $\mathbf{r}_\alpha \cong \mathbf{r}_\beta = \mathbf{r}$. This leads to

$$V_{\mathrm{fi}} \cong \int \mathrm{d}\mathbf{r} \exp(\mathrm{i}\mathbf{k}\cdot\mathbf{r}) \left\{ \int \Psi_b^* \Psi_B^* V \Psi_a \Psi_A \, \mathrm{d}\tau' \right\} \tag{2.53}$$

where $\mathbf{k} = \mathbf{k}_\alpha - \mathbf{k}_\beta$. The global variables in $d\tau$ were separated into variables $d\mathbf{r}$ and $d\tau'$.

Expanding the plane wave in a Legendre polynomial series, we obtain

$$V_{\mathrm{fi}} \cong \sum_{l=0}^{\infty} \mathrm{i}^l (2l+1) \int j_l(kr) P_l(\cos\theta) F(\mathbf{r}) \mathrm{d}\mathbf{r} \tag{2.54}$$

where $F(\mathbf{r}) = \int \Psi_b^* \Psi_B^* V \Psi_a \Psi_A \mathrm{d}\tau'$ contains all the internal properties and is known as the *form factor* of the reaction. The action of V is restricted to the surface of the nucleus: outside the nucleus the action of V is limited by the short range of the nuclear forces and inside the nucleus there is a strong deviation to the absorption channel. Expression (2.54) becomes $V_{\mathrm{fi}} \cong \sum_{l=0}^{\infty} c_l j_l(kR)$, where the coefficients c_l contain information on the form factor $F(\mathbf{r})$. The index l can be identified as the angular momentum transferred and, for a reaction that involves a single value of l, we can write for the differential cross section:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \propto |j_l(kR)|^2 \tag{2.55}$$

where the dependence in θ is contained in

$$k^2 = k_\alpha^2 + k_\beta^2 - 2k_\alpha k_\beta \cos\theta.$$

We have an oscillatory behavior for the angular distribution, the maxima separated by π from each other in the axis kR.

The Born approximation with plane waves predicts for certain cases the correct place of the first peaks in the angular distribution but without reproducing correctly the intensities. A considerable progress can be made in the perturbative calculations if, instead of plane waves in Eq. (2.52), we use *distorted* waves that contain, besides the plane wave, the part dispersed elastically by the optical potential of the target. The Born approximation with distorted waves, or distorted wave Born approximation (DWBA), became a largely employed tool in the analysis of experimental results of direct reactions. With it, one can try to extract with a certain reliability the value of the angular momentum l transferred to the nucleus in a stripping or pickup reaction. An example of this is the already mentioned stripping reaction, $^{31}\mathrm{P}(d,n)^{32}\mathrm{S}$, for deuterons of 25 MeV. For the energy levels shown in Figure 2.11, the assignments of the value of l for the level is, in most cases, univocal.

The angular momentum l transferred in a direct reaction generally modifies the value of the total angular momentum of the nucleus. If J_i is the spin of the target nucleus, the spin J_f of the product nucleus is limited to the values

$$\left| |J_\mathrm{i} - l| - \frac{1}{2} \right| \le J_\mathrm{f} \le J_\mathrm{i} + l + \frac{1}{2} \tag{2.56}$$

and the initial and final parities obey the relationship $\pi_\mathrm{i}\pi_\mathrm{f} = (-1)^l$. Equation (2.56) allows, with the knowledge of the target nucleus and of the transferred angular momentum, the determination of the parity of the product state formed and is a tool for the determination of its spin.

The knowledge of the transferred angular momentum value in a direct reaction opens the possibility to test the predictions of the shell model for the structure of nuclei. In a direct reaction, one assumes that the nucleon is located in an orbit of the nucleus with the same angular momentum as the transferred momentum in the reaction. In almost all cases studied with direct reactions, the value of the assigned l corresponds exactly to that predicted by the shell model. We know, however, that the real situation is more complicated, owing to the presence of the residual interactions that give place to configuration mixing. As a result, the cross section for the formation of a state i of the product nucleus is related to that calculated with DWBA for the formation from a single-particle state by

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\mathrm{exp}} = \frac{2J_\mathrm{B}+1}{2J_\mathrm{A}+1}\mathcal{S}_{ij}\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\mathrm{DWBA}} \tag{2.57}$$

where the *spectroscopic factor* $\mathcal{S}_{ij}$ measures the weight of the configuration j used in the DWBA calculation, in the final state i, with the sum-rule

$$\sum_j \mathcal{S}_{ij} = n_i \tag{2.58}$$

The sum (2.57) embraces all the nucleons in the configurations j of the product nucleus. The statistical weight $(2J_\mathrm{B}+1)/(2J_\mathrm{A}+1)$ that appears in the DWBA calculation involving the angular momentum of the target nucleus J_A and final nucleus J_B is explicitly given in Eq. (2.58).

2.5
Heavy Ion Reactions

2.5.1
Types and Properties

Heavy ion reactions (with $A > 4$) can be separated into three major categories.

1. Owing to their large charge, two heavy nuclei feel a strong mutual Coulomb repulsion. To produce a nuclear reaction, the projectile needs enough energy to overcome the Coulomb barrier. For a very heavy target, such as ^{238}U, about 5 MeV per nucleon is necessary. Then the wavelength of the projectile is small compared with the dimensions of the nuclei and classical and semiclassical methods become useful in the description of the reaction.
2. The projectile carries a large amount of angular momentum and a good part of it can be transferred to the target in the reaction. Rotational bands with several dozens of units of angular momentum can be created. In fact, heavy ion reactions are the best suited to feed high spin levels.
3. Direct reactions and formation of compound nucleus are also common processes in reactions with heavy ions. But some peculiarities of these are not found in reactions with projectile nucleons. One of these processes can be understood as intermediate between a direct reaction and the formation of a compound nucleus. Fusion does not occur but the projectile and target pass a relatively long time under the mutual action of the nuclear forces. Nuclear matter is exchanged between both and there is a strong heating of the two nuclei, with a large transfer of kinetic

energy to the internal degrees of freedom. These are the *deep inelastic collisions*.

The kind of process that prevails depends on the distance of closest approach d between the projectile and the target. If this distance is sufficiently large only the long-range Coulomb interaction acts and, for a classical hyperbolic trajectory, d is related to the impact parameter b and to the energy E of the projectile by $d = a/2 + [(a/2)^2 + b^2]^{1/2}$, where a is the distance of closest approach in a head-on collision. This is related to E by $a = Z_1 Z_2 e^2/4\pi_0 E$.

Experimentally, the variable under control is the energy E of the projectile and, for E sufficiently large, d can be small enough to enter the range of nuclear forces. Collisions near this limit are called *grazing* collisions and are characterized by values of b_{graz} and d_{graz}. Assuming that there is always reaction when $b < b_{\text{graz}}$, the reaction cross section σ_r can be determined geometrically by $\sigma_r = \pi b^2_{\text{graz}}$. The experimental determination of σ_r allows to establish the value $d_{\text{graz}} = 0.5 + 1.36\ (A_1^{1/3} + A_2^{1/3})$ showing that the distance of grazing collision is somewhat larger than that deduced from two touching spheres ($1.36 fm > r_0 = 1.2$ fm).

When the impact parameter is close to b_{graz}, one expects nuclear reactions of short duration, without the contribution of the compound nucleus formation. Such reactions are elastic and inelastic scattering and involve a transfer of few nucleons. When the incident energy is sufficiently high, small values of b can lead to the projectile penetrating the target. Depending on the energy and on the involved masses, the reaction can end in one of the processes below:

1. *Fusion* – this is the preferred process when one has light nuclei and low energy. There is formation of a highly excited compound nucleus that decays by evaporation of particles and γ-radiation emission, leading to a cold residual nucleus. If the energy in the CM is close to the Coulomb barrier energy, the cross section of compound nucleus formation starting from two nuclei is practically equal to the reaction cross section.
2. *Fission* – when the compound nucleus is heavy the fission process competes strongly with the evaporation of particles in each stage of the evaporation process. A very heavy compound nucleus with a large excitation energy has a very small probability of arriving to a cold residual nucleus without fission at some stage of the de-excitation. The role of the angular momentum l transmitted to the target nucleus is also essential. The fission barrier decreases with the increase of l and for a critical value l_{crit} the barrier ceases to exist. A nucleus with angular momentum greater than l_{crit} suffers immediate fission, and this is also a limiting factor in the production of superheavy elements.
3. *Deep inelastic collision (DIC)* – this is a phenomenon characteristic of reactions involving very heavy nuclei ($A > 40$) and with an incident energy of 1–3 MeV above the Coulomb barrier. In DIC, the projectile and the target spend some time under mutual action, exchanging masses and energy but without leading to the formation of a compound nucleus. The projectile escapes after transferring part of its energy and angular momentum to its internal degrees of freedom and to the

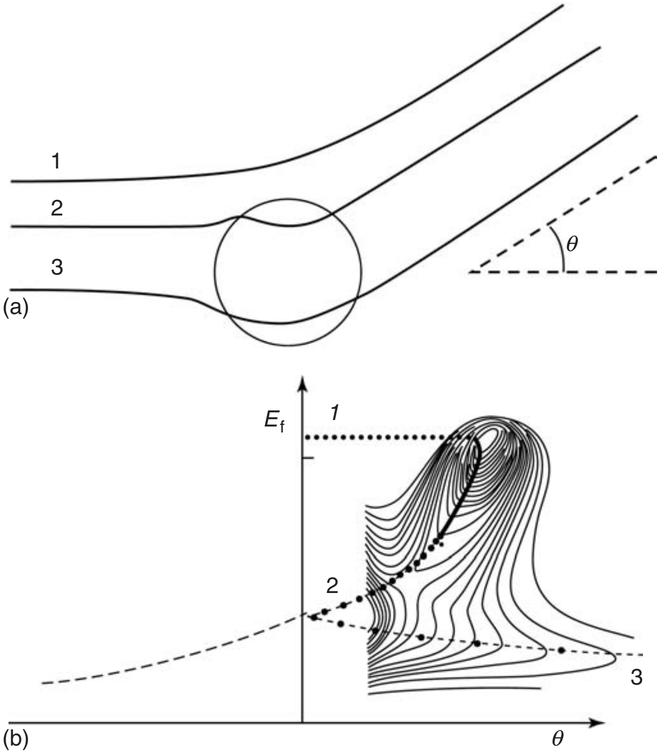

Figure 2.12 (a) Reactions with different impact parameters leading to the same scattering angle θ. (b) Lines of maxima in topographical diagrams of the final energy against the scattering angle.

target, with values reaching 100 MeV and 50ℏ.

One of the most interesting aspects of DIC is the correlation between the energy dissipated in the collision and the scattering angle in the CM. Let us look at Figure 2.12a. Trajectory 1 shows the projectile with an impact parameter that leads it out of the range of nuclear forces. The Coulomb scattering angle will become larger as the impact parameter decreases. In a graph as in Figure 2.12b, where one plots the final energy against the scattering angle, trajectories of type 1 are located in the upper branch, where there is no dissipation and the initial kinetic energy stays unaffected. This upper branch has a maximum value for the scattering angle. At a smaller impact parameter, the nuclear attractive force and, with that, the effects of dissipation of DIC begin to act. A given Coulomb scattering angle θ can also be reached by the combination of the nuclear and Coulomb forces. Only, now there is loss of energy and the events are located in branch 2 of Figure 2.12b. There still is no one-to-one correspondence between angle and energy because an infinite number of trajectories can lead to the same angle θ. Branch 2 should be understood as a line of maxima in a three-dimensional representation (called the *Wilczynski diagram*) where the axis perpendicular to the paper is proportional to the cross section $d^2\sigma/dEd\theta$. The same angle θ can also be obtained by trajectory 3, with a longer interaction time between the nuclei and a larger dissipation. As now the projectile is deflected toward the nucleus, the scattering angle would be formally $-\theta$ but, as there is no experimental distinction between θ and $-\theta$, these events appear as an independent ramification in the lower part of the diagram.

2.5.2
Superheavy Elements

The heaviest element found in Nature is $^{238}_{92}$U. It is radioactive, but it has survived since its formation in supernovae explosions because it has a decay half-life of the order of the age of the Earth. Elements with larger atomic number (transuranic) have shorter half-lives and have disappeared. They are created artificially through nuclear reactions using heavy elements as target. Initially, the projectiles used were light particles: protons, deuterons, α-particles and neutrons. The use of neutrons is justified because the β^--emission of the compound nucleus increases the value of Z and it was in this way [15] that the first transuranic element, neptunium, was obtained: $\text{n}+{}^{238}\text{U}\rightarrow{}^{239}\text{U}\rightarrow{}^{239}\text{Np}+\beta^-$.

Reactions with light particles can produce isotopes up to mendelevium ($Z = 101$), but it is not possible to go beyond that; the half-lives for α-emission or spontaneous fission become extremely short, making the preparation of a target impracticable. The alternative is to place a heavy element under the flux of very intense neutrons. This can be done using special reactors or using the remaining material of nuclear explosions. The elements einsteinium ($Z = 99$) and fermium ($Z = 100$) were discovered in this way in 1955 but the increasing competition of beta decay with alpha decay and with spontaneous fission prevents this method from being used for larger Z.Starting in 1955, heavy ion accelerators began to deliver beams with high enough intensity and energy to compete in the production of transuranic isotopes. The first positive result was the production of two californium isotopes ($Z = 98$) with the fusion of carbon and uranium nuclei:

$$\begin{aligned} {}^{12}_{6}\text{C} + {}^{238}_{92}\text{U} &\rightarrow {}^{244}_{98}\text{Cf} + 6\text{n}, \\ {}^{12}_{6}\text{C} + {}^{238}_{92}\text{U} &\rightarrow {}^{246}_{98}\text{Cf} + 4\text{n} \end{aligned} \tag{2.59}$$

This opened up the possibility of directly reaching the nucleus one wants to create from the fusion of two smaller nuclei. The difficulty of such task is that the cross sections for the production of heavy isotopes are extremely low. For example, the reaction ${}^{50}_{22}\text{Ti} + {}^{208}_{82}\text{Pb} \rightarrow {}^{257}_{104}\text{Rf} + \text{n}$, which produces the element rutherfordium, has a cross section of only 5 nb. A small increase in the charges drastically reduces this value. The cross section for the fusion reaction ${}^{58}_{26}\text{Fe} + {}^{208}_{82}\text{Pb} \rightarrow {}^{265}_{108}\text{Hs} + \text{n}$ is 4 pb. In comparison, the typical cross sections of DIC for heavy nuclei are in the range 1–2 b.

In spite of the experimental refinement that these low cross sections demand, one is able to produce isotopes with charge as heavy as $Z = 118$. The understanding of the mechanisms that lead to fusion is, however, not fully understood. According to the traditionally accepted model, the fusion of two nuclei proceeds in two stages: the formation of a compound nucleus and the de-excitation of the compound nucleus by evaporation of particles, preferentially neutrons. The difficulties for the materialization of the process in very heavy nuclei reside in both stages [16].

2.6
Electromagnetic Probes

2.6.1
Coulomb Excitation

Coulomb excitation is an inelastic scattering process in which a nucleus excites another nucleus with its electromagnetic field V. This field can be decomposed in terms of a series of multipoles, for example, $E1, E2, M1, \cdots$, which carry well-defined angular momenta and parities. At low bombarding energies, $E2$ (quadrupole) excitations are more common, while at higher energies, $E1$ (dipole) excitations dominate. The Coulomb excitation cross section in first-order perturbation theory is given by

$$\frac{d\sigma_{i\to f}}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{el}} \frac{16\pi^2 Z_2^2 e^2}{\hbar^2} \times \sum_{\pi\lambda\mu} \frac{B(\pi\lambda, I_i \to I_f)}{(2\lambda+1)^3} |S(\pi\lambda, \mu)|^2 \tag{2.60}$$

where $(d\sigma/d\Omega)_{\text{el}}$ is the Rutherford elastic scattering cross section, Z_2 is the charge of the projectile, $B(\pi\lambda, I_i \to I_f)$ is the *reduced matrix element* of the target, $\pi\lambda = E1, E2, M1, \ldots$ is the multipolarity of the excitation, and $\mu = -\lambda, -\lambda+1, \ldots, \lambda$. The orbital integrals $S(\pi\lambda, \mu)$ contain information on the dynamics of the reaction [17].

Because Coulomb excitation is an external process, that is, it occurs when the nucleons from one nucleus are outside the nuclear matter distribution from the other nucleus, the matrix elements for Coulomb excitation are the same as those for excitation by real photons (except for $E0$ Coulomb excitations, which are very small). Therefore, Coulomb excitation cross sections can be written as

$$\frac{d\sigma_C(E_x)}{dE_x} = \sum_{E\lambda} \frac{n_{E\lambda}(E_x)}{E_x} \sigma^{\gamma}_{E\lambda}(E_x) + \sum_{M\lambda} \frac{n_{M\lambda}(E_x)}{E_x} \sigma^{\gamma}_{M\lambda}(E_x) \tag{2.61}$$

where $\sigma^{\gamma}_{\pi\lambda}(E_x)$ are the *photonuclear cross sections* for the multipolarity $\pi\lambda$, E_x is the excitation energy, and $n_{M/E\lambda}(E_x)$ are known as *virtual photon numbers* [17].

The photonuclear cross sections are related to the reduced matrix elements, for the excitation energy E_x, through the relation [17]

$$\sigma_{\gamma}^{\pi\lambda}(E_x) = \frac{(2\pi)^3(\lambda+1)}{\lambda[(2\lambda+1)!!]^2} \left(\frac{E_x}{\hbar c}\right)^{2\lambda-1} \times \frac{dB(\pi\lambda, E_x)}{dE_x} \tag{2.62}$$

where dB/dE_x are the *electromagnetic response functions*, such that

$$B(\pi\lambda, I_i \to I_f) = \int dE_x \frac{dB(\pi\lambda, E_x)}{dE_x}$$

For differential cross sections, an analog expression exists, namely,

$$\frac{d\sigma_C(E_x)}{d\Omega} = \frac{1}{E_x} \sum_{\pi\lambda} \frac{dn_{\pi\lambda}}{d\Omega}(E_x, \theta) \sigma_{\gamma}^{\pi\lambda}(E_x) \tag{2.63}$$

where Ω denotes the solid scattering angle. This is not different from Eq. (2.60), only rewritten in a more practical way. It helps us to see how we can access information on phenomena induced by real photons by using the field of a charged particle.

In Figure 2.13, we show a calculation (with $E_\gamma \equiv E_x$) of the virtual photons for the $E1$ multipolarity, "as seen" by a projectile passing by a lead target at impact parameters equal to and exceeding $b = 12.3$ fm, for three typical bombarding energies. As the projectile energy increases,

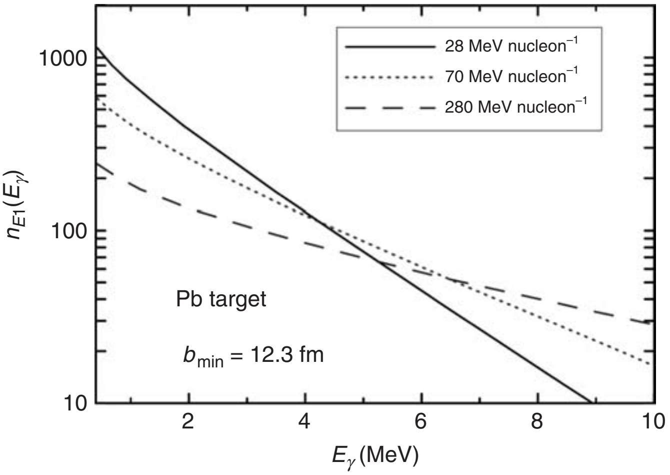

Figure 2.13 Number of virtual photons for the $E1$ multipolarity, "as seen" by a projectile passing by a lead target at impact parameters $b_{\min} = 12.3$ fm and larger, for three typical bombarding energies.

more virtual photons of large energy are available for the reaction. This increases the energy of states probed in the excitation process, making it possible to study giant resonances, lepton and meson production, and so on [17].

2.6.2
Photonuclear Reactions and Giant Resonances

A photonuclear reaction is a reaction resulting from the interaction of the electromagnetic radiation with a nucleus. Therefore, one can access information that are complementary to Coulomb excitation (and vice versa).

When the energy of the photon is located above the separation energy of a nucleon, the cross section of photoabsorption reveals the presence of characteristic sharp resonances. However, when the incident energy reaches the range of 15–25 MeV, a new change appears in the cross section, with the presence of a wide and large peak, called *giant electric dipole resonance* (GDR) ($E1$ excitation). Figure 2.14 exhibits the excitation function of photoabsorption of ^{120}Sn at photon energies around the GDR at 15 MeV.

The giant resonance occurs in nuclei along the whole periodic table, with the resonance energy decreasing as $E_{\text{GDR}}80/A^{1/3}$ for $A > 20$. Their widths are almost all in the range between 3.5 and 5 MeV. In few cases, they can reach 7 MeV. They are a collective excitation, that is, an excitation simultaneously involving many nucleons . The time-varying electric field of the photon is very effective in inducing collective oscillations of protons against neutrons.

The GDR resonance arises from an excitation that transfers by one unit of angular momentum to the nucleus ($\Delta l = 1$). If the nucleus is even–even it is taken to a 1^- state. The transition also changes the isospin of one unit ($\Delta T = 1$) and, so it is also called *isovector resonance*. The photon can excite giant isoscalar

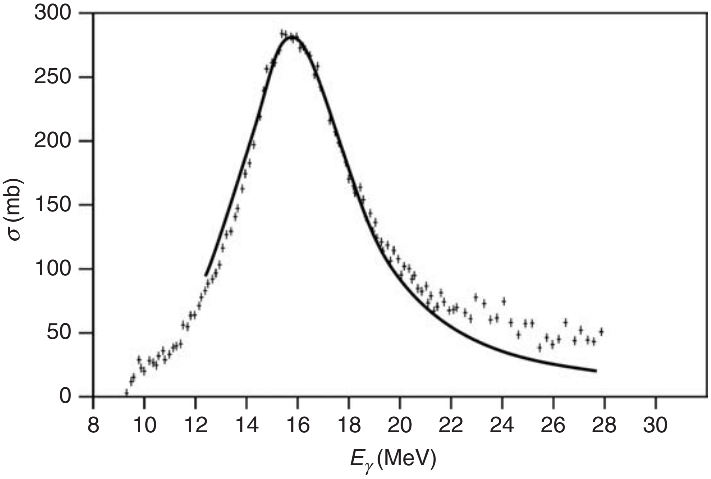

Figure 2.14 Giant resonance in the absorption of photons by ^{120}Sn [18].

resonances less effectively, but still with appreciable cross sections, with $\Delta T = 0$. But electric quadrupole ($\Delta l = 2$) and electric monopole ($\Delta l = 0$) are observed mostly in reactions with charged particles. In a giant electric quadrupole resonance, the nucleus oscillates between a spherical (assuming that this is the form of the ground state) and an ellipsoidal form. If protons and neutrons vibrate in phase, we have an isoscalar resonance ($\Delta T = 0$) and if they are oscillate in opposite phase we have an isovector resonance ($\Delta T = 1$). The giant monopole resonance is a very special case of nuclear excitation where the nucleus contracts and expands radially, maintaining its original form but changing its volume. It is also called *breathing mode*. It can also happen in isoscalar and isovector forms. It is an important way to study the *compressibility of nuclear matter*.

Besides electric giant resonances, associated with a variation in the form of the nucleus, magnetic giant resonances exist, which involve *spin vibrations*. In these, nucleons with spin up move out of phase with nucleons with spin down. The number of nucleons involved in the process cannot be very large because it is limited by the Pauli principle. The magnetic resonances can also separate into isoscalar resonances, where protons and neutrons of the same spin vibrate against protons and neutrons of opposite spin, and isovector, where protons with spin up and neutrons with spin down vibrate against their corresponding partners with opposite spins. The last cases are effectively probed in charge-exchange reactions, that is, when the projectile charge changes to $Z - 1$ or $Z + 1$, as in (d,p) and (d,n). They are known as *giant Gamow–Teller resonances*.

Giant resonances can also be produced in an excited nucleus, a case known as the *Brink–Axel hypothesis* [19]. A special case is when two giant resonances are excited simultaneously in the same nucleus. The double giant dipole resonance (or *multiphonon giant resonance* was observed for the first time in reactions with double charge exchange induced by pions in ^{32}S [20]. But Coulomb excitation proved to be the best probe, as shown theoretically in Refs [17, 21].

2.6.3
Electron Scattering

Electron scattering experiments have provided a rich database on most stable or long-lived nuclei. Electrons are structureless point-like objects that only interact electromagnetically. Therefore, electron scattering avoids the complexity of the strong interaction between the projectile and the target and provides clean information about the charge distribution in the nucleus.

Considering relativity and the spin of the electrons, the differential cross section for elastic scattering by spinless point-like nuclei can be expressed by the *Mott scattering formula* (for simplicity, we use $\hbar = c = 1$ units):

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{Mott}} = \frac{Z_T^2 e^4 \cos^2(\theta/2)}{4p_0^2 \sin^4(\theta/2)[1+(2p_0/M)\sin^2(\theta/2)]} \tag{2.64}$$

where Z_{T_e} and M are the charge and mass of the target nucleus, respectively, and p_0 is the momentum of the incoming electron. As the nucleus is not a point-like particle, the formula is modified by adding the nuclear electric and magnetic form factors, which contain information of the charge and magnetization distributions inside the nucleus.

The *Rosenbluth formula* accounts for the electron spin and explicitly expresses the cross section for arbitrary nuclei as

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right) = \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{Mott}} \Big\{A_0(q^2) + B_0(q^2) \times \left[\frac{1}{2} + \left(1 + \frac{q^2}{4M^2}\right)\right]\tan^2(\theta/2)\Big\}$$

where $q^2 = (\mathbf{p}_\mathrm{f} - \mathbf{p}_\mathrm{i})^2 - (E_\mathrm{f} - E_\mathrm{i})^2$ is the 4-momentum transfer squared, where $\mathbf{p}_\mathrm{i}(\mathbf{p}_\mathrm{f})$ and $E_\mathrm{i}(E_\mathrm{f})$ are the electron incoming (outgoing) momentum and energy. $A_0(q^2)$ and $B_0(q^2)$, functions of q^2, are the form factors associated with the charge and magnetization distribution of the nucleus, respectively. For a spin-0 nucleus,

$$A_0(q^2) = \frac{G_E^2(q^2)}{1 + q^2/4M^2} \quad \text{and} \quad B_0(q^2) = 0 \tag{2.65}$$

where $G_E(q^2)$ is the *Sachs charge form factor*, and the factor $1 + q^2/4M^2$ is the kinematical recoil correction. For $q \to 0, q^2 \approx \mathbf{q}^2$, where $\mathbf{q}$ is the three-momentum transfer, and to leading order in powers of $\mathbf{q}$:

$$G_E(q^2) \simeq G_E(\mathbf{q}^2) = \int \rho_T(\mathbf{r}) \mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{r}} \mathrm{d}^3 r \tag{2.66}$$

One thus sees that electron scattering is related to the Fourier transform of the nuclear charge density, $\rho_T(\mathbf{r})$. If the function $G_E(\mathbf{q}^2)$ is mapped for a sufficient number of momentum transfers $\mathbf{q}^2$, the Fourier transform can be inverted and $\rho_T(\mathbf{r})$ can be mapped with precision. For heavy elements ($A > 10$), this technique shows that the charge radius is closely proportional to 1.12 $A^{1/3}$ fm, where A is the nuclear mass number. This indicates the density saturation of the nuclear matter.

When $\mathbf{q}^2 = 0$, inelastic electron scattering probes the same multipolarity transitions ($E1, E2, \ldots$) as in Coulomb excitation or with real photons. However, in contrast to the later probes, electron scattering also provides information on nuclear excitations for cases in which $\mathbf{q}^2 \neq 0$. This is useful in many aspects. For example, at high momentum transfers, the momentum transfer $\mathbf{q}$ can be absorbed by a nucleon in the nucleus, which acquires an energy of the order of $\mathbf{q}^2/2m_N^*$, thus probing the effective mass m_N^* of a nucleon in the nucleus. This is of relevance to understand the effects of nucleon–nucleon interactions in the nuclear environment. The q-region where this occurs is termed *quasi-free scattering*. As electrons can penetrate the nuclei, they can also more effectively probe monopole (or breathing mode) excitations of the nuclei, a case in which the nuclear mass distribution vibrates radially. This is of importance for determining the *compressibility modulus* of the nuclear matter. Finally, in high-energy electron scattering, the electron can penetrate deep inside the nucleons and probe the spin and charge distributions of quarks and gluons inside the nucleon [22].

2.7
Relativistic Nuclear Collisions

2.7.1
Transport Theories and Equation of State

As the bombarding energy in nucleus–nucleus collisions increases, the structure aspects of the nuclei become less relevant. Except for the bulk properties of the nuclei (size and number of nucleons), the physics involved is primarily due to the individual, and sometimes collective, hadronic collisions. Several theoretical tools are used to describe these reactions, and, in particular, we quote (i) *time-dependent Hartree–Fock* (TDHF), (ii) *anti-symmetrized molecular dynamics* (AMD), (iii) *Boltzmann–Uehling–Uhlenbeck* (BUU), and so on.

At intermediate energies of $E_{\text{lab}} \sim 100 - 1000$ MeV nucleon^{-1}, the nucleons and the products of their collisions can be described individually and their propagation can be described by semiclassical equations. One of such equations, and perhaps the most popular in such studies, is the so-called *BUU equation*:

$$\begin{aligned}\frac{\partial f}{\partial t} + \left(\frac{\mathbf{p}}{m} + \nabla_{\mathbf{p}} U\right)\cdot\nabla_{\mathbf{r}} f - \nabla_{\mathbf{r}} U\cdot\nabla_{\mathbf{r}} f = \\ \int \mathrm{d}^3 p_2 \int \mathrm{d}\Omega\, \sigma_{\mathrm{NN}}(\Omega)|\mathbf{v}_1 - \mathbf{v}_2| \\ \times\left\{f_1' f_2' \left[1 - f_1\right]\left[1 - f_2\right] - f_1 f_2 \left[1 - f_1'\right] \right. \\ \left. \times \left[1 - f_2'\right]\right\}. \qquad (2.67)\end{aligned}$$

If dN is the number of particles in the volume element $\mathrm{d}^3 r$ and whose momenta fall in the momentum element $\mathrm{d}^3 p$ at time t, then the distribution function $f(\mathbf{r}, p, t)$ is given by $\mathrm{d}N = f(\mathbf{r}, p, t)\mathrm{d}^3 r \mathrm{d}^3 p$. Thus, the BUU equation is an equation for the distribution function $f(\mathbf{r}, p, t)$. To account for the effect of each particle interacting with all others, one introduces the concept of *mean-field*, $U(\mathbf{r}, p, t)$. This mean-field exerts a force on each particle, given by $-\nabla_{\mathbf{r}} U(\mathbf{r}, p, t)$. In addition, the momentum dependence of the potential introduces a dependence through the derivative $-\nabla_{\mathbf{p}} U(\mathbf{r}, p, t)$.

Owing to the nucleon–nucleon collisions, the distribution function within $\mathrm{d}^3 r \mathrm{d}^3 p$ can also be modified by nucleons leaving (or entering) this volume. This is taken care by of the *collision term*, that is, the right-hand side of the BUU equation. σ_{NN} is the nucleon–nucleon differential scattering cross section, $\mathbf{v}_1$ and $\mathbf{v}_2$ are the velocities of two colliding nucleons. The first factor inside braces are for collisions populating the volume element and the second term for those depleting it. The factors $(1 - f)$ account for Pauli blocking of final occupied states. The integrals average over scattering angle and over all collisions within $\mathrm{d}^3 r \mathrm{d}^3 p$. The BUU equation falls in the category of what one calls *quantum transport theories*. Hadronic transport theories have been quite successful in applications, describing a multitude of measured particle spectra.

Equation (2.67) needs as basic ingredients the mean-field U and the cross section σ_{NN}. Because these two quantities are related to each other, one should in principle derive them in a self-consistent microscopic approach, as in the *Brueckner theory*.

An important ingredient in the transport theory calculations is the compressibility K of nuclear matter, which refers to the second derivative of the compressional energy E with respect to the density [1]

$$K = 9\rho^2 \frac{\partial^2}{\partial \rho^2}\left(\frac{E}{A}\right) \tag{2.68}$$

This is an important quantity, for example, for nuclear astrophysics. Supernova models might or not lead to explosions depending on the value of K. The central collisions of heavy nuclei are one of the few probes of this quantity in the laboratory. The dependence of the calculations on K follow from the dependence of the mean-field potential U ($U \sim E/A +$ kinetic energy terms) on the particle density ρ. A typical parametrization for U is the Skyrme parametrization $U = a\rho/\rho_0 + b(\rho/\rho_0)^\sigma$.

The output of Eq. (2.67) is the distribution function% $f(\mathbf{r}, p, t)$, which allows one to calculate many properties of heavy ion collisions. Let us quote *collective flows*, proton and neutron production rates (subthreshold and above threshold), pion and kaon yields, and so on. Combining Eq. (2.67) with a *phase–space coalescence model*, one can also calculate such quantities as exclusive flows and intermediate fragment formations.

The dynamics of the central high-energy reactions can be broken down into several stages. Baryon-density contour plots are shown in Figure 2.15 for 400 MeV nucleon^{-1}Au + Au collisions at $b = 0$, which will serve to illustrate our points.

Following an initial interpenetration of projectile and target densities, the NN collisions begin to thermalize matter in the overlap region making the momentum distribution there centered at zero momentum in the CM. The density in the overlap region rises above normal and a disk of excited and compressed matter forms at the center of the system. More and more matter dives into the region with compressed matter that begins to expand in transverse directions. At late stages, when the whole matter is excited, transverse expansion predominates.

2.7.2
Kinematics

In relativistic nucleus–nucleus collisions, other definitions are best suited for discussing relations between energies, momenta, and angles. The *rapidity* is a variable frequently used to describe the behavior of particles in inclusively measured reactions. It is defined by

$$y = \frac{1}{2}\ln\left(\frac{E + p_{\parallel}}{E - p_{\parallel}}\right) \tag{2.69}$$

which corresponds to $\tanh y = p_{\parallel}/E$, where y is the rapidity, $p_{\parallel}$ is the longitudinal momentum along the direction of the incident particle, E is the energy, both defined for a given particle. The accessible range of rapidities for a given reaction is determined by the available CM energy and all participating particles' rest masses. One usually gives the limit for the incident particle, elastically scattered at zero angle:

$$|y_{\max}| = \ln\left[\frac{E + p}{m}\right] = \ln(\gamma + \gamma\beta) \tag{2.70}$$

---

[1] The factor of 9 is a historical artifact from the convention originally defining K.

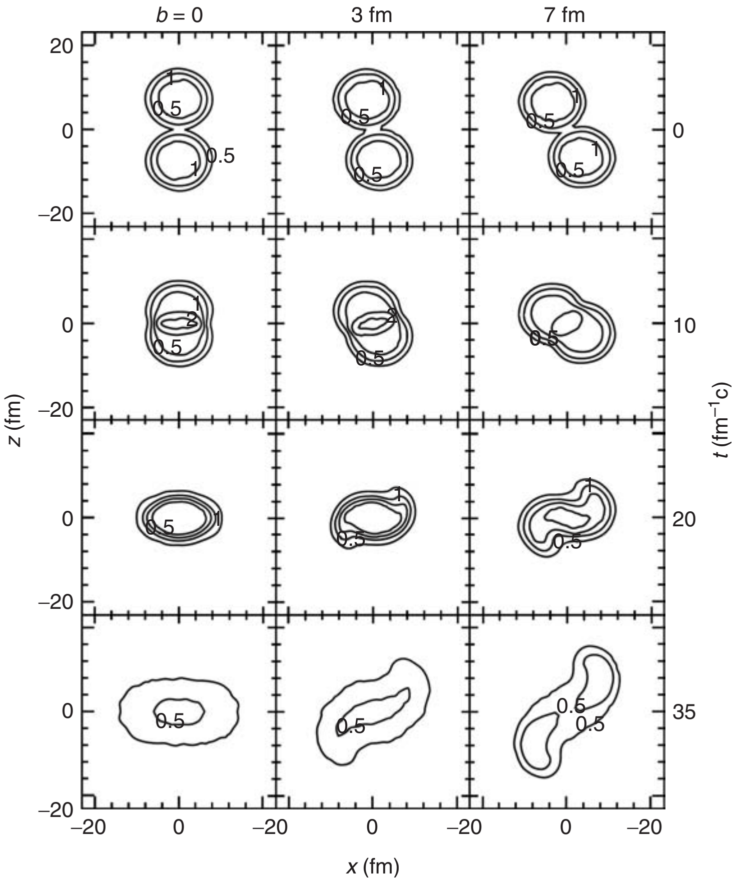

Figure 2.15 Contour plots of baryon density in the reaction plane in Au + Au collisions at 400 MeV nucleon^{-1}. The displayed contour lines are for the densities $\rho/\rho_0 = 0.1$, 0.5, 1, 1.5, and 2 [23].

where $\beta \equiv v$ is the velocity and all variables referring to the through-going particle given in the desired frame of reference (i.e., in the CM).

Note that $\partial y/\partial p_{\parallel} = 1/E$. A Lorentz boost β along the direction of the incident particle adds a constant, ln $(\gamma + \gamma\beta)$, to the rapidity. Rapidity differences, therefore, are invariant to a Lorentz boost. Statistical particle distributions are flat in y for many physics production models. Frequently, the simpler variable *pseudorapidity* η is used instead of rapidity.

The pseudorapidity is a handy variable to approximate the rapidity if the mass and momentum of a particle are not known. It is an angular variable defined by

$$\eta = -\ln\left[\tan\left(\frac{\theta}{2}\right)\right] \tag{2.71}$$

whose inverse function is $\theta = 2\arctan(e^{-\eta})$, where θ is the angle between the particle being considered and the undeflected beam. η is the same as the rapidity y if one sets $\beta = 1$ (or $m = 0$).

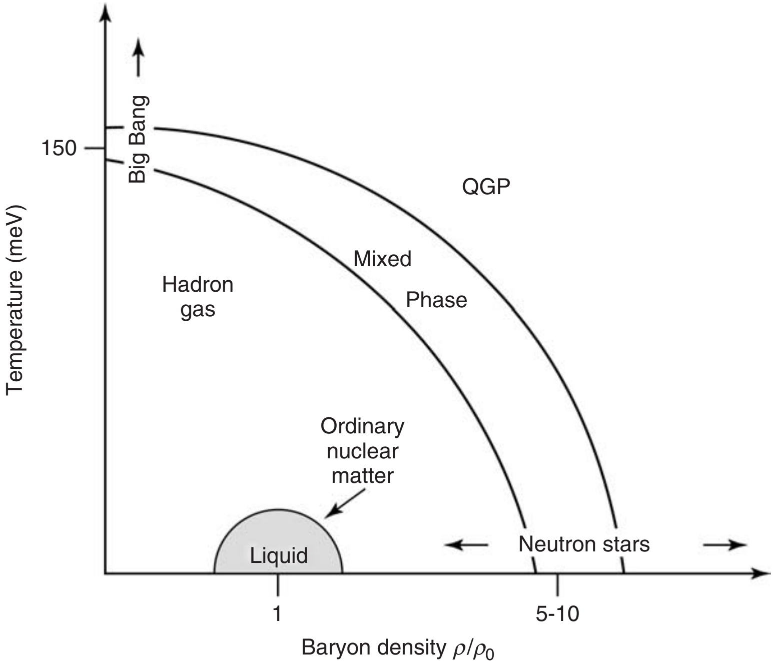

Figure 2.16 As water comes in different phases (solid, liquid, and gas), so nuclear matter can come in its normal hadronic form and at sufficiently high temperature and density, in the form of a deconfined state of quarks and gluons. The diagram shows how nuclear matter should behave as a function of density and temperature.

Statistical distributions plotted in pseudorapidity rather than rapidity undergo transformations that have to be estimated by using a kinematic model for the interaction.

2.7.3
The Quark–Gluon Plasma (QGP)

The primary motivation for studying ultra-relativistic heavy ion collisions is to gain an understanding of the equation of state of nuclear, hadronic, and partonic matter, commonly referred to as *nuclear matter*. Displayed in Figure 2.16 is a schematic phase diagram of nuclear matter. The behavior of nuclear matter as a function of temperature and density (or pressure), shown in Figure 2.16, is governed by its equation of state.

Conventional nuclear physics is concerned primarily with the lower left portion of the diagram at low temperatures and near normal nuclear matter density. Here normal nuclei exist and at low excitation, a liquid–gas phase transition is expected to occur. This is the focus of experimental studies using low-energy heavy ions. At somewhat higher excitation, nucleons are excited into baryonic resonance states, along with accompanying particle production and hadronic resonance formation. In relativistic heavy ion collisions, such excitation is expected to create hadronic resonance matter.

We now briefly discuss the QGP signatures in nucleus–nucleus collisions. For more details see, for example, Refs [24, 25]. One group of such signatures can be classified as *thermodynamic variables*. This class involves determination of the energy density ϵ, pressure P, and entropy density s of the interacting system as a function of the temperature T and the baryochemical potential μ_B. Experimental observables can be identified with these variables and thus their relative behavior can be determined. If a phase transition to QGP occurs, a rapid rise in the effective number of degrees of freedom, expressed by $/T^4$ or s/T^3, should be observed over a small range of T. The variables T, s, and can be identified with the average transverse momentum p_T, the hadron rapidity density $\mathrm{d}N/\mathrm{d}y$, and the transverse energy density $\mathrm{d}E_T/\mathrm{d}y$, respectively. The transverse energy produced in the interaction is $E_T = \sum_i E_i \sin\theta_i$, where E_i and θ_i are the kinetic energies of the ejectiles and the emission angles.

Electromagnetic (EM) probes, such as photons and leptons, provide information on the various stages of the interaction without modification by final state interactions. These probes may provide a measure of the thermal radiation from a QGP, if a region of photon energy, or equivalently lepton pair invariant mass, can be isolated for emission from a QGP relative to other processes. However, the yields for EM probes are small relative to background processes, which are primarily EM decays of hadrons and resonances. Lepton pairs from the QGP are expected to be identifiable in the 1–10 GeV invariant mass range. The widths and positions of the ρ, ω, and ϕ peaks in the lepton pair invariant mass spectrum are expected to be sensitive to medium-induced changes of the hadronic mass spectrum.

The production of J/Ψ particles in a quark–gluon plasma is predicted to be suppressed (Figure 2.17). This is a result of the *Debye screening* of a $c\bar{c}$ pair, initially formed in the QGP by fusion of two incident gluons. Less tightly bound excited states of the $c\bar{c}$ system, such as Ψ' and χ_c, are more easily dissociated and will be suppressed even more than the J/Ψ.

A long-standing prediction for a signature of QGP formation is the enhancement of strange hadrons. The production of strange hadrons relative to nonstrange hadrons is suppressed in hadronic reactions. This suppression increases with increasing strangeness content of the hadron. In a QGP, the strange quark content is rapidly saturated by $s\bar{s}$ pair production in gluon–gluon reactions, resulting in an enhancement in the production of strange hadrons. Thus, multistrange baryons and strange antibaryons are predicted to be strongly enhanced when a QGP is formed.

The connection between energy loss of a quark and the color-dielectric polarizability of the medium can be established in analogy with the theory of electromagnetic energy loss. Although radiation is a very efficient energy loss mechanism for relativistic particles, it is strongly suppressed in a dense medium by the *Landau–Pomeranchuk effect* [24]. Adding the two contributions, the stopping power of a quark–gluon plasma is predicted to be higher than that of hadronic matter. A quark or *gluon jet* propagating through a dense medium will not only lose energy but will also be deflected. This effect destroys the coplanarity of the two jets from a hard parton–parton scattering with the incident beam axis. The angular deflection of the jets also results in an azimuthal asymmetry. The presence of a quark–gluon plasma is

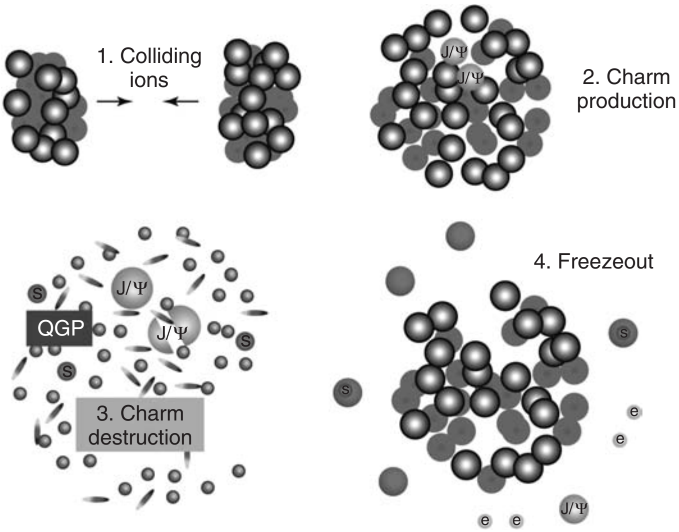

Figure 2.17 Formation and evolution of J/Ψ particles in relativistic heavy ion collisions. After the formation, the J/Ψs are dissociated in the plasma owing to color screening. The end effect is a smaller number J/Ψs than expected from pure hadron–hadron multiple collisions.

also predicted to attenuate the emission of jet pairs opposite to the trigger jet.

All the above quark–gluon plasma signatures have been studied to maturity at the CERN (European Organization for Nuclear Research) – Large Hadron Collider (LHC) and Super Proton Synchrotron (SPS) and the Brookhaven National Laboratory (BNL) – Relativistic Heavy Ion Collider (RHIC) heavy ion accelerator facilities. For more details, the following references discuss: (i) direct photons [26, 27], (ii) dileptons [28], (iii) J/Ψ production [29], and (iv) quark in-medium attenuation, also known as *highp$_T$ quenching* or *jet attenuation* [30].

2.7.4
Ultraperipheral Relativistic Heavy Ion Collisions

Relativistic heavy ion collisions have also been used to study nuclear photoexcitation and photoproduction of hadrons. The strong electromagnetic fields from a heavy ion allow for the study of multiphoton excitation of nuclear targets, for example, the double-giant resonance [17, 21]. Reactions such as multiple vector meson production can be used for studies involving polarized photons [17]. The high photon energies can be used to study the gluon density in heavy nuclei [31] at low Feynman x.

Photon–photon (or two-photon) processes have long been studied at e^+e^- colliders. They are an excellent tool for many aspects of meson spectroscopy and tests of QED [32]. At hadron colliders, they are also used to study atomic physics processes, often involving electrodynamics in strong fields. One striking success was the production of antihydrogen atoms at CERN's LEAR2 [33] and at the Fermilab Tevatron [34]. At the highest energy colliders, reactions such as $\gamma\gamma \to X$ may be used to probe the quark content and spin structure of meson resonances [17]. Production of meson or baryon pairs can also probe the internal structure of hadrons. At the LHC, electroweak processes such as $\gamma\gamma \to W^+W^-$ may be probed. The cross section for two-photon processes is, in analogy to Eq. (2.61), as follows [17]:

$$\sigma = \int \mathrm{d}E_1 \mathrm{d}E_2 \frac{n_1(E_1)}{E_2} \frac{n_1(E_2)}{E_2} \sigma_{\gamma\gamma\to X}(E_1, E_2) \tag{2.72}$$

where $n_i(E_i)$ is the number of virtual photons of energy E_i generated by the ion i, and $\sigma_{\gamma\gamma\to X}(E_1, E_2)$ is the cross sections for production of particle X by two real photons with energies E_1 and E_2.

2.8
Nuclear Reactions in Stars

2.8.1
Hydrogen and CNO Cycles

Energy production in stars is a well-known process. The initial energy that ignites the process arises from the gravitational contraction of a mass of gas. The contraction increases the pressure, temperature, and density, at the center of the star until the values are reached at which the thermonuclear reactions start, initiating the star's lifetime. The energy liberated in these reactions yield a pressure in the plasma, which opposes compression due to gravitation. Thus, an equilibrium is reached for the energy which is produced, the energy which is liberated by radiation, the temperature, and the pressure.

The Sun is a star in its initial phase of evolution. The temperature at its surface is 6000 °C, while in its interior the temperature reaches 1.5×10^7K, with a pressure given by 6×10^{11} atm and density 150g cm^{-3}. The present mass of the Sun is $M_\odot = 2 \times 10^{33}$g and its main composition is hydrogen (70%), helium (29%), and less than 1% of heavier elements, such as carbon, oxygen, and so on.

What are the nuclear processes that originate the huge thermonuclear energy of the Sun, and that have lasted 4.6×10^9 years (the assumed age of the Sun)? It cannot be the simple fusion of two protons, or of α-particles, or even the fusion of protons with α-particles, since neither $^2_2$He,$^8_4$Be, or $^5_3$Li, are stable. The only possibility is the proton–proton fusion in the form

$$\mathrm{p} + \mathrm{p} \to \mathrm{d} + \mathrm{e}^+ + \nu_e \tag{2.73}$$

which occurs via β-decay, that is, due to the weak interaction. The cross section for this reaction for protons of energy around 1 MeV is very small, of the order of 10^{-23} b. The average lifetime of protons in the Sun due to the transformation to deuterons by means of Eq. (2.73) is about 10^{10}y. This explains why the energy radiated from the Sun is approximately constant in time, and not an explosive process.

The deuteron produced in the above reaction is consumed almost immediately in the process

$$\mathrm{d} + \mathrm{p} \to {}^3_2\mathrm{He} + \gamma \tag{2.74}$$

The resulting $^3_2$He reacts by means of

$${}^3_2\mathrm{He} + {}^3_2\mathrm{He} \to {}^4_2\mathrm{He} + 2\mathrm{p} \tag{2.75}$$

which produces the stable nucleus $^4_2$He with a great energy gain, or by means of the reaction

$${}^3_2\mathrm{He} + {}^4_2\mathrm{He} \to {}^7_4\mathrm{Be} + \gamma \tag{2.76}$$

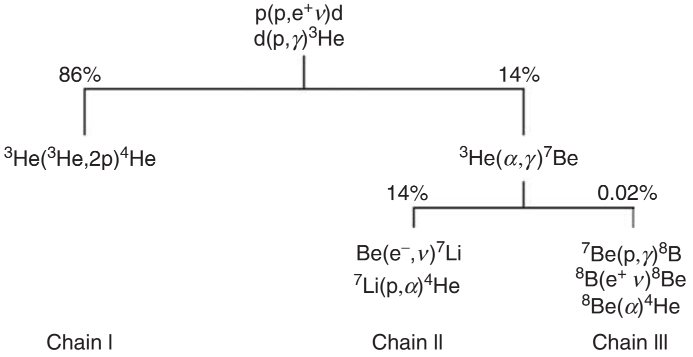

Figure 2.18 The p–p chain reaction (p–p cycle). The percentage for the several branches are calculated in the center of the Sun [35].

In the second case, a chain reaction follows as

$$ {}^7_4\mathrm{Be} + \mathrm{e}^- \to {}^7_3\mathrm{Li} + \nu_e, \quad {}^7_3\mathrm{Li} + \mathrm{p} \to 2({}^4_2\mathrm{He}) \tag{2.77}$$

or

$$\begin{gathered} {}^7_4\mathrm{Be} + \mathrm{p} \to {}^8_5\mathrm{B} + \gamma, \\ {}^8_5\mathrm{B} \to 2({}^4_2\mathrm{He}) + \mathrm{e}^+ + \nu_e \end{gathered} \tag{2.78}$$

The chain reaction (2.73)–(2.78) is called the *hydrogen cycle*. The result of this cycle is the transformation of four protons into an α-particle, with an energy gain of 26.7 MeV, about 20% of which are carried away by the neutrinos (Figure 2.18).

If the star contains heavier elements, another cycle can occur – the *carbon cycle* or *CNO cycle* [36]. In this cycle, the carbon, oxygen, and nitrogen nuclei are catalyzers of nuclear processes, with the end product also in the form $4\mathrm{p} \to {}^4_2$ He. Figure 2.19 describes the CNO cycle. Owing to the larger Coulomb repulsion between the carbon nuclei, it occurs at higher temperatures (larger relative energy between the participant nuclei), up to 1.4×10^7K. In the Sun, the hydrogen cycle prevails. However, in stars with larger temperatures, the CNO cycle is more effective.

After the protons are transformed into helium at the center of a star like our Sun, the fusion reactions start to consume protons at the surface of the star. At this stage, the star starts to become a *red giant*. The energy generated by fusion increases the temperature and expands the surface of the star. The star's luminosity increases. The red giant contracts again after the hydrogen fuel is burned.

Other thermonuclear processes start. The first is the helium burning when the temperature reaches 10^8K and the density becomes 10^6g cm^{-3}. Helium burning starts with the triple-capture reaction

$$3({}^4_2\mathrm{He}) \to {}^{12}_6\mathrm{C} + 7.65\mathrm{MeV} \tag{2.79}$$

followed by the formation of oxygen via the reaction

$${}^{12}_6\mathrm{C} + {}^4_2\mathrm{He} \to {}^{16}_8\mathrm{O} + \gamma \tag{2.80}$$

For a star with the mass of the Sun, helium burning occurs in about 10^7y. For a much heavier star, the temperature can reach 10^9K. The compression process followed by the burning of heavier elements

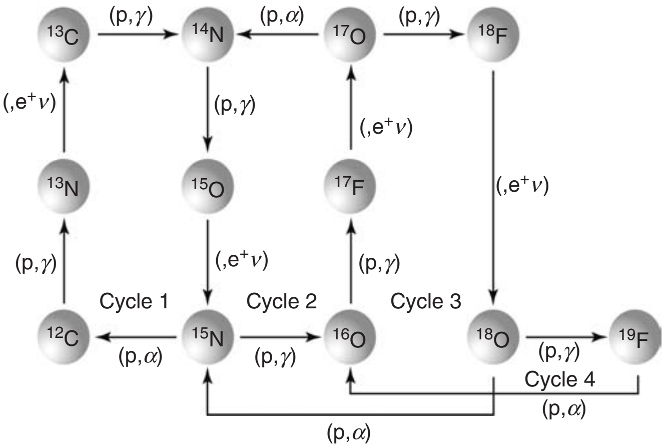

Figure 2.19 The CNO cycle. (Courtesy of Frank Timmes.)

can lead to the formation of iron and nickel. After that, the thermonuclear reactions are no more energetic and the star stops producing nuclear energy.

2.8.2
Synthesis of Heavier Elements

In Figure 2.20, we show the relative distribution of elements in our galaxy. It has two distinct regions: in the region $A < 100$ it decreases with A approximately like an exponential, whereas for $A > 100$ it is approximately constant, except for the peaks in the region of the magic numbers $Z = 50$ and $N = 50, 82, 126$.

The thermonuclear processes (2.73)–(2.80) can explain the relative abundance of $^4_2$He, $^{12}_6$C, and $^{16}_8$O. The processes occurring after $^4_2$He burning mainly form isotopes of $^{20}_{10}$Ne, $^{24}_{12}$Mg, and $^{28}_{14}$Si. We can understand the small abundance of the elements Li, Be, and B as due to the small velocity with which they are formed via the reaction (2.76) and the first equation of (2.77), while they are rapidly consumed by the second reaction in (2.77) and the first reaction in (2.78).

The synthesis of elements heavier than oxygen occur when, after helium burning, a new compression and heating of the star raises the temperature to values higher than 6×10^8K. This situation ignites an intense carbon burning:

$$\begin{aligned} {}^{12}_{6}\mathrm{C} + {}^{12}_{6}\mathrm{C} &\rightarrow {}^{20}_{10}\mathrm{Ne} + {}^{4}_{2}\mathrm{He} \rightarrow {}^{23}_{11}\mathrm{Na} + \mathrm{p} \\ &\rightarrow {}^{23}_{12}\mathrm{Mg} + \mathrm{n} \rightarrow {}^{24}_{12}\mathrm{Mg} + \gamma \end{aligned} \tag{2.81}$$

Carbon and oxygen can also burn simultaneously:

$$\begin{aligned} {}^{12}_{6}\mathrm{C} + {}^{16}_{8}\mathrm{O} &\rightarrow {}^{24}_{12}\mathrm{Mg} + {}^{4}_{2}\mathrm{He}, \text{etc.}, \\ {}^{16}_{8}\mathrm{O} + {}^{16}_{8}\mathrm{O} &\rightarrow {}^{28}_{14}\mathrm{Si} + {}^{4}_{2}\mathrm{He}, \text{etc.} \end{aligned} \tag{2.82}$$

For temperatures above 3×10^9K, more photonuclear processes appear. These yield more nuclei to be burned and heavier nuclei are produced:

$$\begin{aligned} \gamma + {}^{28}_{14}\mathrm{Si} &\rightarrow {}^{24}_{12}\mathrm{Mg} + {}^{4}_{2}\mathrm{He}, \\ {}^{4}_{2}\mathrm{He} + {}^{28}_{14}\mathrm{O} &\rightarrow {}^{32}_{16}\mathrm{S} + \gamma, \text{etc.} \end{aligned} \tag{2.83}$$

Owing to the large number of free neutrons, many (n, γ)-reactions (radiative neutron capture) elements in the mass range $A = 28, \ldots, 57$ are formed. This

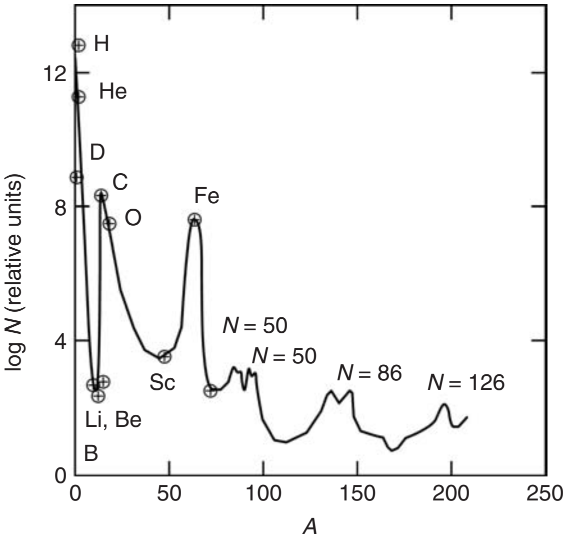

Figure 2.20 Relative distribution of elements in our galaxy.

leads to a large abundance of elements in the iron mass region, which have the largest binding energy per nucleon. For elements heavier than iron, the nuclear fusion processes do not generate energy.

For $A > 100$, the distribution of nuclei cannot be explained in terms of fusion reactions with charged particles. They are formed by the successive capture of slow neutrons and of β^--decay. The maxima of the element distribution in $N = 50, 82, 126$ are due to the small capture cross sections corresponding to the magic numbers. This yields a slew of isotopes at the observed element distribution.

2.8.3
Thermonuclear Cross Sections

The nuclear cross section for a reaction between target j and projectile k is defined by

$$\sigma = \frac{\text{number of reactions (target}^{-1}s^{-1})}{\text{flux of incoming projectiles}} = \frac{r/n_j}{n_k v} \tag{2.84}$$

where the target number density is given by n_j, the projectile number density is given by n_k , and v is the relative velocity between target and projectile nuclei. Then r, the number of reactions per cubic centimeter per second, can be expressed as $r = \sigma v n_j n_k$, or, more generally,

$$r_{j,k} = \int \sigma |v_j - v_k| \mathrm{d}^3 n_j \mathrm{d}^3 n_k \tag{2.85}$$

The evaluation of this integral depends on the type of particles and distributions that are involved. For nuclei j and k in an astrophysical plasma, obeying an MB distribution,

$$\mathrm{d}^3 n_j = n_j \left(\frac{m_j}{2\pi kT}\right)^{\frac{3}{2}} \exp\left(-\frac{m_j v_j^2}{2kT}\right) \mathrm{d}^3 v_j \tag{2.86}$$

Eq. (2.85) simplifies to $r_{j,k} =< \sigma v > n_j n_k$, where $< \sigma v >$ is the average of σv over the temperature distribution in Eq. (2.86).

In astrophysical plasmas with high densities and/or low temperatures, effects of electron screening become highly important. This means that the reacting nuclei, due to the background of electrons and nuclei, feel a different Coulomb repulsion than in the case of bare nuclei. Under most conditions (with nonvanishing temperatures), the generalized reaction rate integral can be separated into the traditional expression without screening and a screening factor

$$< \sigma v >^*_{j,k} = f_{\text{scr}}(Z_j, Z_k, \rho, T, Y_i) < \sigma v >_{j,k} \tag{2.87}$$

This screening factor is dependent on the charge of the involved particles, the density, temperature, and the composition of the plasma. Here Y_i denotes the abundance of nucleus i defined by $Y_i = n_i/(\rho N_A)$, where n_i is the number density of nuclei per unit volume and N_A Avogadro's number. At high densities and low temperatures, screening factors can enhance reactions by many orders of magnitude and lead to pycnonuclear ignition.

When in Eq. (2.85), particle k is a photon, the relative velocity is always c and quantities in the integral are not dependent on $d^3 n_j$. Thus, it simplifies to $r_j = \lambda_{j,\gamma} n_j$ and $\lambda_{j,\gamma}$ results from an integration of the photodisintegration cross section over a Planck distribution for photons of temperature T

$$r_j = \frac{1}{\pi^2 (c\hbar)^3} \int d^3 n_j \times \int_0^\infty \frac{c\sigma(E_\gamma) E_\gamma^2}{\exp(E_\gamma/kT) - 1} dE_\gamma \tag{2.88}$$

There is, however, no direct need to evaluate photodisintegration cross sections, because, due to detailed balance, they can be expressed by the capture cross sections for the inverse reaction $l + m \to j + \gamma$.

A procedure similar to Eq. (2.88) is used for electron captures by nuclei. Because the electron is about 2000 times less massive than a nucleon, the velocity of the nucleus j is negligible in the CM system in comparison to the electron velocity ($|v_j - v_e| \approx |v_e|$). The electron capture cross section has to be integrated over a Boltzmann, partially degenerate, or Fermi distribution of electrons, depending on the astrophysical conditions. The electron capture rates are a function of T and $n_e = Y_e \rho N_A$, the electron number density [37]. In a neutral, completely ionized plasma, the electron abundance is equal to the total proton abundance in nuclei $Y_e = \sum_i Z_i Y_i$ and $r_j = \lambda_{j,e}(T, \rho Y_e) n_j$.

This treatment can be generalized for the capture of positrons, which are in a thermal equilibrium with photons, electrons, and nuclei. At high densities ($\rho > 10^{12}$ g cm^{-3}), the size of the neutrino scattering cross section on nuclei and electrons ensures that enough scattering events occur to thermalize a neutrino distribution. The inverse process to electron capture (neutrino capture) can occur even then and the neutrino capture rate can be expressed similarly to Eq. (2.88), integrating over the neutrino distribution. Also inelastic neutrino scattering on nuclei can be expressed in this form. Finally, for normal decays, like β or α decays with half-life $\tau_{1/2}$, we obtain an equation similar to Eq. (2.88) or r_j of the previous paragraph with a decay constant $\lambda_j = \ln 2/\tau_{1/2}$ and $r_j = \lambda_j n_j$.

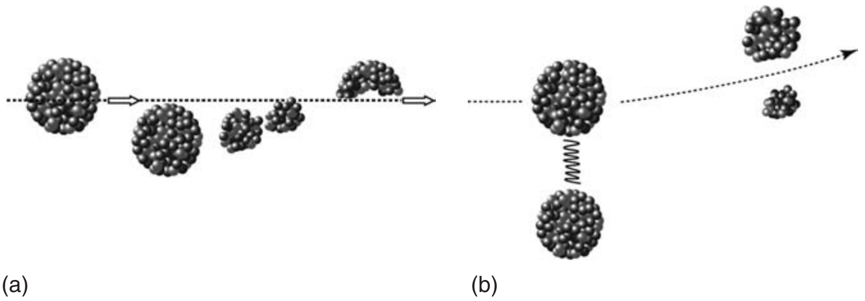
2.9
Reactions with Radioactive Nuclear Beams

The basic research activity in nuclear physics, driven by the desire to understand the forces that dictate the properties of nuclei, has spawned a large number of beneficial applications. Among its many progeny, we can count reactor- and spallation-based neutron sources, synchrotron radiation sources, particle physics, materials modification by implantation, carbon dating, and much more. It is an excellent example of the return to society of investment in basic research.

All these achievements have been realized by accelerating the 283 stable or long-lived nuclear species we find here on Earth. In recent years, however, it has become evident that it is now technically possible to create and accelerate unstable nuclei and that there are some 6000–7000 distinct nuclear species which live long enough to be candidates for acceleration. They are the nuclei within the so-called *drip-lines*, the point where the nucleus can no longer hold another particle. This has led to many new opportunities in industry, medicine, materials studies, and the environment.

Assume that a highly energetic uranium projectile ($N/Z \sim 1.6$) hits a target nucleus in an almost central collision, as shown in Figure 2.21. A part of the projectile (*participant*) is scrapped off and forms a highly excited mixture of nucleons with a part of the target. A piece of the projectile (*spectator*) flies away with nearly the same velocity as that of the beam. The neutron-to-proton ratio of the spectator is nearly equal to that of the projectile. Since the N/Z ratio of light nuclei (stable) is close to one, the fragment is far from the stability line. Statistically, a large number of fragments with different N/Z ratios are created and several new exotic nuclei have been discovered in this way. These nuclei can be collected in a secondary beam and further accelerated; they can induce reactions with a target nucleus. This method has become an important tool to study the properties of short-lived isotopes.

Experiments with secondary beams are limited by reaction cross section and *luminosity*. The luminosity L is defined as the product of beam intensity i and target thickness $t, L = i \times t$. The reaction rate N is the product of luminosity and reaction cross section $\sigma_r, N = \sigma_r \times L$. In most of the reactions, the usable target thickness is limited by the width of the excitation function (i.e., the cross section as a function of the excitation energy). Production reactions with a wide excitation function covering a broad energy range can profit in luminosity by the use of thick targets.



(a) (b)

Figure 2.21 (a) Schematic description of a nuclear fragmentation reaction producing rare isotopes. The lower fragments are called *participants*, while the upper one is called the *spectator*. Using uranium projectiles ($N/Z \sim 1.6$), one expects to produce (light) spectator nuclei of about the same N/Z ratio. (b) Coulomb fission of relativistic projectiles leading to the production of rare isotopes. For a heavy unstable projectile, an exchanged photon with the target can give it enough energy to fragment into several types of isotopes.

The condition for fragmentation of heavy ions is that the projectile should move faster than nucleons move inside the nucleus. The projectile energy should be sufficiently above the Fermi domain, for example, above 100 A MeV. The usable target thickness for these high energies is of the order of several grams per square centimeter, corresponding to 10^{23} atoms cm^{-2}. The excitation function for complete fusion of heavy ions, however, has a width of only 10 MeV. This corresponds to a usable target thickness of the order of 1 mg cm^{-2} or 10^{18}atoms cm^{-2}. Consequently, beam intensities for the investigation of complete fusion reactions must be by 4–5 orders higher to achieve the same luminosity as for fragmentation.

Figure 2.22 shows an example of the production cross sections for tin isotopes from complete fusion (dotted line), nuclear fragmentation (solid line), and Coulomb fission of ^{238}U (dashed line). The symbols represent experimental data. The fragmentation cross sections (solid line) have been calculated with a semiempirical code [Sue00].

The first experiments with unstable nuclear beams were designed to measure the nuclear sizes, namely, the matter distribution of protons and neutrons. For stable nuclei, such experiments are best accomplished with electron beams, which probe the nuclear charge (proton) distribution. Electron scattering experiments with unstable beams can only be performed in an electron–nucleus collider. However, the easiest solution is to measure the *reaction cross section* in collisions of unstable beams with a fixed target nucleus [38].

The reaction cross section in high-energy collisions is given by

$$\sigma_R = 2\pi \int [1 - T(b)] b db \qquad (2.89)$$

where

$$T(b) = \exp\left\{-\sigma_{\mathrm{NN}} \int_{-\infty}^{\infty} \mathrm{d}z \times \int \rho_P(\mathbf{r})\rho_T(\mathbf{R}+\mathbf{r})\,\mathrm{d}^3r\right\} \qquad (2.90)$$

with $\mathbf{R} = (\mathbf{b}, z)$. σ_{NN} is the nucleon–nucleon cross section at the corresponding bombarding energy,

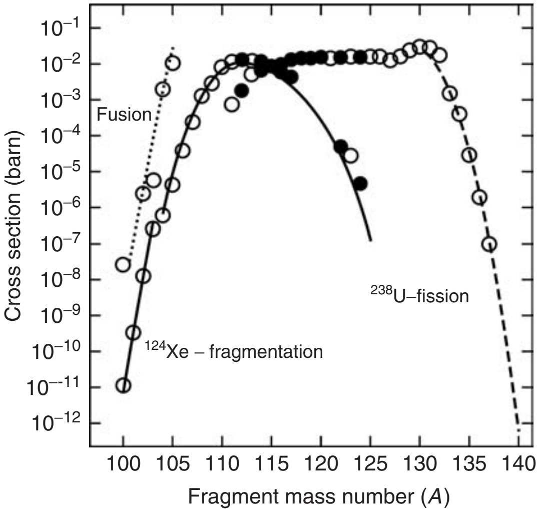


Figure 2.22 Production cross sections for the tin isotopes from complete fusion (dotted line), fragmentation (solid line), and projectile fission of ^{238}U (dashed line). The symbols represent experimental data. The fragmentation cross sections (solid line) have been calculated with a semiempirical code.

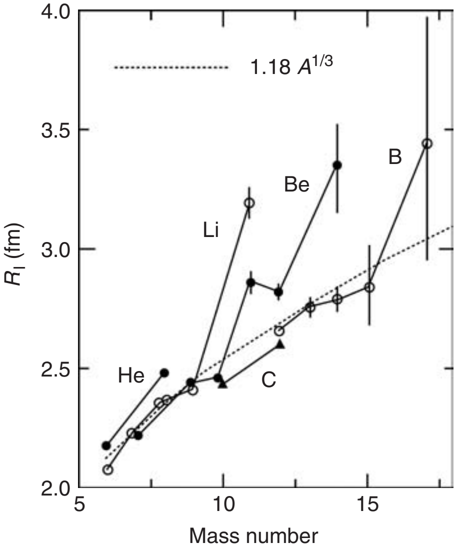

Figure 2.23 The matter density radii of several light nuclei compared to the trend $R \sim 1.18\ A^{1/3}$ fm (dashed line) for normal nuclei. The solid lines are guides to the eyes.

and $\rho_{P(T)}$ is the projectile (target) matter density distribution. $T(b)$ is known as the *transparency function* or *survival probability*. The factor $1 - T(b)$ is the probability that a reaction occurs for a collision with impact parameter b. The factor $\left[\sigma_{\mathrm{NN}} \int \rho_P \rho_T \mathrm{d}^3 r\right]^{-1}$ is interpreted as the mean free path for a nucleon–nucleon collision. The reaction cross sections can be calculated using the matter distributions of the target in Eq. (2.16).

Experimentally, a significant increase in the root mean square radii for the neutron-rich isotopes ^{6}He,^{8}He, and ^{11}Li (Figure 2.23) was observed. Thus, the addition of the neutrons to ^{4}He and ^{9}Li nuclei increase their radii considerably. This can be understood in terms of the binding energy of the outer nucleons. The large matter radii of these nuclei have lead the experimentalists to call them "*halo nuclei*." The binding energy of the last two neutrons in ^{11}Li is about 300 keV. In ^{6}He, it is 0.97 MeV. These are very small values and should be compared with $S_n =$ 6–8 MeV, which is the average binding of nucleons in stable nuclei. Abnormally large radii were also found for other light neutron-rich nuclei.

The matter density radii of these nuclei do not follow the observed trend $R \sim 1.18\ A^{1/3}$ fm of normal nuclei. Thus, the halo seems to be a common feature of loosely bound neutron-rich nuclei.

Several other methods have been devised to probe the structure of nuclei far from the valley of stability. Among these are (i) Coulomb dissociation [39], (ii) Trojan horse method [40], (iii) asymptotic normalization coefficients [41], (iv) heavy ion charge exchange [42], (v) knockout [43], and (vi) fusion reactions [44]. These methods yield different insights into the structure of exotic nuclei and comprise most of the experiments in radioactive beam facilities [45].

Reactions producing rare nuclear isotopes have opened a new research front in nuclear physics with applications in many areas of science: the rapid production of short-lived nuclei, many of which are poorly known, is important for astrophysics (r-process) and cosmology; nuclear medicine benefits from studies of new nuclear isotopes; and the list goes on.

However, the basic question still remains: what combinations of neutrons and protons can make up a nucleus? The experimental detection of new nuclear isotopes is an ongoing research that will ultimately lead to new insight and development of nuclear science, with enormous profit for mankind [46].

1.1
Introduction

The study of nuclear structure today encompasses a vast territory from the study of simple, few-particle systems to systems with close to 300 particles, from stable nuclei to the short-lived exotic nuclei, from ground-state properties to excitations of such energy that the nucleus disintegrates into substructures and individual constituents, from the strong force that hold the atomic nucleus together to the effective interactions that describe the collective behavior observed in many heavy nuclei.

After the discovery of different kinds of radioactive decays, the discovery of the structure of the atomic nucleus begins with the fundamental paper by Ernest Rutherford [1], in which he explained the large-angle alpha (α)-particle scattering from gold that had been discovered earlier by Hans W. Geiger and Ernest Marsden. Indeed, Rutherford shows that the atom holds in its center a very tiny, positively charged nucleus that contains 99.98% of the atomic mass. In 1914, Henry Moseley [2, 3] showed that the nuclear charge number Z equaled the atomic number. Using the first mass separators, Soddy [4] was able to show that one chemical element could contain atomic nuclei with different masses, forming different isotopes. With the availability of α-sources, due to the works of the Curies in Paris, Rutherford [5] was able to perform the first nuclear reactions on nitrogen. The first attempt at understanding the relative stability of nuclear systems was made by Harkins and Majorsky [6]. This model, like many others of the time, consisted of protons and electrons. In 1924, Wolfgang Pauli [7] suggested that the optical hyperfine structure might be explained if the nucleus had a magnetic dipole moment, while later Giulio Racah [8] investigated the effect on the hyperfine structure if the nuclear charge were not spherically symmetric – that is, if it had an electric quadrupole moment.

All of these structure suggestions occurred before James Chadwick [9] discovered the neutron, which not only explained certain difficulties of previous models (e.g., the problems of the confinement of the electron or the spins of light nuclei), but opened the way to a very rapid expansion of our knowledge of the structure of the nucleus. Shortly after the discovery of the neutron, Heisenberg [10] proposed that the proton and neutron are two states of the nucleon classified by a new spin quantum number, the isospin. It may be difficult to believe today, 60 years after Chadwick's discovery, just how rapidly our knowledge of the nucleus increased in the mid-1930s.

Encyclopedia of Nuclear Physics and its Applications, First Edition. Edited by Reinhard Stock.

Hans A. Bethe's review articles [11, 12], one of the earliest and certainly the best known, discuss many of the areas that not only form the basis of our current knowledge but that are still being investigated, albeit with much more sophisticated methods.

The organization here will begin with general nuclear properties, such as size, charge, and mass for the stable nuclei, as well as half-lives and decay modes (α, β, γ, and fission) for unstable systems. Binding energies and the mass defect lead to a discussion of the stability of systems and the possibility of nuclear fusion and fission. Then follow details of the charge and current distributions, which, in turn, lead to an understanding of static electromagnetic moments (magnetic dipole and octupole, electric quadrupole, etc.) and transitions. Next follows the discussion of single-particle and collective levels for the three classes of nuclei: even–even, odd-A, and odd–odd (i.e., odd Z and odd N). With these mainly experimental details in hand, a discussion of various major nuclear models follows. These discussions attempt, in their own way, to categorize and explain the mass of experimental data.

1.2
General Nuclear Properties

1.2.1
Properties of Stable Nuclei

The discovery of the neutron allowed each nucleus to be assigned a number, A, the mass number, which is the sum of the number of protons (Z) and neutrons (N) in the particular nucleus. The atomic number of chemistry is identical to the proton number Z. The mass number A is the integer closest to the ratio between the mass of a nucleus and the fundamental mass unit. This mass unit, the unified atomic mass unit, has the value $1\ \mathrm{u} = 1.660538921(73) \times 10^{-27}\ \mathrm{kg} = 931.494061(21)\ \mathrm{MeV\,c^{-2}}$. It has been picked so that the atomic mass of a $^{12}\mathrm{C}_6$ atom is exactly equal to 12 u. The notation here is $^{A}\mathrm{X}_{N}$, where X is the chemical symbol for the given element, which fixes the number of electrons and hence the number of protons Z. This commonly used notation contains some redundancy because $A = Z + N$ but avoids the need for one to look up the Z-value for each chemical element. From this last expression, one can see that there may be several combinations of Z and N to yield the same A. These nuclides are called *isobars*. An example might be the pair $^{196}\mathrm{Pt}_{118}$ and $^{196}\mathrm{Au}_{117}$. Furthermore, an examination of a table of nuclides shows many examples of nuclei with the same Z-value but different A- and N-values. Such nuclei are said to be *isotopes* of the element. For example, oxygen (O) has three stable isotopes: $^{16}\mathrm{O}_8$, $^{17}\mathrm{O}_9$, and $^{18}\mathrm{O}_{10}$. A group of nuclei that have the same number of neutrons, N, but different numbers of protons, Z (and, of course, A), are called *isotones*. An example might be $^{38}\mathrm{Ar}_{20}$, $^{39}\mathrm{K}_{20}$, and $^{40}\mathrm{Ca}_{20}$. Some elements have but one stable isotope (e.g., $^{9}\mathrm{Be}_5$, $^{19}\mathrm{F}_{10}$, and $^{197}\mathrm{Au}_{118}$), others, two, three, or more. Tin ($Z = 50$) has the most at 10. Finally, the element technetium has no stable isotope at all. A final definition of use for light nuclei is a *mirror pair*, which is a pair of nuclei with N and Z interchanged. An example of such a pair would be $^{23}\mathrm{Na}_{12}$ and $^{23}\mathrm{Mg}_{11}$.

The nuclear masses of stable isotopes are determined with a mass spectrometer, and we shall return to this fundamental property when we discuss the nuclear binding energy and the mass defect in Section 1.3. After mass, the next property of interest is the size of a nucleus. The simplest assumption here is that the mass and charge form a uniform sphere whose size is determined by the radius. While not all nuclei are spherical or of uniform density, the assumption of a uniform mass/charge density and spherical shape is an adequate starting assumption (more complicated charge distributions are discussed in Section 1.4 and beyond). The nuclear radius and, therefore, the nuclear volume or size is usually determined by electron-scattering experiments; the radius is given by the relation

$$R = r_0 A^{1/3} \tag{1.1}$$

which, with $r_0 = 1.25$ fm, gives an adequate fit over the entire range of nuclei near stability. An expression such as Eq. (1.1) implies that nuclei have a density independent of A, that is, they are incompressible. A somewhat better fit to the nuclear sizes can be obtained from the Coulomb energy difference of mirror nuclei, which covers but a fifth of the total range of A. This yields $r_0 = 1.22$ fm. Even if the charge and/or mass distribution is neither spherical nor uniform, one can still define an equivalent radius as a size parameter.

Two important properties of a nuclide are the spin J and the parity π, often expressed jointly as J^π, of its ground state. These are usually listed in a table of isotopes and give important information about the structure of the nuclide of interest. An examination of such a table will show that the ground state and parity of all even–even nuclei is 0^+. The spin and parity assignments of the odd-A and odd–odd nuclei tell a great deal about the nature of the principal parts of their ground-state wave functions. A final property of a given element is the relative abundance of its stable isotopes. These are determined again with a mass spectrograph and listed in various tables of the nuclides.

1.2.2
Properties of Radioactive Nuclei

A nucleus that is unstable, that is, it can decay to a different or *daughter* nucleus, is characterized not only by its mass, size, spin, and parity but also by its lifetime τ and decay mode or modes. (In fact, each level of a nucleus is characterized by its spin, parity, lifetime, and decay modes.) The law of radioactive decay is simply

$$N(t) = N(0)\mathrm{e}^{-\lambda t} = N(0)\mathrm{e}^{-t/\tau} \tag{1.2}$$

where $N(0)$ is the number of nuclei initially present, λ is the decay constant, and its reciprocal τ is the lifetime. Instead of the lifetime, often the half-life $T_{1/2}$ is used. It is the time in which half of the nuclei decay. By setting $N(T_{1/2}) = N(0)/2$ in Eq. (1.2), one obtains the relation

$$T_{1/2} = \ln(2)\tau = 0.693\tau \tag{1.3}$$

The decay mode of ground states can be α, β, or spontaneous fission. Excited states mostly decay by γ-emission. More exotic decays are observed in unstable nuclei far from stability where nuclei decay takes place by emission of a proton or neutron.

In α-decay, the parent nucleus emits an α-particle (a nucleus of ${}^4\mathrm{He}_2$), leaving the daughter with two fewer neutrons and protons:

$$ {}^{A}\mathrm{X}_N \rightarrow {}^{A-4}\mathrm{Y}_{N-2} + {}^4\mathrm{He}_2 \tag{1.4}$$

The α-particle has zero spin, but it can carry off angular momentum. In β-decay the weak interaction converts neutrons into protons (β^--decay) or protons into neutrons (β^+-decay). Which of the two decays takes place depends strongly on the masses of the initial and final nuclei. Because a neutron is heavier than a proton, the free neutron is unstable against β^--decay and has a lifetime of 878.5(10) s. The mass excess in β^--decay is released as kinetic energy of the final particles. In the case of the free neutron, the final particles are a proton, an electron, and an antineutrino, denoted by $\overline{\nu}$. All of these particles have spin 1/2 and can also carry off angular momentum. In the case of β^+-decay, the final particles are a bound proton, an antielectron or positron, and a neutrino. Finally, as an alternative to β^+-decay the initial nucleus can capture an inner electron. In this so-called electron capture decay, only a neutrino, ν, is emitted by the final nucleus. In general, the decays can be written as

$$\beta^-\text{-decay}: \quad {}^{A}\mathrm{X}_N \to {}^{A}\mathrm{Y}_{N-1} + \mathrm{e}^- + \overline{\nu} \tag{1.5a}$$

$$\beta^+\text{-decay}: \quad {}^{A}\mathrm{X}_N \to {}^{A}\mathrm{Y}_{N+1} + \mathrm{e}^+ + \nu \tag{1.5b}$$

$$\beta^+\text{-decay (ec)}: {}^{A}\mathrm{X}_N + \mathrm{e}^- \to {}^{A}\mathrm{Y}_{N-1} + \nu \tag{1.5c}$$

One very rare mode of decay is double β-decay, in which a nucleus is unable to β-decay to a $Z+1$ daughter for energy reasons but can emit two electrons and make a transition to a $Z+2$ daughter. An example is ${}^{82}\mathrm{Se}_{48} \to {}^{82}\mathrm{Kr}_{46}$ with a half-life of $(1.7 \pm 0.3) \times 10^{20}$ years. Double β-decay is observed under the emission of two neutrinos. Neutrinoless double β-decay is intensively searched for in ${}^{76}\mathrm{Ge}$ because it is forbidden for massless neutrinos with definite helicities. Enriched Ge is hence used as it allows the use of a large single crystal as source and detector (for a review see [13]).

In spontaneous fission, a very heavy nucleus simply breaks into two heavy pieces. For a given nuclide, the decay mode is not necessarily unique. If more than one mode occurs, then the branching ratio is also a characteristic of the radioactive nucleus in question.

An interesting example of a multimode radioactive nucleus is ${}^{242}\mathrm{Am}_{147}$. Its ground state ($J^\pi = 1^-$, $T_{1/2} = 16.01\,\mathrm{h}$) can decay either by electron capture (17.3% of the time) to ${}^{242}\mathrm{Pu}_{148}$ or by β^- decay (82.7% of the time) to ${}^{242}\mathrm{Cm}_{146}$. On the other hand, a low-lying excited state at 0.04863 MeV ($J^\pi = 5^-$, $T_{1/2} = 152$ years) can decay either by emitting a γ-ray (99.52% of the time) and going to the ground state or by emitting an α-particle (0.48% of the time) and going to ${}^{238}\mathrm{Np}_{145}$. There is an excited state at 2.3 MeV with a half-life of 14.0 ms that undergoes spontaneous fission [14]. The overall measured half-life of ${}^{242}\mathrm{Am}_{147}$ is then determined by that of the 0.04863 MeV state. Such long-lived excited states are known as *isomeric states*. From this information on branching ratios, one easily finds the several partial decay constants for ${}^{242}\mathrm{Am}_{147}$. For the ground state, $\lambda_{\mathrm{ec}} = 2.080 \times 10^{-6}\,\mathrm{s}^{-1}$ and $\lambda_{\beta-} = 9.944 \times 10^{-6}\,\mathrm{s}^{-1}$, while for the excited state at 0.04863 MeV, $\lambda_\gamma = 1.439 \times 10^{-10}\,\mathrm{s}^{-1}$ and $\lambda_\alpha = 6.639 \times 10^{-13}\,\mathrm{s}^{-1}$ and for the excited state at 2.3 MeV, $\lambda_{\mathrm{SF}} = 49.5\,\mathrm{s}^{-1}$.

1.3
Nuclear Binding Energies and the Semiempirical Mass Formula

1.3.1
Nuclear Binding Energies

One of the more important properties of any compound system, whether molecular, atomic, or nuclear, is the amount of energy needed to pull it apart, or, alternatively, the energy released in assembling it from it constituent parts. In the case of nuclei, these are protons and neutrons. The binding energy of a nucleus ${}^{A}X_{N}$ can be defined as

$$B(A, Z) = ZM_{\mathrm{H}} + NM_{\mathrm{n}} - M_{\mathrm{X}}(Z, A) \quad (1.6)$$

where M_{H} is the mass of a hydrogen atom, M_{n} the mass of a neutron, and $M_{\mathrm{X}}(Z,A)$ the mass of a neutral atom of isotope A. Because the binding energy of atomic electrons is very much less than nuclear binding energies, they have been neglected in Eq. (1.6). The usual units are atomic mass units, u. Another quantity that contains essentially the same information as the binding energy is the *mass excess* or the *mass defect*, $\Delta = M(A) - A$. (Another useful quantity is the *packing fraction* $P = [M(A) - A]/A = \Delta/A$.) The most interesting experimental quantity $B(A,Z)/A$ is the binding energy per nucleon, which varies from somewhat more than 1 MeV nucleon^{-1} (1.112 MeV nucleon^{-1}) for deuterium (${}^{2}\mathrm{H}_{1}$) to a peak near ${}^{56}\mathrm{Fe}_{30}$ of 8.790 MeV nucleon^{-1} and then falls slowly until, at ${}^{235}\mathrm{U}_{143}$, it is 7.591 MeV nucleon^{-1}. Except for the very light nuclei, this quantity is roughly (within about 10%) 8 MeV nucleon^{-1}. A strongly bound light nucleus is the α-particle, as for ${}^{4}\mathrm{He}_{2}$ the binding energy is 7.074 MeV nucleon^{-1}. It is instructive to plot, for a given mass number, the packing fraction as a function of Z. These plots are quite accurately parabolas with the most β-stable nuclide at the bottom. The β^{-} emitters will occur on one side of the parabola (the left or lower two side) and the β^{+} emitters on the other side. For odd-A nuclei, there is but one parabola, the β-unstable nuclei proceeding down each side of the parabola until the bottom or most stable nucleus is reached. For the even-A nuclei, there are two parabolas, with the odd–odd one lying above the even–even parabola. The fact that the odd–odd parabola is above the even–even one indicates that a pairing force exists that tends to increase the binding energy of the even–even nuclei. See Figure 1.1 for the $A = 100$ mass chain. Other indications of the importance of this pairing force are the before-mentioned 0^{+} ground states of all even–even nuclei and the fact that only four stable odd–odd nuclei exist: ${}^{2}\mathrm{H}_{1}$, ${}^{6}\mathrm{Li}_{3}$, ${}^{10}\mathrm{B}_{5}$, and ${}^{14}\mathrm{N}_{7}$. For even-A nuclei, the β-unstable nuclei zig-zag between the odd–odd parabola and the even–even parabola until arriving at the most β-stable nuclide, usually an even–even one. If the masses for each A are assembled into a three-dimensional plot (with N running along one long axis, Z along a perpendicular axis, and $M(A,Z)$ mutually perpendicular to these two), one finds a "landscape" with a deep valley running from one end to the other. This valley is known as the *valley of stability*.

The immediate consequence of the behavior of $B(A,Z)/A$ is that a very large amount of energy per nucleon is to be gained from combining two neutrons and two protons to form a helium nucleus. This process is called *fusion*. The release of energy in the fission process follows from the fact that $B(A,Z)/A$ for uranium is less than for nuclei with more or less half the number of protons. Finally, the fact that the binding energy per nucleon peaks near iron is important to the understanding of those stellar explosions known as *supernovae*. In Figure 1.2, the packing fraction, $P = \Delta/A$, is plotted against A for the most stable nuclei for a given mass number. Note that P has a broad minimum near iron ($A = 56$) and rises slowly until lawrencium ($A = 260$). This shows most clearly the

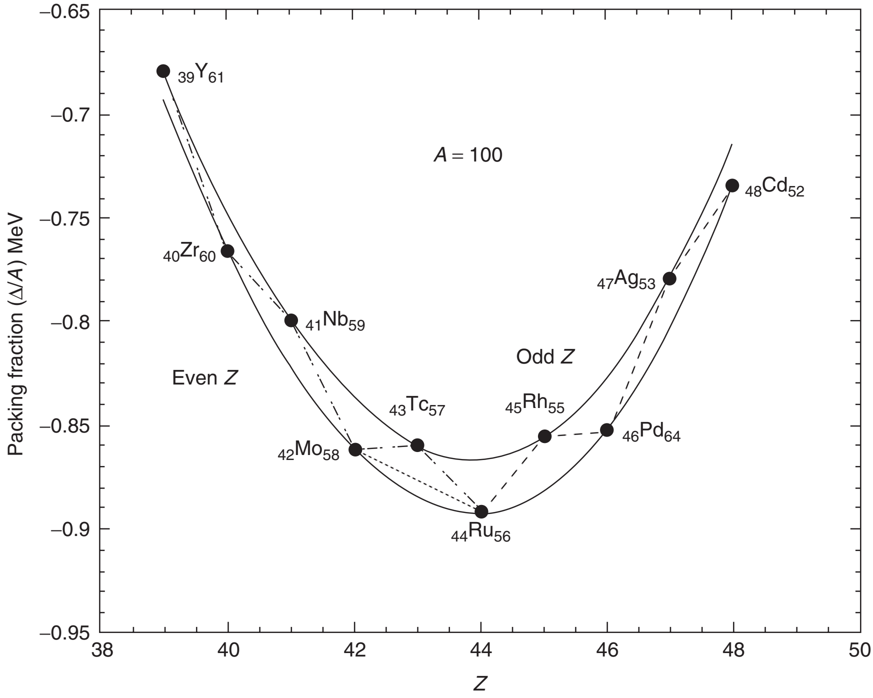

Figure 1.1 The packing fraction Δ/A plotted against the nuclear charge Z for nuclei with mass number $A = 100$. Note that the odd–odd nuclei lie above the even–even ones. The β^- transitions are indicated by - • -, the β^+ transitions by ---, while the double β-decay $^{100}_{42}\mathrm{Mo}_{58} \to ^{100}_{44}\mathrm{Ru}_{56}$ is denoted by• • •. Data from [14]. The double β-decay from [15].

energy gain from the fission of very heavy elements.

1.3.2
The Semiempirical Mass Formula

The semiempirical mass formula may be looked upon as simply the expansion of $B(A,Z)$ in terms of the mass number. Because $B(A,Z)/A$ is nearly constant, the most important term in this expansion must be the term in A. From Eq. (1.1) relating the nuclear radius to $A^{1/3}$, we see that a term proportional to A is a volume term. However, this term overbinds the system because it assumes that each nucleon is surrounded by the same number of neighbors. Clearly, this is not true for surface nucleons, and so a surface term proportional to $A^{2/3}$ must be subtracted from the volume term. (One might identify this with the surface tension found in a liquid drop.) Next, the repulsive Coulomb forces between protons must be included. As this force is between pairs of protons, this term will be of the form $Z\{Z-1)/2$, the number of pairs of Z protons, divided by a characteristic nuclear length or $A^{1/3}$. Two other terms are necessary in this simple model. One term takes into account that, in general, $Z \sim A/2$, clearly true for stable light nuclei, and less so for heavier stable

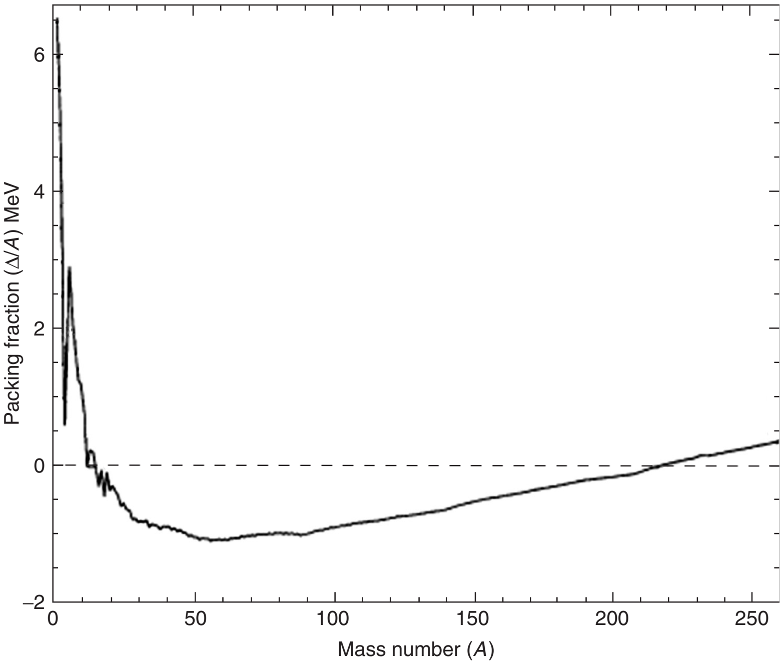

Figure 1.2 The packing fraction Δ/A plotted against the mass number A for all nuclei from ${}^{2}_{1}D_{1}$ to ${}^{260}_{103}Lr_{157}$. Data from [14].

nuclei where more neutrons are needed to overcome the mutual repulsion of the protons. This term is generally taken to be of the form $a_{\text{sym}}\,(N-Z)^2/A$. The other term takes into account the fact, noted in Section 1.3.1, that even–even nuclei are more tightly bound than odd–odd nuclei because all of the nucleons of the former are paired off. This is done by adding a term $\delta/2$ that is positive for even–even systems and negative for odd–odd systems and zero for odd-A nuclei. Thus, the two parabolas for even A are separated by δ. From Eq. (1.6), the semiempirical Bethe–Weisäcker mass formula then becomes $M(A,Z) = ZM_{\text{H}} + NM_{\text{n}} - B(A,Z)$ with

$$B(A,Z) = a_{\text{v}}A - a_{\text{s}}A^{2/3} - a_{\text{c}}Z(Z-1)A^{-1/3} - a_{\text{sym}}(N-Z)^2A^{-1} + \frac{\delta}{2} \qquad (1.7)$$

Originally, the constants were fixed by the measured binding energies and adjusted to give appropriate behavior with the mass number [16]. Myers and Swiatecki [17] (see also [18]) have included other terms to account for regions of nuclear deformation, as well as an exponential term of the form $-a_{\text{a}}A\exp(-\gamma A^{1/3})$, for which they provide no physical explanation beyond the fact that it reduces the deviation from experiment. Their model evolved into the macroscopic-microscopic global mass formula, called the *finite-range droplet model* (see [19]) and the *DZ-model* proposed by Duflo and Zuker [20], and more microscopic models, called *HFB* [21]. The many adjustable parameters of the available mass formulas are then fitted to masses of 1760 atomic nuclei [22]. The formulas fit binding energies quite well with errors below 1%, but still have problems to predict masses far from stability. As those are important for nuclear astrophysics, the measurement of masses of exotic nuclei is an important field today.

A number of consequences flow from even a superficial examination of Eq. (1.7). The fact that the binding energy per nucleon, B/A, is essentially constant with A implies that the nuclear density is constant and, thus, the nuclear force saturates. That is, nucleons interact only with a small number of their neighbors. This is a consequence of the very short range of the strong force. If this were not so, then each nucleon would interact with all others in the given nucleus (just as the protons interact with all other protons), and the leading term in $B(A,Z)$ would be proportional to the number of pairs of nucleons, which is $A(A-1)/2$ or roughly A^2. This would imply that B/A would go as A. Thus, not only does the nuclear force saturate (the Coulomb force does not) but it is also of very short range (that of the Coulomb force is infinite) as the sizes of nuclei are of the order of 3.0 fm (recall Eq. (1.1)).

1.4
Nuclear Charge and Mass Distributions

1.4.1
General Comments

In his 1911 paper, Rutherford was able to conclude that the positive charge of the atom was concentrated within a sphere of radius $<10^{-14}$ m (10 fm). This result came from α-particle scattering. However, for energetic enough α-particles, the scattering result will contain a component due to nuclear interactions of the α-particle, as well as the Coulomb interaction. For probing the structure of nuclei, electrons have the advantage that their scattering is purely Coulombic; however, to determine details of the internal nuclear structure, electron energies must be well over 100 MeV for their de Broglie wavelengths to be less than nuclear dimensions. Well before the existence of such high-energy electron beams, nuclear structure effects were extracted from information provided by optical hyperfine spectra. In particular, nuclear charge distributions (electric quadrupole moments) and current distributions (magnetic dipole moments) were deduced from very accurate optical measurements (see the following section). A result involving the innermost electrons of heavy atoms is the *isotope shift*, which can be observed in atomic X-rays. This arises because the nuclear radii for two different isotopes of the same atom will produce slightly different binding energies of their K-shell electrons. Thus, the K X-rays of these isotopes will be very slightly different in energy. As an example, the isotopic pair $^{203}\mathrm{Tl}_{122}$ and $^{205}\mathrm{Tl}_{124}$ have an isotope shift of about 0.05 eV. Another early method to determine the charge radius is to take the difference between the binding energies of two mirror nuclei (cf. Section 1.2.1). This leads to an expression that only involves a_c and, thus, the nuclear radius. This is useful for light nuclei for which mirror pairs occur.

With the advent of copious beams of negative muons, much more accurate optical-type hyperfine spectrum studies could be made. The process is quite simple, and the advantages obvious. By stopping negative muons in a target, an exotic atom is formed in which the muon replaces an orbital electron and transitions to the muonic K-shell follow. These transitions of the muon to the $1s_{1/2}$ state emit photons of the appropriate (but high) energies. (As the muon is more than 200 times as massive as the electron, the radii of the muon orbits are reduced by that amount, so that electron-shielding problems are much reduced.) The energies of the photons are such that the $2p_{1/2}-2_{3/2}$ splitting is easily measured (in $^{116}Sn_{66}$, it is 45.666 keV). Thus, both nuclear charge radii and isotope shifts are quite accurately determined. In some recent experiments, root mean square (RMS) charge radii have been measured with a precision of 2×10^{-18} m. As electron scattering and muonic atoms are the two methods of measuring characteristics of the nuclear charge radius most susceptible of the greatest accuracy, they will be discussed in turn.

1.4.2
Nuclear Charge Distributions from Electron Scattering

In any scattering experiment, what is measured is the differential cross section $(d\sigma/d\Omega)$. Rutherford developed an expression for α-particle scattering that can be used for low-energy, spinless particles incident on a spinless target. Both incident and target particles are assumed to be point particles. The differential cross section for scattering relativistic electrons off point-charged particles leads to the expression for Mott scattering, while, if the target particle has nonzero spin (there is then a magnetic contribution), one obtains the Dirac scattering formula for $(d\sigma/d\Omega)$. However, real nuclei are not point particles, so one needs to make use of the charge form factor $F(\vec{q})$ with $\vec{q}$ the transferred momentum. The form factor $F(\vec{q})$ is then the Fourier transform of the charge density $\rho_{ch}(\vec{r})$:

$$F(\vec{q}) = \int \rho_{ch}(\vec{r}) e^{i\vec{q}\cdot\vec{r}}\, d\tau \qquad (1.8)$$

If one restricts the problem to spherically symmetric distributions, the angular integration of the Fourier integral follows at once, so that

$$F(q) = \frac{4\pi}{q}\int \rho_{ch}(r)\sin(qr) r dr \qquad (1.9)$$

If the target nucleus has zero spin (applicable to all even–even nuclei), then the differential cross sections for a point target and a finite-sized target are related by

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{Ruth.}} F(q)^2 \qquad (1.10)$$

With the charge form factor determined experimentally, the inverse transform yields the radial charge density

$$\rho_{ch}(r) = \frac{1}{2\pi^2 r}\int F(q)\sin(qr) q dq \qquad (1.11)$$

If the target nucleus is not of spin zero, then an additional term containing the so-called transverse form factor, $F_T(q)$, is needed. (The form factor defined in Eq. (1.9) is sometimes called the *longitudinal form factor*.) In any event, the charge distribution must be normalized to the number of protons (Z) in the target nucleus.

At this point, there are two ways to proceed. The first is a model-independent analysis of the form factor, or, second, one can assume a model with several parameters and fit these to the data. Limiting oneself to small momentum transfers, one can obtain the form factor as a power series in q^2 by expanding $\sin(qr)$ in Eq. (1.9) in a power series of its argument. Keeping only the lowest term of order q^2, one obtains

$$F(q) = Z\left(1 - \frac{1}{6}q^2\langle r^2\rangle\right) \qquad (1.12)$$

with

$$\langle r^2 \rangle = \int r^2 \rho_{\mathrm{ch}}(r) 4\pi r^2 \mathrm{d}r \qquad (1.13)$$

the RMS radius of the charge distribution. It should be noted that this is not the nuclear radius R, which is usually taken as the radius of the constant-density sphere. This yields

$$\langle r^2 \rangle = \frac{3}{5} R^2 \qquad (1.14)$$

Data compilations [23] show that for most stable nuclei,

$$R \approx 1.25 A^{1/3} \qquad (1.15)$$

As was stated in Section 1.2.1, a better way to describe the charge distribution is to use a Fermi distribution which takes account of the constant charge density, ρ_0, at the center of the nucleus and the gradual decrease near the surface. This is achieved by

$$\rho_{\mathrm{ch}}(r) = \rho_0 \frac{1}{1 + \mathrm{e}^{\frac{r - R_{1/2}}{a}}} \qquad (1.16)$$

with $R_{1/2}$ the radius at half density and a the diffuseness parameter indicating the distance at which the density falls from 90 to 10% of the constant density ρ_0. For heavy nuclei, the following parameterization holds:

$$\begin{aligned} \rho_0 &= 0.17 \frac{Ze}{A}\,\mathrm{fm}^{-3} \\ a &= 2.4\,\mathrm{fm} \\ R_{1/2} &= 1.128 A^{1/3} - 0.89 A^{-1/3}\,\mathrm{fm} \end{aligned} \qquad (1.17)$$

There are enough experimental electron-scattering data available throughout all regions of the stable nuclei that quite accurate charge parameters exist for almost all of the systems. The compendium by de Vries *et al.* [23] lists these parameters fitted to the data for several distribution functions in addition to the two-parameter Fermi functions.

1.4.3
Nuclear Charge Distributions from Atomic Transitions

During the last decades, tremendous progress was obtained in the study of atomic transitions using high-precision laser spectroscopy. This allows the measurement of nuclear charge radii and also of nuclear moments for stable and even unstable isotopes. This is because the difference between a point nucleus and a finite-size nucleus causes a very small change in the Coulomb potential the atomic electrons feel. A small energy difference on the atomic levels results when we assume that the nucleus is a sphere with constant charge density. For 1s electrons one obtains

$$\Delta E_{1\mathrm{s}} = \frac{2}{5} \frac{Z^4 e^2}{4\pi\varepsilon_0} \frac{R^2}{a_0^3} \qquad (1.18)$$

with a_0 the Bohr radius. Because no point nucleus exists and the theoretical calculations are not accurate enough to calculate the small shift exactly, one generally measures isotope shifts as the frequency difference of atomic transitions measured in two isotopes of a given element. This then yield the differences in the nuclear radius. Starting from known radii of stable isotopes, it is then possible to determine the radii of unstable nuclei on which one cannot perform electron scattering. It is also possible to measure isotope shifts using optical transitions. Because these are caused by the outermost electrons, the shifts are very small in the order of parts per million. As indicated above, they are still within reach of modern laser techniques.

The small shift for 1s binding energies is related to the large difference between the Bohr radius and the nuclear radius. On replacing one electron by a muon, the muonic orbits shrink by a factor of 207, the mass difference between the heavy muon and the light electron. At the same time, the muon binding energy is increased by a similar factor, making the transition energies in the mega electron volt region. The energies are so high (in $^{238}\mathrm{U}_{146}$, the measured 2p–1s transition is about 6.1 MeV) that one must generate Dirac solutions for the muon moving in a Coulomb potential generated by a non-point-charge distribution. To these initial Dirac solutions, one must add corrections, which, in order of size, are vacuum polarization, nuclear polarization, the Lamb shift, and relativistic recoil. Electronscreening corrections are often included, but they are very tiny (for the ls muonic state in $^{238}\mathrm{U}_{146}$, this correction has the value of 11 eV).

As many nuclei are not spherical, several studies have used as the appropriate charge distribution a slightly modified form of Eq. (1.16), which includes the deformations

$$\rho_{\mathrm{ch}}(r) = \rho_0 \left\{ 1 + \exp\left(\frac{r - R_{1/2}\left(1 + \sum_{n=1} \beta_n Y_{n0}(\theta, \phi)\right)}{a} \right) \right\}^{-1} \tag{1.19}$$

Here the β_{n} are deformation parameters that determine the nuclear shape. As an example, the nuclear mean square radius may be expressed as

$$\begin{aligned} &\langle r^2 \rangle_{\mathrm{deformed}} \\ &\approx \langle r^2 \rangle_{\mathrm{sph}} \left(1 + \frac{5}{4\pi} \left(\beta_2^2 + \beta_4^2 + \cdots \right) \right) \end{aligned} \tag{1.20}$$

Experiments to fit a, c, and, in deformed regions, β_{n} have been made throughout the periodic table with results consistent with the electron data. However, to combine the results of electron-scattering experiments with those from muonic atoms, it is necessary to use the so-called Barrett moment

$$\left\langle r^k \mathrm{e}^{-\alpha r} \right\rangle = \frac{4\pi}{Z} \int_0^\infty \rho(r) \mathrm{e}^{-\alpha r} r^{k+2} \mathrm{d}r \tag{1.21}$$

where k and α are fitted to the experimental data. The muonic data are equivalent to data from electron-scattering experiments at low momentum transfer. The inclusion of the muonic Barrett moment improves the overall fit by reducing normalization errors. This then reduces the uncertainties over what would be obtained by fitting either the electron-scattering or the muonic atom data alone. Extensive tables of data fitted by various charge distribution models as well as model independent analyzes can be found in de Vries *et al.* [23].

1.4.4
Nuclear Mass Distributions

While the measurement of the charge distribution can be made using electromagnetic probes, this is not possible for the mass distribution because of the uncharged neutron. Instead, the nuclear strong force has to be used. This is more complicated as mostly both Coulomb force and strong force are present. Nevertheless, from α-scattering experiments, information of the mass distribution is obtained. There are also indirect ways in which one can get information on nuclear mass radii. One example is the dependence of α-decay rate on the nuclear radius that defines the Coulomb barrier. In deformed nuclei, this causes an anisotropy because the Coulomb barrier is lower in the direction of the longest axis, making the tunnel probability enhanced. A second way is to use pions instead of muons. These interact with the nucleus through both the Coulomb force and strong force, which, in comparison to muonic atoms, causes an extra shift that allows the determination of the mass radius. The result of these experiments on stable nuclei finds that the charge and mass radii are equal to within about 0.1 fm. This somewhat surprising result can be understood as a balance between the proton Coulomb repulsion that tends to push the protons to the outside and a strongly attractive neutron–proton strong force that tends to pull the extra neutrons to the inward.

Recently, the common opinion that the radii scale with $A^{1/3}$ was found to be heavily violated in more exotic nuclei.

Especially in light nuclei with a large neutron number, so-called halo-nuclei, strong deviations were observed (an early review is given in [24]). Using the radioactive beam techniques, very neutron-rich He, Li, and Be isotopes can be created and studied in the laboratory. It turned out that these loosely bound nuclei show very extended neutron radii whereby two neutrons are moving at radii similar to the radii of Pb isotopes. Moreover, as is the case of $^{11}\mathrm{Li}_8$, the bound system consists of three entities: two neutrons and a $^{9}\mathrm{Li}_6$ that cannot exist two by two, as the dineutron and $^{10}\mathrm{Li}_7$ are unbound. The research on exotic nuclei is still in its infancy and more exotic features such as proton halos or neutron skins are expected. They are of importance as they may influence the creation of the elements under astrophysical conditions.

1.5
Electromagnetic Transitions and Static Moments

1.5.1
General Comments

Static electromagnetic nuclear moments played an important role in the unscrambling of the detailed measurements of atomic optical hyperfine structure well before the gross components of atomic nuclei were in hand. Almost a decade before the discovery of the neutron, Pauli [7] suggested that the optical hyperfine splitting might be due, in part, to the interaction with a nuclear magnetic moment (μ). This suggestion lay fallow until 1930, when Goudsmit and Young, using the spectroscopic data of Schiller and of Granath, deduced the nuclear magnetic moment of ^{7}Li to be $\mu = 3.29\mu_{\mathrm{N}}$, where the nuclear magneton equals

$$\mu_{\mathrm{N}} = \frac{e\hbar}{2M_{\mathrm{p}}} = 5.050789 \times 10^{-27}\,\frac{\mathrm{J}}{\mathrm{T}} \tag{1.22}$$

This value is quite close to the currently accepted value ($\mu = 2.327\mu_{\mathrm{N}}$). Because of the existence, by then, of extensive hyperfine optical spectroscopic data, Goudsmit, in 1933, was able to publish a table of some 20 nuclear magnetic moments ranging from ^{7}Li to ^{209}Bi. In 1937, Schmidt published a simple, single-particle model of nuclear magnetic moments and supported it with the experimental moments of 32 odd-proton nuclei and 15 odd-neutron nuclei. This simple model yields what is now known as the *Schmidt limits*, within which almost all nuclear magnetic moments lie (see the following).

The suggestion that the nuclear electric quadrupole moments (Q) might also play an important role in optical hyperfine structure was again made before the discovery of the neutron. Racah [8] was the first to work out the theory associated with "nuclear charge asymmetry" and the interaction with the atomic electrons. Casimir [25], sometime later, developed the theory of nuclear electric quadrupole hyperfine interaction and applied it to ^{151}Eu and ^{153}Eu. In this paper, Casimir mentions work by Schiller and Schmidt, who determined Q for ^{175}Lu. A short time later, Gollnow [26] obtained $Q = 5.9$ b for this nucleus, quite close to the currently accepted value of 5.68 b. This very large quadrupole moment (very much larger than can be accounted for by the single-particle shell model) was to provide, 20 years later, strong impetus for the development of the collective model of the nucleus. In 1954, Schwartz [27] extended the theory of nuclear hyperfine structure to examine the magnetic octupole hyperfine interaction and calculated the first four nuclear magnetic octupole moments (O) from data of the hyperfine structure of the nuclear ground states. The next nuclear moment is the hexadecapole (H); however, no direct measurements of such static moments exist. What is known about these moments comes mainly from electromagnetic transitions of electrons and negative muons. For an in-depth theoretical study of all of these moments and how they can be used to test various nuclear models see, in particular, the text by Castel and Towner [28].

Nowadays, the measurement of moments is still very important to assess the single-particle structure of exotic nuclei and several powerful techniques have been developed in this domain [29]. Most information is, however, gathered via the determination of electromagnetic transitions by γ-ray spectroscopy. This is to a large extent due to the availability of large-volume semiconductor detectors for γ-ray detection and the high computing power that allows one to analyze more and more complex measured spectra using coincidence conditions. The recent development of γ-ray tracking detectors out of segmented Ge-detectors offers very high perspectives in the field of exotic nuclei [30].

1.5.2
Electromagnetic Transitions and Selection Rules

Without going into a detailed discussion on how matrix elements are calculated, we review here the calculation of electromagnetic transitions. The interested reader can find more details in Heyde [31]. The calculation of transitions and also moments involves the wavefunctions of nuclear states and forms a very sensitive probe for nuclear structure research. On the other hand these transitions and moments are electromagnetic in nature making the interaction very well understood. Using the long-wavelength approximation $\lambda \gg R$ and a multipole expansion of the electromagnetic operators, the transition rates per unit of time can be expressed as

$$T(L) = \frac{2}{\varepsilon_0 \hbar} \frac{L+1}{(L[(2L+1)!!]^2)} \left(\frac{\omega}{c}\right)^{2L+1} B(L) \tag{1.23}$$

with L the multipolarity, ω the angular frequency of the radiation such that $\hbar\omega \cong E_i - E_f$ up to a small nuclear recoil correction, and $B(L)$ the reduced transition probability

$$B(J_i \to J_f; L) = \sum_{M_i, M_f} \left| \left\langle \alpha_f; J_f M_f \right| O(LM) \left| \alpha_i; J_i M_i \right\rangle \right|^2 \tag{1.24}$$

in units of $e^2 b^L$ and $\mu_N b^{L-2}$ for electric and magnetic $B(LM)$ values. The labels α identify the initial and final states and $O(LM)$ is the electric or magnetic multipole operator of rank LM. As all states have good angular momentum, one can now use for the transition rates the Wigner–Eckart theorem to remove all reference to the M projections. This yields

$$B(J_i \to J_f; L) = \frac{1}{2J_i + 1} \left| \left\langle \alpha_f; J_f \left\| O(L) \right\| \alpha_i; J_i \right\rangle \right|^2 \tag{1.25}$$

The electric multipole operator for a number of point charges becomes

$$O(E; LM) = \sum_i e_{\text{eff}}(i) r_i{}^L Y_{L,M}(\theta_i, \phi_i) \tag{1.26}$$

with $e_{\text{eff}}(i)$ the effective charge of the ith nucleon. Here it is anticipated that owing to core polarization effects and truncations of the model space, other values than the free charges $+e(0)$ for proton (neutron) need to be used. Instead of the operator (Eq. (1.25)), one can also use a similar operator but using the nuclear electric charge density ρ_{ch} and an integration over the nuclear volume. These are used as several models describe the nucleus as a droplet (Section 1.7). For the magnetic multipole operator, we have

$$\begin{aligned} O(M; LM) = {} & \sqrt{L(2L+1)}\mu_N \sum_i r_i{}^{L-1} \\ & \times \left\{ \frac{e_{\text{eff}}(i)}{e} \frac{2}{L+1} [Y_{L-1} \otimes j_i]^{(L)} \right. \\ & + \left(g_s(i) - \frac{e_{\text{eff}}(i)}{e} \frac{1}{L+1} \right) \\ & \left. \times \left[Y_{L-1} \otimes s_i \right]^{(L)} \right\} \end{aligned} \tag{1.27}$$

with the effective gyromagnetic ratio g_s which also may differ from the free ones.

The multipole expansion and the fact that states in atomic nuclei have good angular momentum and parity leads to several selection rules. The first one is related to the vector coupling of the angular momentum and states $|J_i - J_f| \le L \le J_i + J_f$. The second is due to the parity of the operators, which clearly is $(-1)^L$ for the electric and $(-1)^{L-1}$ for the magnetic operator. Owing to this, electric and magnetic transitions of order L cannot take place at the same time between states, and moments such as the electric dipole moment are forbidden. While the selection rules allow the determination of the spin and parities of nuclear excited states, they are also (at a higher level) invaluable to test nuclear models (Section 1.7).

Weisskopf has estimated the so-called single-particle values or Weisskopf units (W.u.) by assuming that a single-particle makes a transition with multipole L from a state with spin $L + 1/2$ toward a state with spin $1/2$, that the radial part of the wavefunction can be approximated by a constant value up to the radius R, and that certain values for the effective charges hold. This leads to the following estimates for the half-lives corresponding to the single-particle values:

$$T_{1/2}(E1) = \frac{6.764 \times 10^{-6}}{E_\gamma^3 A^{2/3}} \quad \text{(s)}$$

$$T_{1/2}(M1) = \frac{2.202 \times 10^{-5}}{E_\gamma^3} \quad \text{(s)}$$

$$T_{1/2}(E2) = \frac{9.527 \times 10^{6}}{E_\gamma^5 A^{4/3}} \quad \text{(s)}$$

$$T_{1/2}(M2) = \frac{3.102 \times 10^{7}}{E_\gamma^5 A^{2/3}} \quad \text{(s)}$$

$$T_{1/2}(E3) = \frac{2.045 \times 10^{19}}{E_\gamma^7 A^{2}} \quad \text{(s)}$$

$$T_{1/2}(M3) = \frac{6.659 \times 10^{19}}{E_\gamma^7 A^{4/3}} \text{ (s)} \quad (1.28)$$

One notices that transition rates of the lower multipolarities are faster than the higher by orders of magnitude and that for a given multipolarity, the electric ones are about 100–1000 faster as the magnetic ones. Owing to the selection rules and enhanced quadrupole collectivity, only $E2$ and $M1$ transitions happen on similar timescales. In this case, one has a transition of mixed multipolarity.

The Weisskopf estimates are very crucial to determine whether a transition is caused by a single nucleon changing orbits or by several nucleons acting in a collective way. The measurement of transition rates of excited states delivers very important information on nuclear structure, but is also quite involved. One needs to measure the lifetime of a state, the (mixed) multipolarity, and the energy and intensities of the transitions deexiting a given state. To this end, γ-ray arrays consisting of several Ge-detectors are appropriate. Besides this, electromagnetic decay can also take place with the emission of conversion electrons. These electrons allow one to determine the multipolarity as well as to observe the by γ-emission forbidden $E0$ transitions (due to the fact that the photon has spin 1 with projection +1 and −1).

1.5.3
Static Moments

In contrast to the transition rates, the *multipole moments* are generally defined as the matrix element of the $M=0$ component of the moment operator for a single state with magnetic projection $M=+J$. Of the moments, the two lowest are the most important.

1.5.3.1 Magnetic Dipole Moments

If one assumes that the magnetic properties are associated with the individual nucleons, then the magnetic moment is defined as

$$\mu = \langle \alpha, JJ| \sum_i g_l(i) l_{z,i} + g_s(i) s_{z,i} |\alpha; JJ\rangle \quad (1.29)$$

where the sum extends over all of the A nucleons. Generally, this will not be needed; for instance, the magnetic moment of an odd-A nucleus will be generated by the last neutron and proton as the adjacent even–even ground state has no magnetic moment. In Eq. (1.29), g_l and g_s are the orbital and spin gyromagnetic ratios. They are often chosen as $0.7g_{\text{free}}$ where the free-particle values are $g_l = 1$, $g_s = 5.587$ for protons and $g_l = 0$, $g_s = -3.826$ for neutrons (all in μ_N). It is instructive to calculate the magnetic moment for a single nucleon (which, as explained earlier, is a good approximation for the ground state of odd-A nuclei). Using the total angular momentum and the Wigner–Eckart theorem, one deduces the single-particle magnetic moments for aligned and antialigned orbital momentum and spin:

$$\mu(j = l + 1/2) = j\left(g_l + \frac{(g_s - g_l)}{2}\right) \quad (1.30a)$$

$$\mu(j = l - 1/2) = \left(jg_l - \frac{j}{j+1}\frac{(g_s - g_l)}{2}\right) \quad (1.30b)$$

The magnetic moments plotted as a function of spin form the so-called Schmidt lines. It is interesting that, when plotted, almost all of these moments lie between the Schmidt lines. The moments that lie outside these limits occur mainly for some very light nuclei. One may conclude that the single-particle model does possess some validity. Another set of limits, the Margenau–Wigner (M-W) limits, is obtained by replacing the free-particle values for the orbital gyromagnetic ratios, g_l, by the uniform value Z/A. The justification for this is that one is in effect averaging over all states that lead to the correct nuclear spin. This calculation represents an early attempt to account for core contributions to the dipole-moment operator. Figure 1.3 and Figure 1.4 show plots of a number of the ground-state magnetic moments for odd-Z (Figure 1.3) and odd-N (Figure 1.4) nuclei.

Besides the ground state, excited states can have magnetic moment and their measurement is often used to extract information on the underlying single-particle structure. Common in nuclear structure physics is the use of g-factors that are analogous to the single-particle gyromagnetic ratios, except that they are dimensionless. They are defined as

$$\mu = gI\mu_\mathrm{N} \tag{1.31}$$

One way to determine the g-factor is to measure the Lamor frequency when excited nuclei are placed in an external magnetic field B. Then,

$$\omega_\mathrm{L} = \frac{gB\mu_\mathrm{N}}{\hbar} \tag{1.32}$$

The main problem hereby is to align the spins of an ensemble of atomic nuclei.

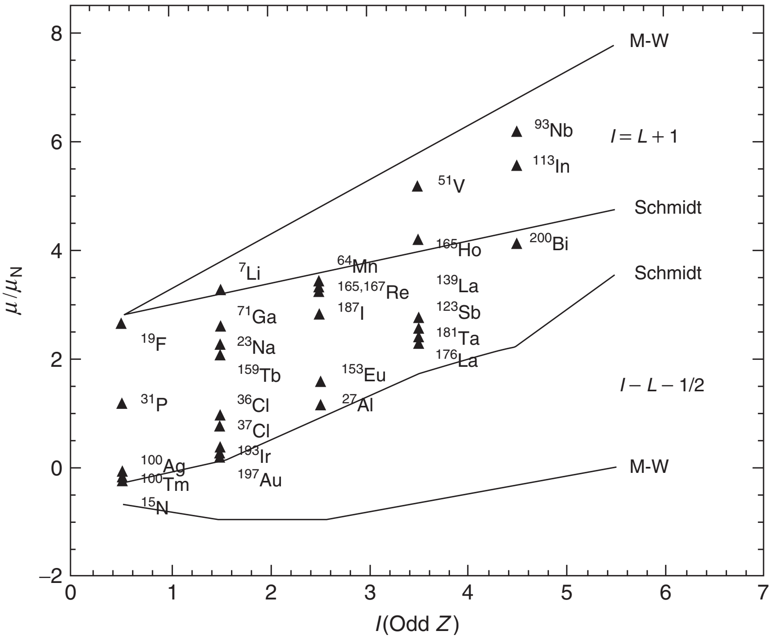

Figure 1.3 Nuclear magnetic moments in units of the nuclear magneton (μ/μ_N) plotted against the nuclear spin (I) for a number of odd-Z nuclei. The Schmidt limits, as well as the Margenau–Wigner (M-W) limits, are shown as solid lines. Data from [14].

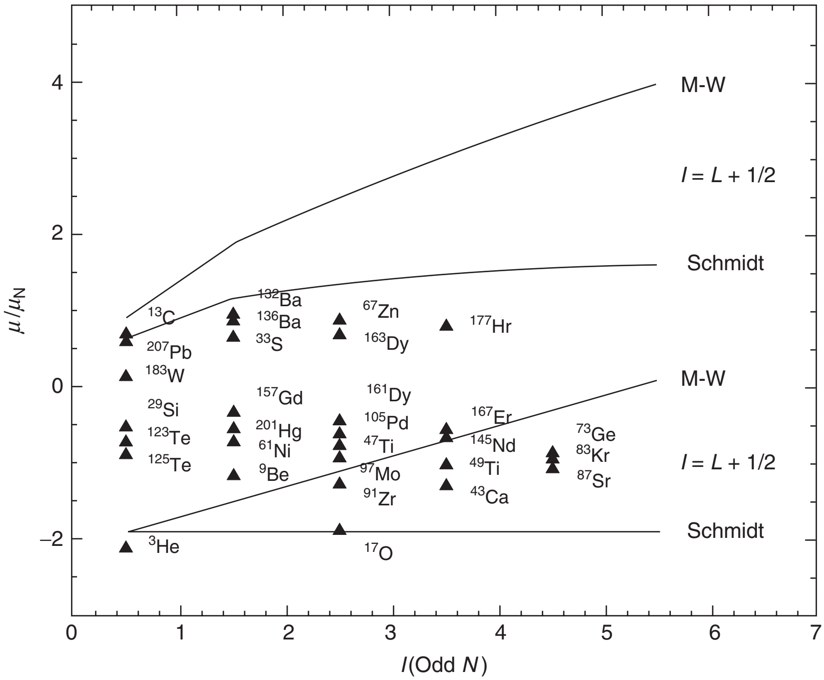

Figure 1.4 Nuclear magnetic moments in units of the nuclear magneton (μ/μ_N) plotted against the nuclear spin (I) for a number of odd-N nuclei. The Schmidt limits, as well as the Margenau–Wigner (M-W) limits, are shown as solid lines. Data from [14].

This has to be done by the nuclear reaction used, cooling in an external magnetic field, or via the observation of changes in angular correlations.

1.5.3.2 Electric Quadrupole Moments

As a general definition of the quadrupole moment, we have the expectation value of $(3z^2 - r^2)$. Using the proportionality of the quantity with $Y_{20}(\theta,\phi)$ one gets

$$Q(J) = \sqrt{\frac{16\pi}{5}} \times \left\langle \alpha; JJ \left| \sum_i \frac{e_{\text{eff}}\,(i)}{e} r_i^{\,2} Y_{2,0}(\theta_i, \phi_i) \right| \alpha; JJ \right\rangle \tag{1.33}$$

or, using the Wigner–Eckart theorem,

$$Q(J) = \sqrt{\frac{16\pi}{5}} \sqrt{\frac{J(2J-1)}{(2J+1)(2J+3)(J+1)}} \times \left\langle \alpha; J \left\| \sum_i \frac{e_{\text{eff}}\,(i)}{e} r_i^{\,2} Y_2(\theta_i, \phi_i) \right\| \alpha; J \right\rangle \tag{1.34}$$

The quadrupole moment can also be calculated for a single nucleon in an orbit $j = J$. This yields

$$Q(j) = -\frac{(2j-1)}{(2j+2)} \frac{e_{\text{eff}}(i)}{e} \langle r^2 \rangle \tag{1.35}$$

One thus obtains a negative quadrupole moment for a single nucleon. If the orbit is filled up to a single hole, a quadrupole moment as in Eq. (1.35) but with a positive sign is expected. We would like to illustrate the application of Eq. (1.35) with examples near the doubly magic nucleus $^{16}O_8$ (see also Section 1.7). The orbit that the ninth nucleon can occupy has $j = 5/2$ and we can use Eqs. (1.13) and (1.14) to estimate $<r^2>$. This yields for $^{17}F_8$ using the free-proton charge $Q = -5.9\,\text{fm}^2$, which is in excellent agreement with the experimental absolute value given in Firestone *et al.* (1996) of $|Q| = 5.8(4)\,\text{fm}^2$. For the odd neutron nucleus $^{17}O_9$, one finds experimentally $Q = -2.578\,\text{fm}^2$, which shows the need for effective charges and can be reproduced using $0.44e$ as neutron effective charge. Finally, if we place five neutrons in the $j = 5/2$ orbit, we have the $N = 13$ isotones and expect moments of $Q = +2.6\,\text{fm}^2$. Experimentally, one finds $Q = 20.1(3)\,\text{fm}^2$ in $^{25}Mg_{13}$ and $Q = 10.1(2)\,\text{fm}^2$ in $^{23}Ne_{13}$. This observation of much larger quadrupole moments occurs for most atomic nuclei having several nucleons in an orbit or in several orbits, indicating that the model is too simple and that all of the electric charges must be considered. This holds especially if the core is not spherically symmetric and the motion becomes collective.

1.6
Excited States and Level Structures

1.6.1
The First Excited State in Even–Even Nuclei

The most obvious characteristic of the various nuclei is that all of the even–even nuclei have ground-state spins and parities of 0^+. This not only categorizes one large group of nuclei but also indicates that the nuclear force is such that it couples, preferentially, pairs of like nucleons to angular momentum zero. The second observation is that the first excited state in even–even nuclei is almost always a 2^+ excitation. This can be understood by the combination of good total angular momentum and the Pauli principle. If one couples two nucleons in orbit j and implies the antisymmetrization, one obtains

$$\varphi(j,j;JM) = \frac{1}{2}\sum_{mm'}(jmjm'|JM)(\psi_1(jm)\,\psi_2(jm') - \psi_2(jm)\psi_1(jm')) \tag{1.36}$$

with the Clebsch–Gordan coupling coefficient for the angular momentum coupling. This can, however, be rewritten as the m-values are in the summation. Using the symmetry properties, one arrives at

$$\varphi\,(j,j;JM) = \frac{1}{2}\left(1-(-1)^{2j-J}\right) \times\sum_{mm'}(jmjm'|JM)\,\psi_1(jm)\psi_2(jm') \tag{1.37}$$

The phase factor, and the fact that $2j$ is an odd number, imply that states with odd values of J do not exist. One might wonder whether this is an essential property of fermions, but surprisingly it is not. Consider bosons with integer angular momentum ℓ. Then, owing to symmetrization, Eq. (1.36) becomes

$$\varphi(\ell,\ell;JM) = \frac{1}{2}\sum_{mm'}(\ell m\ell m'|JM) \times(\psi_1(\ell m)\psi_2(\ell m') + \psi_2(\ell m)\psi_1(\ell m')) \tag{1.38}$$

which yields after reordering,

$$\varphi(\ell,\ell;JM) = \frac{1}{2}\left(1+(-1)^{2\ell-J}\right)\sum_{mm'} \times(\ell m\ell m'|JM)\psi_1(\ell m)\psi_2(\ell m') \tag{1.39}$$

but now 2ℓ is even and again all states with odd J-values disappear. The fact that both bosons and fermions yield similar results is very important for nuclear models. It means that one can often describe even–even atomic nuclei using either fermionic nucleons or collective bosons such as phonons.

1.6.2
Regions of Different Level Structures

The existence of a low-lying 2^+ excitation can be explained in different ways, that is, short-range interaction, a collective quadrupole vibration, or as a first excited state of a rotational band. Which interpretation is right or better and which mixture of interpretations is right depends a lot on where on the Segre chart the nucleus is located and how the higher excitations behave. This is illustrated in Figure 1.5, which shows the known energies of the first excited states in the even–even Cd and Hf isotopes. One notices huge differences in the absolute excitation energies but also a quite smooth behavior. If one now also considers the next excited state, which is a 4^+ excitation and plots the ratio $R4/2$,

$$R4/2 = \frac{E_{\mathrm{exc}}(4^+)}{E_{\mathrm{exc}}(2^+)} \tag{1.40}$$

(see also Figure 1.5) more information can be obtained. In the Hf isotopes, a clear saturation near $R4/2 = 3.33$ occurs indicating that a rotational band, with its typical $I(I+1)$ energy dependence, is built on the ground state. For Cd, we observe very high 2^+ excitation energies and low $R4/2$ ratios at the beginning and end of the isotope chain. This is a clear evidence that at the extremes, a shell closure occurs, when $N = 50$ and 82. In the middle, one finds, compared to Hf, much higher 2^+ excitation energies and $R4/2$ ratios slightly above 2, indicating an anharmonic quadrupole vibrational nature at mid shell.

While the strong pairing of like nucleons can explain the ground state of even–even nuclei, it does not yield predictions for the ground-state spins and parities of odd-A and odd–odd nuclei. Nevertheless, it simplifies this task a lot, as in most cases one can conclude that the ground-state spin and parity of an odd-A nucleus is equal to the one of the last odd nucleon. This forms an important testing ground for the shell model, which predicts the single-particle energy, spin, and parity of the subsequent orbits.

1.6.3
Shell Structures

Various sets of nuclear data indicate that certain numbers of nucleons, either neutrons or protons, correspond to the filling of angular momentum “shells.” These are similar to the atomic shells often denoted as the K-shell, L-shell, and so on. In nuclei, the shell filling is similar but not identical, and the principal shell closings occur at experimentally observed numbers. These are for either *N or Z* equal to 2, 8, 20, 28, 50, 82, and 126. These are the *magic numbers*. They occur where there are drastic changes in neutron cross sections, nucleon separation energies, and so on. An interesting, but small, group of nuclei comprises the doubly magic ones – that is, nuclei with both neutron and proton numbers magic. The five stable ones are $^{4}\mathrm{He}_{2}$, $^{16}\mathrm{O}_{8}$, $^{40}\mathrm{Ca}_{20}$, $^{48}\mathrm{Ca}_{28}$, and $^{208}\mathrm{Pb}_{126}$. Note that no stable doubly magic nuclei with 50 and 82 exist. What is notable about the doubly magic nuclei is that their first excited states are at a very

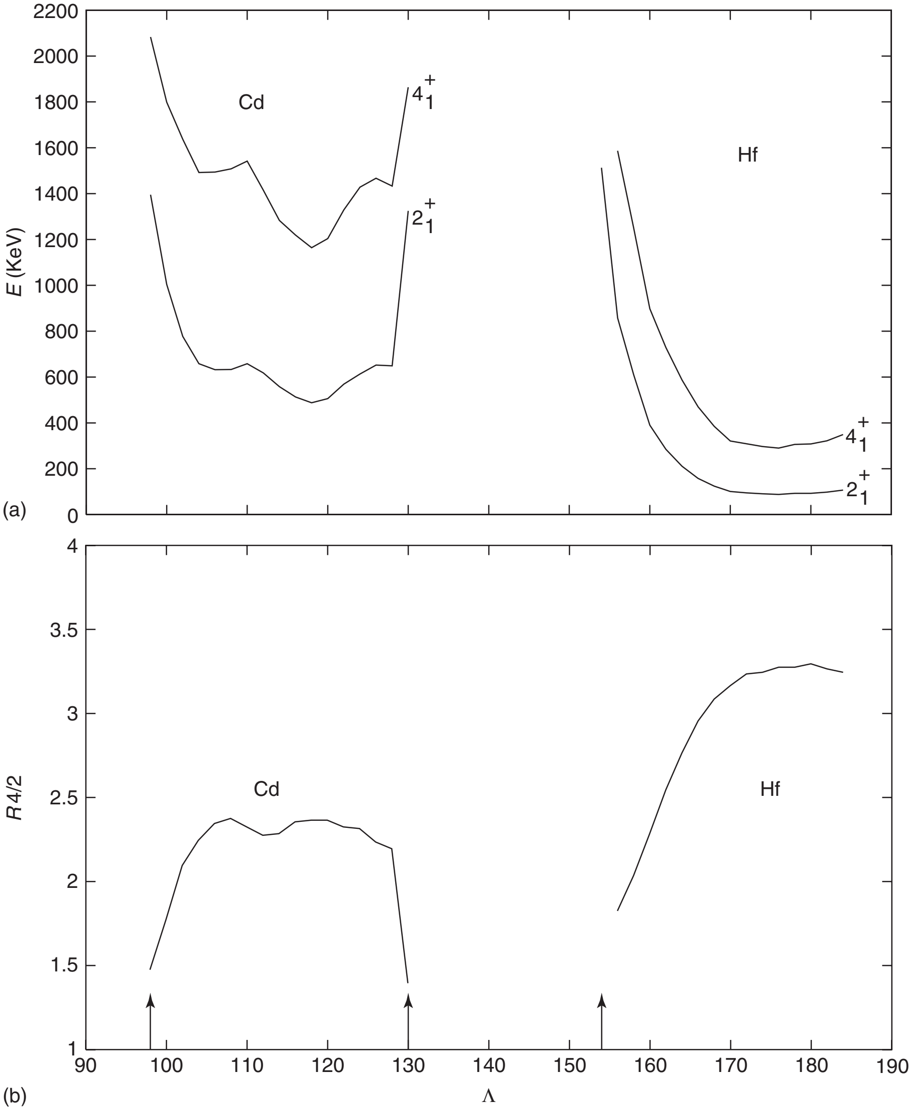

Figure 1.5 The known energies of the first excited states in the even–even Cd and Hf isotopes (a). The $R4/2$ ratios are also given (b). The left side represents the Cd isotopes and the right side the Hf isotopes. Arrows mark the closed shells at $A = 98$, 130, and 154.

high energy compared with their non-doubly magic neighbors. The energy in megaelectronvolts, spin, and parity of these first excited states is 20.1, 0^+; 6.05, 0^+; 3.35, 0^+; 3.83, 2^+; and 2.61, 3^-, respectively. Also the observed spins (and parities) of the first excited states is very different from that of all other even–even nuclei.

Because of these large gaps or changes in nuclear properties, they divide the low-lying excited states of nuclei into roughly three regions. These are, broadly, the nuclei in the neighborhood of the magic numbers that are dominated by shell or single-particle structures and those further away, which show collective behavior. Of particular interest are the ones found between these two, as they may give clues to the onset of collective motion in atomic nuclei and other systems. We mentioned earlier that 126 is a magic number, but strictly speaking, this holds only for neutrons as the unstable element with $Z = 126$ has not yet been observed. Nowadays, there is a strong interest to study whether magic numbers still stay valid in exotic nuclei far from stability and which is the next magic number for superheavy isotopes.

1.6.4
Collective Structures

Within major divisions (even–even, odd-A, and odd–odd), the excited levels are further divided into groups that are single-particle or collective (vibrational or rotational) in nature. However, because of the strong pairing force, even–even nuclei do not show single-particle excited levels but rather one- or two-particle-hole excitations or two-quasiparticle excitations. Here, we introduce the most general features of the two major classes of collective nuclei. We restrict ourselves to even–even nuclei for the sake of simplicity.

1.6.4.1 Vibrational Levels

The intermediate systems between the tightly bound magic nuclei and the deformed nuclei are the so-called vibrational nuclei. Here the number of nucleons outside of a deformable core is small, and the zero-point energy of the lowest oscillations is greater than the energy of deformation, so that the shape of the core is not stabilized. The motion then is of quantized surface oscillations with angular momentum two. One can introduce creation and destruction phonon operators Q^{+}_{LM} and Q_{LM} which fulfill the boson commutation rules:

$$[Q_{LM}, Q^{+}_{L'M'}] = \delta_{LL'}\delta_{MM'} \tag{1.41}$$

and for which all other commutators are zero. The angular momentum of the phonon is L, its magnetic projection M and its parity $\pi = (-1)^L$. The magnetic projection is mostly not of great importance. In this representation, the number operator counting the number of L phonons is given by

$$\widehat{N}_L = \sum_M Q^{+}_{LM} Q_{LM} \tag{1.42}$$

Using the number operator, the simplest Hamiltonian becomes

$$\widehat{H} = \sum_L \hbar\omega_L \left(\widehat{N}_L + L + \frac{1}{2}\right) \tag{1.43}$$

where the additional factors are chosen such that the Hamiltonian corresponds to the quantized harmonic oscillators for L phonons. Each of the phonons has energy $\hbar\omega_L$. Because most even–even nuclei have as first excited state a 2^+ state, the $L = 2$ quadrupole phonons are dominant. At higher energy, there is evidence for the presence of $L = 3$ octupole phonon making a 3^- state. Using the energy solution of the Hamiltonian equation (Eq. (1.43)),

$$E(N_L, L) = \sum_L \hbar\omega_L \left(N_L + L + \frac{1}{2}\right) \tag{1.44}$$

and the proper angular momentum coupling and symmetrization given in Eq. (1.39), one arrives at a very simple prediction. The one-quadrupole phonon state has $L=2$ and $E_{\text{exc}} = \hbar\omega_2$ and the two-phonon states have $L=0$, 2, 4 and $E_{\text{exc}} = 2\hbar\omega_2$. This exactly yields the $R4/2$ ratio of 2 observed in Figure 1.5.

A nice example of a ''good'' vibrational even–even nucleus is $^{110}\text{Cd}_{62}$. The first excited 2^+ state is at 0.6578 MeV followed by a 0^+, 2^+, 4^+ states at 1.473, 1.476, and 1.542 MeV. The ratio $R4/2=2.35$ is somewhat larger than the one the simple model gives.

1.6.4.2 **Rotational Levels**

If the number of nucleons outside the deformable core is such that the zero-point oscillations are much less than the energy of deformation, then the system will have a stable but deformed shape and one must quantize a rigid rotator. From classical considerations, we know that, if the system has a permanent, nonspherical shape, there exists a body-fixed system in which the inertial tensor $\mathfrak{I}$ is diagonal and is related to the laboratory-fixed system by an Euler transformation. We denote these two coordinate systems as (1,2,3) and (x,y,z), respectively. The inertial tensor then has components $\mathfrak{I}_1$, $\mathfrak{I}_2$, and $\mathfrak{I}_3$, so that the Hamiltonian is just

$$\widehat{H} = \frac{1}{2}\left(\frac{\widehat{L}_1^2}{\mathfrak{I}_1} + \frac{\widehat{L}_2^2}{\mathfrak{I}_2} + \frac{\widehat{L}_3^2}{\mathfrak{I}_3}\right) \tag{1.45}$$

with $\widehat{L}_{1,2,3}$ the body-fixed angular momentum. The simplest system is the one for which all moments of inertia are equal: $\mathfrak{I}_1 = \mathfrak{I}_2 = \mathfrak{I}_3 = \mathfrak{I}$. Then the energies are directly found:

$$\widehat{H} = \frac{\hbar^2}{2\mathfrak{I}}(L(L+1)) \tag{1.46}$$

The system specified by Eq. (1.45) possesses the symmetry properties belonging to the point group D_2 for which four representations exist. The Hamiltonian operator (Eq. (1.45)) does not mix different representations. The basis functions are those of a symmetric top, $|LMK>$ being diagonal in $\boldsymbol{L}^2$, $\boldsymbol{L}_z$, and $\boldsymbol{L}_3$ with the usual eigenvalues $L(L+1)$, M, and K, respectively. Here K is the projection of the angular momentum on the body-fixed frame. Applying this formula for the ground-state rotational band with $K=0$, we find now $R4/2=3.33$. However, states with different K-values are degenerated. This is not found in real deformed nuclei.

If the inertia tensor is such that $\mathfrak{I}_1 \neq \mathfrak{I}_2 \neq \mathfrak{I}_3$, an asymmetric top problem results. In this case, the wave functions are to be expanded in terms of the symmetric-top functions:

$$|LM\rangle = \sum_{K=-L}^{+L} A_K \, |LMK\rangle \tag{1.47}$$

The 1, 2, 3 labels of the momental ellipsoid's semiaxes are quite arbitrary and can be chosen in 24 different ways for right- (left-) handed systems. These 24 relabelings can be produced by three different relabeling transformations T_1, T_2, and T_3 [32], which correspond to label interchanges and operate on the $|LM>$ wave functions. They have the properties

$$T_1^2 = T_2^4 = T_3^3 = 1 \tag{1.48}$$

From these relations, one can generate Table 1.1, relating the four representations and the values of angular momentum and parity allowed in each. Note in particular that the A and B_2 representations are associated with positive-parity $(\pi=+)$ states, while B_1 and B_3 representations are associated with negative parity $(\pi=-)$

Table 1.1 The representation of the point group D_2 to which the states belong, and the allowed values of the angular momentum and parity associated with them.

Representation	K	Parity	Allowed L-values
A	Even	$+$	$L=0,2,2,3,4,4,4,5,5$
B_1	Even	$-$	$L=1,2,3,3,4,4,5,5,5$
B_2	Odd	$+$	$L=1,2,3,3,4,4,5,5,5$
B_3	Odd	$-$	$L=1,2,3,3,4,4,5,5,5$

states. From this table, we note that only the rigid rotator systems belonging to the A representation have a zero angular momentum state. They must be associated with the lowest levels of even–even nuclei and form the $K=0$ ground-state band with $K=0$ and $L=0, 2, 4, 6, \ldots$ followed by the γ-vibrational band with $K=2$ and $L=2, 3, 4, 5, \ldots$.

Negative-parity states in even–even nuclei could be associated with either the B_1 or B_3 representations. If one argues that, given two (or more) possibilities, the lowest set of states will be the most symmetric, then because the B_1 representation arises from sums over even K quantum numbers, one should associate this representation with the lowest-lying negative-parity states in even–even systems. Furthermore, in the deformed regions, the negative-parity bands in these nuclei not only lie above the ground-state rotational band but they also have as their band head a 1^- level. This is another indication that these negative-parity rotational bands belong to the B_1 representation.

The problem of solving the asymmetric, rigid rotor is far more involved than the symmetric rotor as all of the latter's eigenvalues can be given in closed form. To proceed along this line, one sets $\mathfrak{I}_0=\mathfrak{I}_1=\mathfrak{I}_2\neq\mathfrak{I}_3$. The Hamiltonian of the system then becomes

$$\widehat{H}_{\text{sym}}=\frac{1}{2}\left(\frac{\widehat{L}_1^2+\widehat{L}_2^2}{\mathfrak{I}_0}+\frac{\widehat{L}_3^2}{\mathfrak{I}_3}\right)=\frac{1}{2}\left(\frac{\widehat{L}^2}{\mathfrak{I}_0}+\left(\frac{1}{\mathfrak{I}_3}-\frac{1}{\mathfrak{I}_0}\right)\widehat{L}_3^2\right) \quad (1.49)$$

and both of the operators appearing are diagonal. Thus, we obtain immediately the eigenvalues

$$E_{\text{sym}}=\frac{h^2}{2}\left(\frac{L(L+1)}{\mathfrak{I}_0}+\left(\frac{1}{\mathfrak{I}_3}-\frac{1}{\mathfrak{I}_0}\right)K^2\right) \quad (1.50)$$

This expression is model independent and only depends upon the ratio of the moments of inertia $\mathfrak{I}_0/\mathfrak{I}_3$. There have been recent observations of "superdeformation" for rare earth nuclei with spheroidal-axes ratios of 2 : 1. For symmetric rotational systems with $K=0$, the ratio $R4/2$ is 10/3 rather than 2 for the vibrational systems. Thus, this ratio differentiates well between rotational and vibrational systems. In recent years, there was quite some interest in how these shape changes occur [33, 34], as they can be treated as quantum-phase transitions. Atomic nuclei that have an $R4/2$ ratio of around 2.9 lie at the critical point of the spherical-deformed phase transition.

1.6.5
Odd-A Nuclei

1.6.5.1 Single-Particle Levels

Near the magic numbers, the ground and lower excited states appear to be mainly single-particle states, that is, states that do not seem to possess collective properties. For instance, near the doubly magic nucleus $^{16}O_8$, one finds that both $^{15}N_8$ and $^{15}O_7$ have $1/2^-$ ground states and nearly identical lower excited states. This shows that the $N=Z=8$ shell is filled by a $p_{1/2}$ orbit. Above the closed shell are $^{17}F_8$ and $^{17}O_9$ both of which have the expected $5/2^+$ ground state from the $d_{5/2}$ orbit. These data clearly support the notion that angular momentum shells are filled in a manner similar to the electronic shells of the elements.

1.6.5.2 Vibrational Levels

The nucleons all possess intrinsic spin 1/2 and angular momentum l, so that the simplest model for vibrational odd-A nuclei that one might construct is to add a single nucleon to an even–even core in which the nucleons of each kind pair to zero angular momentum. If the core is a good vibrational nucleus ($R4/2 \sim 2$), then the ground state of the odd-A system will have the angular momentum properties of the odd nucleon. Furthermore, by coupling this nucleon to the excited states of the core, one should expect to be able to determine the angular momenta of the odd-A nucleus's excited states. An example is the coupling of a neutron to the vibrational nucleus $^{110}Cd_{62}$ (Section 1.6.2) to yield the odd-A nucleus $^{111}Cd_{63}$, which has a ground-state spin of $1/2^+$. One might expect that there would be two excited states built on the first excited 2^+ state with spins $3/2^+$ and $5/2^+$. This nucleus does indeed have a $3/2^+$, $5/2^+$ pair as its first excited states, which are at 245.4 and 342.1 keV. Coupling of the $1/2^+$ neutron with the two-phonon states would lead to excited state spins from $1/2^+$ through $9/2^+$. Such a set of states does appear at higher energies. However, it is difficult to pick out which states might belong to the two-phonon core states. Below them there is a first negative parity state with spin $11/2^-$ at 396.22 keV, which indicates that one has the presence of a low-lying $h_{11/2}$ neutron orbit.

1.6.5.3 Rotational Levels

One might expect that a simple model for the odd-A rotational levels would follow that of the vibrational levels. However, the experimental data do not show such a similar structure. As an example we consider $^{157}Gd_{93}$ which has a $3/2^-$ ground state. Following the reasoning for vibrational nuclei, one expects from the coupling with the first excited 2+ state a multiplet with spins $1/2^-$, $3/2^-$, $5/2^-$, and $7/2^-$. Instead, one observes a rotational-like band with the spin sequence: $5/2^-$, $7/2^-$, $9/2^-$, $11/2^-$, ... This is due to the fact that the ground-state band has also a given value of K and we conclude that $K=3/2$.

1.6.6
Odd–Odd Nuclei

As noted in Section 1.6.1, there are only four stable odd–odd nuclei; however, a great deal of data exist for all of this class of nuclei. Again, one might feel that these nuclei would be well represented by an even–even core plus a neutron–proton pair. Even if these are coupled to a spin-zero core, there is still considerable ambiguity as to how these couple to form the ground-state spin of the system. For instance, if the proton and neutron angular momenta are j_p, j_n, respectively, then their vector sum can lead to the range of J values

$$\left|j_{\rm p} - j_{\rm n}\right| \leq J \leq j_{\rm p} + j_{\rm n} \qquad (1.51)$$

One can obtain the values of $j_{\rm p}$ and $j_{\rm n}$ from the ground-state spins of the neighboring odd-A nuclei with one less neutron or one less proton, respectively. In order to determine more exactly the range of the possible ground-state spins of these nuclei, one must make use of Nordheim's rules, which are the following:Strong rule, for $\eta = 0$:

$$J = \left|j_{\rm p} - j_{\rm n}\right| \qquad (1.52)$$

Weak rule, for $\eta = \pm 1$:

$$J = \left|j_{\rm p} - j_{\rm n}\right| \ \text{ or } \ j_{\rm p} + j_{\rm n} \qquad (1.53)$$

with

$$\eta = (j_{\rm p} - l_{\rm p}) + (j_{\rm n} - l_{\rm n}) \qquad (1.54)$$

In general, these do not work all of the time. To predict the excited states spins is even more difficult, making odd–odd nuclei the most difficult to describe.

1.7
Nuclear Models

1.7.1
Introduction

The nucleus, being a many-body collection of A particles interacting through a short range but strong force, is not easily dealt with. From a theoretical point of view, making use of an accurate many-body calculation is impossible because these are beyond the scope of current theoretical methods. Thus, calculations based upon various simple models are able to provide a good deal of physical insight as well as making predictions of measurable properties, providing a way to categorize the vast amounts of data available from nuclear physics laboratories. While these approaches may seem to be organized in an historical order, all are to greater or less extent being continuously refined.

The nuclear many-body problem is not solved definitely, owing to the large number of strongly interacting particles. To illustrate the difficulties, we take the example of ^{208}Pb. If we consider up to two-body interactions between the nucleons, the general Hamiltonian is given by

$$H = \sum_{i=1}^{208} t_i + \frac{1}{2}\sum_{i \neq j}^{208} V_{ij} \qquad (1.55)$$

The radius of this nucleus is 7 fm, while the strong force between two nucleons varies significantly on the scale of 0.2 fm. If one would calculate only the two-body interaction on a mesh, one should foresee for each nucleon at least 100 mesh points in each direction and for all 208 nucleons the number of possible combinations would be $100^{3.208}$. For a fast computer today 10^9 operations per second are feasible, which gives 10^{16} operations per year. Thus to perform the calculation one would need 10^{1232} years, while the age of our universe is only 2×10^{10} years.

As an exact treatment is impossible, one of the major characteristics of nuclear structure calculations is the choice of the right approximations and truncations needed to make a calculation feasible while keeping the essential physics. Of great help thereby is the extensive use of symmetry concepts, which allow one to simplify the many-body problem and make the calculations tractable. Many quite different approaches have turned out to be successful for certain classes of atomic nuclei. Most theoretical models rely on spherical symmetry, which allow the use of the very powerful ‘‘Racah machinery,’’ originally developed for atomic physics by Guilio Racah. The introduction of irreducible tensors and coupling coefficients then provides the necessary technical skills to perform nuclear structure calculations.

The first approach is based on the experimental observation of magic numbers and leads to the nuclear shell model as described in Section 1.7.2. In Section 1.7.3 we introduce the deformed shell model, which allows the description of medium-heavy nuclei that are deformed. Section 1.7.4 is devoted to the collective model in which medium heavy and heavy nuclei are described by a quantum liquid droplet.

In Section 1.7.5, we will deal with a new theoretical approach to many-body problems originating from nuclear physics: the interacting boson approximation (IBA). Although the IBA is a method that was developed to describe the atomic nucleus, it has since been applied to molecules, quarks, and fullerenes. The major assumption of the interacting boson model (IBM) is twofold. First, because of the shell structure evinced by many experiments, only the valence nucleons are considered to be important for the low-energy excited states of the atomic nucleus. Those move to a first approximation in orbits formed by their commonly created average field, which is spherical symmetric. Secondly, between like nucleons, either protons or neutrons, there is a dominant pairing force when they occupy the same orbit. This allows to replace coupled fermion pairs by real bosons that are simpler to deal with.

1.7.2
The Spherical-Shell Model

One of the first and best understood nuclear models is the nuclear shell model. The major assumption of this model is that nucleons up to a good approximation move independently in a spherically symmetric averaged field $U(r_i)$ created by the other nucleons. This means that the many-body Hamiltonian is rewritten as

$$H = H_0 + V_{\text{res}} \tag{1.56}$$

with

$$H_0 = \sum_{i=1}^{N} t_i + \sum_{i=1}^{N} U(r_i) \tag{1.57}$$

and the residual interaction V_{res} is given by

$$V_{\text{res}} = \frac{1}{2}\sum_{i\neq j}^{N} V_{ij} - \sum_{i=1}^{N} U(r_i) \tag{1.58}$$

The shell model uses the ansatz (Eq. (1.57)) in which the single particles move in a potential well provided by the other particles. While it might seem improbable that nuclei made up of a large number of strongly interacting particles could in any way be represented by such a model, one must recall that the Pauli principle prevents most interactions of a nucleon in the nucleus. In general, scattering cannot take place, as most of the states into which a low-energy nucleon can scatter are filled. This implies that the mean free path for nucleon motion is quite long, and a single-particle model is worth exploring.

One obvious and important characteristic of odd-A nuclei is their ground-state spins and parities. Starting with the lightest nuclei, the general order of odd-A ground-state spins and parities is $1/2^{+}$ for neutron and proton and after the strongly bound ^{4}He $3/2^{-}$, $1/2^{-}$ then, after $^{16}O_8$, it becomes $5/2^{+}$, $3/2^{+}$, $1/2^{+}$ and then, after $^{40}Ca_{20}$, $7/2^{-}$, $5/2^{-}$, $3/2^{-}$, $1/2^{-}$ an order reminiscent of the atomic shells in which the alternating parities are related to the orbital angular momentum suggesting a sequence: s-p-d and s-f and p to which a spin one-half is coupled. To obtain a model with such an ordering of angular momentum l-values requires solving a single-particle Schrodinger equation with a reasonable potential function. The form of this potential is not too important because only minor changes in l-value order occur using one or another r dependence. The two simplest to calculate are the isotropic harmonic oscillator and the infinite square well. The latter is not realistic because the nucleon separation energy is quite finite and well-known for most nuclei. (One might also consider a potential function related to the charge distributions of Eqs. (1.16) and (1.19); however, these would require extensive numerical computing to extract the eigenvalues.) The angular momentum order of the levels and the number of particles in each for the isotropic harmonic oscillator is 1s (2); 1p (6), 1d, 2s (12); If, 2p (20); lg, 2d, 3s (30); and so on. (The semicolons separate the levels with different quanta of energy $\hbar\omega$, and most are degenerate.) The total number of levels thus becomes 2, 8, 20, 40, 70, 112, 168, which only agrees with the lowest observed "magic numbers" 2, 8, 20, 28, 50, 82, and 126 (cf. Section 1.6.1).

It took the genius of Maria Goeppert Mayer [35] and others [36] to realize that by adding a spin–orbit term of the form

$$V_{\mathrm{ls}} = -V(r)\,\vec{l}\cdot\vec{s} \tag{1.59}$$

the theoretical order could be brought into agreement with that observed. The minus sign guarantees that the $j = l + 1/2$ level will lie below the $j = l - 1/2$ level, as observed and the dependence on l makes that the effect increases with l leaving the shell closures at 2, 8, 20 unaffected while introducing a new shell closure at 28 due to the lowering of the $1f_{7/2}$ orbit. Further, the observed closures at 50, 82, 126, are obtained in a natural way. Also the spins of the odd-A ground states is mostly correctly predicted. The shell model explains via large gaps between the single-particle orbital energies the large binding energies of nuclei having Z or N a magic number making the number of stable isotopes/isotones particularly large, for example, there are 10 stable Sn isotopes with $Z = 50$. For the excited states, magic nuclei show them at very high excitation energies as one needs to break the closed shell and lift one particle over the large shell gap. As an example in the doubly magic nucleus ^{208}Pb, an energy of 2.6 MeV is needed to create the first excited 3^{-} state and even 4.085 MeV for the 2^{+} state.

The robustness of double-magic nuclei allows a major truncation for shell model calculations. It turns out that they can in first instance be treated as inert cores, whereby the spins of all of the particles in the core pair off to zero. Thereby, only the so-called valence nucleons need to be considered. This is of importance as with increasing number of nucleons and possible orbitals, the shell model allows for many different configurations. As angular momentum and parity are conserved, the residual interaction used can be diagonalized separately for a given spin and parity. Nevertheless, the dimensions become quickly huge.

Although the shell model is one of the older nuclear models, it has become of increasing use in the last decades. This is due to two key aspects. The first is the tremendous increase in computing power allowing large-scale shell model codes to be developed, including quantum Monte Carlo diagonalization. The second is the construction of effective *in medium* interactions starting from the nucleon–nucleon scattering data. Hereby the elimination of the hard core repulsion of the nucleon–nucleon interaction was crucial and produced a universal, so-called $V^{\text{low-}k}$ interaction. The recent progress opens the direct way from quantum chromodynamics (QCD) to the effective interactions, which is in particular very much needed for the study of exotic nuclei. The most involved calculations are done for light nuclei up to ^{11}B. Here no-core shell model calculations are able to describe accurately binding energies and excited states for very light nuclei [37].

1.7.3
The Deformed Shell Model

As the very large quadrupole moments of the nuclei in the middle of the higher shells cannot be explained by the simple spherical model, their explanation requires large contributions from the even–even core, which carries all (or almost all) of the charge. It can be shown that a single-particle moving in a nonrigid potential well will have a lower energy if the well is not spherical, rather than if it is spherical. As the lowering of the particle energy is proportional to the eccentricity, such a system will assume a deformed equilibrium shape. The nuclear Hamiltonian will now contain a term that produces deviations from spherical:

$$H = H_0 + H_\text{d} - V_\text{ls}(r) + \text{c}l^2 \tag{1.60}$$

where H_0 is the isotropic harmonic oscillator Hamiltonian and $V_\text{ls}(r)$ is the spin–orbit term, both of which have proved so successful for the spherical-shell model. (The l^2 term helps give the proper level order in the isotropic limit.) Expanding the nuclear surface in spherical harmonics gives

$$S(\theta,\phi) = R_0 \left[a_0 + \sum_{\lambda>1,\mu} a_{\lambda\mu} Y_{\lambda\mu}(\theta,\phi) \right] \tag{1.61}$$

where R_0 is the radius of the spherical nucleus and a_0 is unity to quantities of second order and assures that the volume remains constant for small deformations. Taking the lowest order, one has that

$$S(\theta,\phi) = R_0 \left[1 + \sum_{-2}^{+2} a_{2\mu} Y_{2\mu}(\theta,\phi) \right] \tag{1.62}$$

[This expression should be compared with the nuclear charge distribution of Eq. (1.19).] It is customary to take only the symmetric term a_{20} in this equation to be nonzero. This then leads to the deformation term in the Hamiltonian

$$H_\text{d} = -Ka_{20}\omega_0^2 r^2 Y_{20}(\theta,\phi) \tag{1.63}$$

The full Hamiltonian can now be diagonalized using a set of spherical shell model basis states, and the resulting deformed, single-particle states are called *Nilsson* states after Sven Gosta Nilsson [38], who first carried out this diagonalization. The operators in Eq. (1.60) do not connect oscillator states differing by one principal oscillator quantum number, N, but do connect states differing by two. Nilsson neglected matrix elements not diagonal in N. This is a reasonably good assumption as oscillator states differing by $N = 2$ are rather far apart, except for states belonging to large N and large deformation (i.e., nuclei with large A and large quadrupole moments). The Nilsson levels are labeled $\Omega|N,n_3,\Lambda]$. The symbol Ω is the projection of the particle angular momentum j on the three axes of the body-fixed axis system and is a good quantum number. In the limit of very large deformations, the single-particle energy is given by

$$E = \left(n_3 + \frac{1}{2}\right)\hbar\omega_3 + (n_\perp + 1)\hbar\omega_\perp \tag{1.64}$$

where the symbol ω_3 is the oscillator frequency along the symmetry axis and the symbol $\omega_\perp$ is the oscillator frequency in the perpendicular directions. Thus, in the limit of very large deformations, one has $N = n_3 + n_\perp$. In this same limit, the projection of the orbital angular momentum on the symmetry axis becomes the last label,

$$N = \pm n_\perp, \pm n_\perp - 2, \ldots, \pm 1 \text{ or } 0 \tag{1.65}$$

This scheme is used to label not only the ground states of deformed nuclei but also the excited state rotational band heads. The level order will now be L, $L+1$, $L+2$, …, as a result of core rotation, so that, when a level does not fit into this sequence, it must belong to a different single-particle band. One now proceeds to assign quantum numbers to the states by determining the odd-nucleon number; then, because the Nilsson energy levels are plotted against the core deformation, one assigns the deformation by finding that place where a Nilsson level appears with the measured ground-state spin. The next Nilsson level up should give the excited-band head, and so on. As an example, consider the nucleus $^{173}\mathrm{Lu}_{102}$, which has a $7/2^+$ ground state. Following the procedure above, the appropriate level is the 7/2[404], with excited members $9/2^+$, $11/2^+$, $13/2^+$. Just above the $9/2^+$ level is a close doublet with spins $5/2^-$, $1/2^-$, which has been assigned to the 1/2[541] Nilsson level. The $3/2^-$ level belonging to this band lies above the $9/2^+$ state. This nonuniform order of a 1/2 band is an example of Coriolis coupling, which mixes the level order of $\Omega = 1/2$ bands.

1.7.4
Collective Models of Even–Even Nuclei

In Section 1.6.4.2, where the rotational-level structures of even–even nuclei were discussed, it was pointed out that the moments of inertia play a crucial role to describe the atomic nucleus as a rigid-body momental ellipsoid. Bohr [32] proposed a model of the momental ellipsoid and thus of deformed even–even nuclei and the cores of odd-A and odd–odd nuclei. Several important assumptions were made in order to extract these moments of inertia. The first is that the nuclear core is incompressible, so that the nuclear density is constant. Second, the flow is assumed to be irrotational, so that a velocity potential exists and satisfies Laplace's equation. Finally, it must be assumed that the motion is such as to preserve the principal axis system. The moments of inertia for quadrupole deformations then are

$$\Im_k^2 = 4B_2\beta^2\sin^2\left(\gamma - \frac{2\pi}{3}k\right) \tag{1.66}$$

Here B_2 and β are the quadrupole mass and deformation parameters, while γ is an asymmetry parameter whose range is $0 \le \gamma \le \pi/6$. There are similar relations for other deformations such as octupole ($Y3$), hexadecapole ($Y4$), and so on. The Hamiltonian for this system is now

$$H_{\text{quad}} = \frac{1}{2}B_2(\dot{\beta}^2 + \beta^2\dot{\gamma}) + \frac{1}{B_2\beta^2}\sum_{k=1}^{3}\frac{L_k^2}{\sin^2\left(\gamma - \frac{2\pi}{k}\right)} + \frac{1}{2}C_2\beta^2 \tag{1.67}$$

If the system is not rigid, then the deformation and asymmetry parameters are no longer fixed, and the system can execute either deformation (β) vibrations or asymmetry (γ) vibrations, or both. The β-vibrational bands have angular momentum 0 – they are akin to molecular "breathing" modes – and the γ-vibrational bands have angular momentum 2. Thus, nuclei will exhibit ground-state bands where $n_\beta = 0$ and $n_\gamma = 0$, β-bands $n_\beta = 1$, $n_\gamma = 0$), γ-bands ($n_\beta = 0$, $n_\gamma = 1$), and higher order bands. Although the β-vibrations are the simplest, they are not really well established [39], much better established are γ-bands of which double excitations with $n_\gamma = 2$ are found in nature [40].

In his original paper, Bohr [32] argued that the nucleus would stabilize around $\gamma = 0$, so that the momental ellipsoid was symmetric (long and thin, cigarlike), while the surface itself was spheroidal. Then $\mathfrak{I}_3 = 0$. This leads to difficulties as Eq. (1.50) shows that the energy eigenvalues become infinite unless $K = 0$. Thus, the ground-state bands of even–even nuclei have $K = 0$, and the angular momentum sequence becomes 0, 2, 4, 6, . . . , which is what is observed. These models automatically conform to the A representation. Again, if the system is not rigid, against β-vibrations, there will be one or more β-bands above the ground-state rotational band that mimic the ground-state band in spin sequence, but because $<\beta^2>$ will be greater than for the ground state, the levels will be closer together.

Finally, in this model if γ is not constant, γ-vibrations can arise with angular momentum 2. (One might think of these as equatorial bulges moving around the nuclear equator. They are akin to the well-known Jacobi ellipsoids of a self-gravitating, rotating fluid.) These γ-vibrations then produce a γ-band that is different in spin sequence from the β- and ground-state bands. This occurs because $K_\gamma = 2$, not 0. The γ-band sequence is 2, 3, 4, 5, ... There can be several γ-bands with different K values and different spin sequences. The lowest one has $K_\gamma = 2$, while the next will have $K_\gamma = 0$ and 4, and so on.

It must be made clear that the Bohr model is only applicable for the low-lying positive-parity levels. The negative-parity levels belonging to the B_1 representation have moments of inertia that are considerably more complicated as they represent an octupole or pearlike shape.

An example of a well-developed rotational system is $^{154}\text{Sm}_{92}$ where $R4/2 = 3.25$. This nucleus has a well-developed ground-state rotational band with the spin sequence 0^+, 2^+, 4^+, . . . , 12^+ with the first excited state rather low in energy at 81.99 keV. It has a β-band with a 0^+ band head 1099.28 keV, followed by the first excited 2^+ state at 1177.78 keV ($\Delta E = 78.52$ keV). This is a striking example of the increase in the moment of inertia due to the quantum of β-vibrational energy. Furthermore, the $K = 2$ γ-band, with sequence 2^+, 3^+, 4^+, . . . , starts at 1440.05 keV.

Also to be seen is an octupole band starting with the 1^- level at 921.39 keV, followed by the 2^-, 3^-, 5^-, . . . in the expected order. Thus, one sees four well-developed rotational bands fitting quite nicely into the model scheme.

Further, the collective behavior manifests itself in the quadrupole moments and electric quadrupole transitions. The axially symmetric core collective model yields for a state with quantum numbers K and I a laboratory quadrupole moment Q:

$$Q = \frac{3K^2 - I(I+1)}{(I+1)(2I+3)} Q_0 \tag{1.68}$$

with an intrinsic quadrupole moment Q_0 given by

$$Q_0 = \frac{3}{\sqrt{5\pi}} Z R_0^2 \beta (1 + 0.16\beta) \tag{1.69}$$

The fact that by definition K has to be lower than I (Eq. (1.74)) produces almost always a change of sign between intrinsic and laboratory quadrupole moments. Related to the intrinsic quadrupole moments are the $B(E2)$ values. In between states belonging to a given K band, they are given by

$$B(E2;\, I_i \to I_f) = \frac{5}{16\pi} e^2 Q_0^2 \left\langle I_i K 20 | I_f K \right\rangle^2 \tag{1.70}$$

When comparing Eq. (1.70) directly with the data, one often extracts the transition quadrupole moment Q_t as being the Q_0 value obtained for a given transition. A very useful relation is obtained for $B(E2)$ ratios between states belonging to bands having different K quantum numbers. These relations are called the *Alaga rules* and yield

$$\frac{B(E2;\, I_i \to I_f)}{B(E2;\, I_i \to I'_f)} = \left(\frac{\left\langle I_i K 2 \Delta K | I_f K_f \right\rangle}{\left\langle I_i K 2 \Delta K | I'_f K_f \right\rangle} \right)^2 \tag{1.71}$$

whereby $\Delta K = K_f - K$ as is expected for an angular momentum projection quantum number. Using the Alaga rules it is possible to determine the K values of rotational bands.

If one does not follow the Bohr assumption that the nucleus will stabilize around $\gamma = 0$ but around some other value within its range, then one has to deal with an asymmetric rotator, which will have a considerably more complicated eigenvalue structure. Davydov and Filippov [41] made an extensive investigation and showed that one obtained better results with such a model than with a symmetric one. However, one loses the computational simplicity of the symmetric model.

1.7.5
Boson Models

The models discussed up until now and that have been used most extensively would seem to be almost mutually exclusive. The shell model and its modifications, such as Nilsson's extension to a deformed system, focus on the single-particle aspects of nuclear structure. On the other hand, the collective model of Bohr and Mottelson, and extensions, place the emphasis on the cooperative, or fluid, aspects of these systems. Thus, they seem to stand apart and be almost unrelated. This has led to the next step, the investigation of models that are called *microscopic models* or *calculations*. These include pairing models (similar to the Bardeen–Cooper–Schriefer theory of superconductivity) and the random-phase approximation, to name but two. A more recent and still developing set of microscopic models is called the *interacting boson models*, which we present here briefly.

The solutions of the nuclear shell model lead to single-particle orbits that can be occupied by the neutrons and protons. Because of the Pauli principle, each nucleon in an atomic nucleus can occupy only different orbits. It turns out that once more the short range of the nuclear force leads to a dominant component when one wants to take account of the residual interaction. The dominant component is called *pairing interaction* and energetically favors the formation of nucleon pairs made out of two nucleons moving in orbits |njm> and |nj-m>, coupling to a two-nucleon state with total spin $J = 0$. To a lesser extent, the formation of nucleon pairs with spin $J = 2$, 4, 6 in that sequence is also favored. As the number of protons and neutrons is generally different in not too light nuclei, the single-particle orbits occupied by both will generally be very different and thus the pairing will be effective only between like nucleons (either protons or neutrons). When one is mainly interested in the low-energy excitations of the atomic nucleus, one can treat this structure in terms of interacting, nucleon pairs via the residual interaction. However, a many-body problem composed of paired fermions, although more correct, is still very difficult to solve. Instead by replacing these $n = n_\nu + n_\pi$ fermions by

$$N = \frac{n_\nu + n_\pi}{2} \tag{1.72}$$

real bosons with $L = 0$, 2 (and eventually 4, 6, ...), one has enormously simplified the original n-body problem. For instance, one does not need to bother about which orbits are occupied by the protons and neutrons, while keeping the essential physics. This is the essence of what is now called the *interacting boson approximation*, which was proposed and elaborated by Iachello and Arima in the second half of the 1970s [42].

The simplest version of the model is called *IBM-1* and deals with s ($L = 0$) and d ($L = 2$) bosons. Considering the constraint that the number of bosons is fixed $N = n_\mathrm{s} + n_\mathrm{d}$ and limiting the Hamiltonian to one- and two-body interactions, one obtains the multipole expansion form

$$\begin{aligned}\widehat{H} = \varepsilon \widehat{n}_d + c_1 \widehat{L} \cdot \widehat{L} + c_2 \widehat{Q} \cdot \widehat{Q} \\ + c_3 \widehat{T}_3 \cdot \widehat{T}_3 + c_4 \widehat{T}_4 \cdot \widehat{T}_4\end{aligned} \tag{1.73}$$

with the operators

$$\widehat{L}_m = \sqrt{10} (d^\dagger \times \widetilde{d})^{(1)}_m \tag{1.74a}$$

$$\begin{aligned}\widehat{Q}_m = \quad & (s^\dagger \times \widetilde{d} + d^\dagger \times s)^{(2)}_m \\ & + \chi (d^\dagger \times \widetilde{d})^{(2)}_m\end{aligned} \tag{1.74b}$$

$$\widehat{T}_{3m} = (d^\dagger \times \widetilde{d})^{(3)}_m \tag{1.74c}$$

$$\widehat{T}_{4m} = (d^\dagger \times \widetilde{d})^{(4)}_m \tag{1.74d}$$

The factor $\sqrt{10}$ is used in order to make the dipole operator an angular momentum operator and the first term in Eq. (1.73) contains the d-boson number operator. The multipole expansion has six free parameters of which two are needed for the quadrupole–quadrupole interaction. The use of the multipole expansion is especially advantageous because numerical studies have shown that the values of the octupole and hexadecapole interaction are generally very small. Thus, up to a good approximation, one can describe a variety of atomic nuclei at low excitation energies by the simple four-parameter Hamiltonian:

$$\widehat{H}^\chi = \varepsilon \widehat{n}_d + c_1 \widehat{L} \times \widehat{L} + c_2 \widehat{Q}^\chi \times \widehat{Q}^\chi \tag{1.75}$$

The index in Eq. (1.75) makes explicit that the quadrupole operator contains an additional parameter.

Of importance in the development of the IBM is the use of dynamical symmetries providing analytic solutions of the many-body problem. Because there are in total six distinct bosons when considering the magnetic projections, the symmetry of the many-body problem is $U(6)$ while the physical symmetry is given by SO(3) the Lie algebra of the angular momentum. Three dynamical symmetries are obtained. They can be schematically represented by the chains

$$U(6)\left\{\begin{array}{l}\left.\begin{array}{l}\supset U(5)\\ \supset O(6)\end{array}\right\} \quad \supset O(5)\\ \supset SU(3)\end{array}\right\} \supset O(3) \tag{1.76}$$

Each of the three chains can be used to provide a complete basis to analytically solve the N s, d boson model. One can also rewrite the general Hamiltonian as a combination of all previously determined Casimir operators:

$$\begin{aligned}\widehat{H} = {} & \varepsilon C_1[U(5)] + \alpha C_2[U(5)] \\ & + \delta C_2[SU(3)] + \eta C_2[O(6)] \\ & + \beta C_2[O(5)] + \gamma C_2[O(3)]\end{aligned} \tag{1.77}$$

where we have omitted all constant terms that contribute only to the binding energies. The Casimir form Eq. (1.77), like Eq. (1.73), contains six parameters and, once more, all three forms can be transformed into each other. The advantage of the form Eq. (1.77) lies in the fact that the three different limits correspond to three classes of atomic nuclei: vibrational, rotational, and γ-unstable nuclei correspond to the Hamiltonian with $\delta = \eta = 0$ ($U(5)$ limit), $\varepsilon = \alpha = \eta = \beta = 0$ (SU(3) limit) and $\varepsilon = \alpha = \delta = 0$ ($O(6)$ limit) . In these cases, closed analytic expressions for excitation energies and wavefunctions can be obtained [42]. Two of the limits already had known counterparts in the collective model. It was the discovery of the third, the $O(6)$ limit, in the Pt nuclei at the end of the 1970s [43], that boosted the use of the model. Soon it became evident that it formed a good approximation for the nuclear many-body problem in many nuclei. Outside the limits the model needs to be solved numerically and the transitional nuclei can be described.

The IBM-1 model describes only positive-parity levels of even–even nuclei. To describe negative-parity states, one must use negative parity p and f bosons constructed in a similar way to the s and d bosons. Furthermore, the IBM-1 has no explicit neutron–proton degree of freedom. This is introduced in the IBM-2 where a neutron–proton label is introduced for the s and d bosons. As the neutron and proton bosons are distinguishable, the IBM-2 leads to new sets of states, called *mixed symmetry states* (in the neutron–proton degree of freedom). Furthermore, analytical solutions can be derived for the IBM-2 [44]. Mixed symmetry states have been observed in many atomic nuclei, especially in deformed nuclei where the lowest state is a 1^+ state called the *scissor state* [45], and also recently in vibrational nuclei [46].

Finally, if one wants to describe odd-A nuclei, a model denoted interacting boson–fermion model (IBFM) must be used. Odd-A nuclei always have an unpaired nucleon that cannot form an s or d boson because a partner is missing. Therefore, an odd–even nucleus is described in the model with N bosons and one fermion, the unpaired nucleon, which can occupy several orbitals j. In addition, for such systems dynamical symmetries, called *Bose–Fermi symmetries*, can be used, although their elaboration is much more complex [47]. The symmetry starts then from the product $U^{\mathrm{B}}(6) \times U^{\mathrm{F}}(M)$ with

$$M = \sum_j 2j + 1 \tag{1.78}$$

and ends with SU(2). In 1980, a daring extension of the model was proposed [48]. Using supersymmetry, the structure of some odd–even nuclei could be related

to that of the much simpler even–even nuclei via the embedding of the dynamical symmetries in a supersymmetry:

$$\begin{array}{ccccc} U(6/M) & \supset & U^{\mathrm{B}}(6) & \times & U^{\mathrm{F}}(M) \\ | & & | & & | \\ [N] & & [\mathrm{N}] & & [1^{m}] \end{array} \qquad (1.79)$$

connecting the N s, d bosons + 1 fermion problem to the N + 1 boson problem by the supersymmetric reduction rule $N = \mathrm{N} + m$. This embedding when realized in nature would reveal itself through the possibility to describe excited states in an odd–even nucleus and in the adjacent even–even nuclei using a common set of quantum numbers and parameters related via the supergroup. If dynamical symmetries are required, only a limited class of atomic nuclei can be described in this way. During the 1980s, experimental evidence was accumulated, but unfortunately it was not possible to determine completely the structure of the odd–even nucleus starting from the even–even nucleus alone.

Later an extension of supersymmetry was proposed, which incorporates a distinction between neutrons and protons. This extended supersymmetry allows one to describe a quartet of nuclei in a common framework. This quartet, called a *magic square*, consists of nuclei having the same total number of bosons (paired nucleons) and fermions (unpaired nucleons). It consists of an even–even nucleus, two odd–even nuclei and an odd–odd nucleus. The latter is interesting in two respects: its energy spectrum can be predicted from those of the other three members and heavy odd–odd nuclei are the most complex objects found in low-energy nuclear structure. If dynamical supersymmetry is able to describe these nuclei, which could not be described by other theoretical models, strong evidence for its existence can be obtained. This development is of importance not only for nuclear physics but for all other applications of supersymmetry in physics.

The odd–odd nucleus ^{196}Au is considered to be the ultimate test of supersymmetry in nuclear physics for three reasons. It is situated in a region of nuclei that was known to exhibit dynamical symmetries and supersymmetries. At the same time, it is the most difficult mass region in which to describe odd–odd nuclei. Finally, when its excitations with negative parity were predicted in 1989 on the basis of the three other nuclei, none of them were experimentally known. In a detailed spectroscopic study the excited states of ^{196}Au were determined and a good agreement with the supersymmetric model was obtained [49]. The results of this combined effort are illustrated in Figure 1.6. They reveal good agreement with the analytical prediction:

Figure 1.6 The lowest observed states (b), are compared to the theoretical result (a) for the four members of the quartet (note that one is dealing with holes in the doubly closed shell nucleus ^{208}Pb). The even–even nucleus ^{194}Pt, the negative parity states in the odd-neutron nucleus ^{195}Pt, the positive parity states in the odd-proton nucleus ^{195}Au and the negative-parity states in the odd–odd nucleus ^{196}Au up to 500 keV can be described using the formula (Eq. (1.88)) based on dynamical supersymmetry. Not shown are higher-lying states of the even–even and odd–even nuclei, which are also described by supersymmetry. Together with the spin and parities, the quantum numbers $[N_1,N_2]$, $<\Sigma_1,\Sigma_2>$, $<\sigma_1,\sigma_2,\sigma_3>$, and (τ_1,τ_2) are also indicated. (Based on [49].)

$$\begin{aligned}E = {} & A(N_1(N_1+5)+N_2(N_2+3)) \\ & +B(\Sigma_1(\Sigma_1+4)+\Sigma_2(\Sigma_2+2)) \\ & +B'(\sigma_1(\sigma_1+4)+\sigma_2(\sigma_2+2)+\sigma_3^2) \\ & +C(\tau_1(\tau_1+3)+\tau_2(\tau_2+1)) \\ & +DL(L+1)+EJ(J+1) \qquad (1.80)\end{aligned}$$

obtained using dynamical supersymmetry.

Glossary

Bosons: Quantum particles obeying Bose–Einstein statistics, so having integral spin.

Daughter: In a radioactive decay in which the radioactive nucleus A decays into nucleus B the nucleus B is said to be the daughter of nucleus A.

de Broglie wavelength: The wavelength λ of a particle given by the relation $\lambda = hp$, where h is Planck's constant and p the momentum of the particle.

Decay constant λ: If N nuclei are present at time t, then the decay constant is given by the number of decaying nuclei $-\mathrm{d}N/\mathrm{d}t$ divided by N.

Electron capture: A radioactive decay process, sometimes called *K capture*, where the decay energy Q is greater than the binding energy of one of the atom's cloud of electrons ($Q > BEe$). The nucleus absorbs one of the atomic electrons to undergo β^+ decay and emits thereby a neutrino. If $Q > 2m_\mathrm{e}c^2$, then electron capture competes with normal β^+ decay, whereby a positron and an electron neutrino are created.

Fermions: Half integer spin particles obeying Fermi–Dirac statistics.

Half-life $T_{1/2}$: In radioactive decay, the time in which half of the nuclei initially present decay.

Isobars: Nuclei with the same mass number A but with different numbers of protons (Z) and neutrons (N).

Isomeric state: An excited nuclear state whose half-life for γ-emission is quite long; similar to a metastable state of an atomic system.

Isotones: Nuclei with the same number of neutrons (N) but different numbers of protons (Z) and thus, different values for A.

Isotope shift: Small changes in the wavelengths of X-ray optical, and especially muonic transitions in going from one isotope to the next, which give a measure of the change in the nuclear radius as A changes by one unit.

Isotopes: Nuclei with the same number of protons (Z) but different numbers of neutrons (N) and thus, different values of A.

Lamb shift: A small quantum electrodynamic effect that is principally due to the radiative coupling of the orbiting electron (or muon) with the vacuum field and the finite nucleus.

Lifetime τ: The reciprocal of the decay constant. The lifetime is related to the half-life by $T_{1/2} = \ln(2)\tau$.

Mass defect: The difference between the mass of a nucleus of mass number A in atomic mass units less A, $\Delta = M(A) - A$.

Mass excess: Negative of *mass defect*.

Mirror pair: Two light nuclei with the same mass number A but with numbers of protons (Z) and neutrons (N) interchanged.

Muon: A member of the lepton family of elementary particles with spin one-half. The muon is 207 times as heavy as an electron and has a lifetime of

2.197×10^{-6} s. The muon, like the electron, has a negative charge.

Nuclear polarization: A small reduction in the Coulomb potential caused by the penetration of the nuclear volume by the bound orbiting particle (an electron or muon).

Packing fraction: The mass defect per unit mass number $P = \Delta/A$.

Parity π**:** The behavior of a state function upon reflection of the coordinates through the origin, $r \rightarrow -r$, then either $\phi(-r) = +\phi(r)$ and the state is said to have *positive parity* or $\phi(-r) = -\phi(r)$ and the state is said to have *negative parity*.

Pauli principle: The requirement that in a system of like particles obeying Fermi–Dirac statistics (half integer spin particles), no two particles can have the same set of quantum numbers. More generally, the Pauli principle requires wavefunctions for identical particles to be antisymmetric for fermions and symmetric for bosons upon interchange of two particles.

Phonon: In nuclear physics a phonon is a quantized surface vibration of a quantum fluid.

Vacuum polarization: A small radiative correction to the Coulomb potential of an atom arising from the emission and reabsorption of virtual positron–electron pairs.

Valley of stability: In a three-dimensional plot of the nuclear masses $M(Z,N)$ with the proton number Z as abscissa neutron number N as ordinate and $M(Z,N)$ normal to the Z–N-plane, the stable nuclei will be found along a region where $N \sim Z$, which appears to form a deep valley – *the valley of stability*.

Woods–Saxon potential: For a real potential function, this is written with an adjustable surface diffuseness parameter and a radius parameter R. For a complex potential, one adds a similar term, V_{Im}.

INTRODUCTION

Because nuclear (radioactive) waste decays to background levels of radioactivity with time, the ultimate goal of radioactive waste management is quite obvious—store the material until it is no longer harmful. The difficulty with this approach is in the implementation of the theory. What does "no longer harmful" mean in both technical and public perception terms? What are the "best" ways to store material safely and in a cost-effective

---

manner? Only recently has public insistence been directed toward efforts to find environmentally acceptable methods of managing radioactive waste. This insistence has led to a more nearly complete understanding, by both scientists and policymakers, of the importance of developing cost-effective technologies to dispose of radioactive waste.

1. CLASSIFICATION OF RADIOACTIVE WASTE

A number of different schemes exist for the classification of radioactive waste. Some of these are based on the origin of the waste (defense/nondefense wastes, medical wastes, utility wastes, nuclear fuel cycle wastes, etc.); the type of material present in the waste (transuranic, mixed wastes, etc.); the level of radioactivity (high, low, intermediate, etc.); the form of the waste (dry solid, wet solid, liquid, etc.); and, in some cases, legally mandated definitions that may or may not be identical to a straightforward technical or intuitive definition. An example of the latter is the presence in the United States of waste that is defined as low-level but which may have a relatively high level of radioactivity. A general classification of the various radioactive waste categories currently used in various radioactive-waste–producing countries follows.

1.1 Spent Fuel

Spent fuel consists of irradiated fuel assemblies discharged from a nuclear reactor. Spent fuel may be stored at the reactor for reuse in the future, scheduled for reprocessing at some later date, or considered to be eligible for either permanent or temporary storage at a geological repository. In some definitions, especially if long-term disposal is being considered, the spent fuel may also be considered high-level waste. Spent fuel may derive from either commercial (utility) or noncommercial (research or defense) reactors. Spent fuel is usually highly irradiated (high activity), but it may be irradiated to a lesser degree.

1.2 High-Level Waste

High-level waste is usually defined as highly radioactive material resulting from the reprocessing of spent nuclear fuel. This material includes primarily the liquid waste remaining from the recovery of uranium and plutonium in a fuel reprocessing plant. High-level waste may also be in the form of sludge, calcine, vitrified glass, or other products into which such liquid waste is converted to facilitate its handling, storage, or disposal. High-level waste contains fission products that result in the release of considerable decay energy. For this reason, heavy shielding is required to control penetrating radiation, and provisions (e.g., cooling systems) are often needed to dissipate decay heat from the high-level waste.

1.3 Transuranic Waste

Only the U.S. Department of Energy (DOE) manages material specifically classified as "transuranic waste." In the United States, this term refers to radioactive waste that contains more than 100 nCi/g of alpha-emitting isotopes with atomic numbers greater than 92 and half-lives greater than 20 years. Such waste results primarily from fuel reprocessing and from the fabrication of plutonium weapons and plutonium-bearing reactor fuel. Generally, little or no shielding is required ("contact-handled" transuranic waste), but energetic gamma and neutron emissions from certain transuranic nuclides and fission-product contaminants may require shielding or remote handling ("remote-handled" transuranic waste). Although the United States is one of the few countries that recognize transuranic waste as a separate waste classification, any country with a plutonium nuclear weapons program or extensive spent-fuel reprocessing activities will generate similar material. Depending on the country and the specific radioactivity characteristics, this waste may be managed as either low- or high-level waste. Outside the United States, waste of this type is usually categorized as intermediate- or medium-level waste, but it also may be called transuranic-bearing waste or any of a number of similar terms.

1.4 Intermediate- or Medium-Level Waste

Intermediate- or medium-level waste is generally a non-U.S. category for waste that contains higher levels of radioactivity than low-level wastes and so requires some shielding. The boundary between this category and low-level waste varies depending on the country. Treatment and disposal of intermediate-level waste vary depending on the waste form and whether it contains short- or long-lived radioactive isotopes. In general, short-lived intermediate-level waste can be disposed of as low-level waste, but long-lived intermediate-level waste will need to be disposed of similarly to high-level waste.

1.5 Low-Level Waste

Low-level waste is generally considered radioactive waste not classified as spent fuel, high-level waste, transuranic waste, or any other specific category of radioactive waste. The radiation levels from this type of waste are generally quite low, although occasionally the radiation levels may be high enough to require shielding for handling and transport.

1.6 Mixed Waste

Mixed waste contains concentrations of both radioactive materials and nonradioactive hazardous chemicals. All radioactive waste forms may have the potential for being classified as mixed waste, but usually only mixed low-level radioactive waste requires the consideration of management practices separate from low-level radioactive waste. Management practices for spent fuel, high-level waste, and transuranic waste are generally stringent enough to minimize any problems arising from the hazardous components. The United States considers both the radioactive and the hazardous components as separate materials requiring independent regulation. However, most European communities treat low-level mixed waste as if it were strictly low-level waste. For them, the disposal risks for the hazardous components are less than the risks associated with the radioactive components.

1.7 Uranium Mill Tailings

Commercial uranium mill tailings are the earthen residues that remain after the extraction of uranium from ores. Tailings are generated in very large volumes and contain low concentrations of naturally occurring radioactive materials. Because they provide a potential health hazard, the isotopes that concern us most are ^{226}Ra and its daughter, ^{222}Rn.

2. SPENT-FUEL MANAGEMENT

Historically, storage facilities for both commercial and noncommercial spent fuel were limited in capacity. It was generally understood that the spent fuel would be stored only on-site for a limited time and then shipped to a reprocessing facility. However, only a few countries have reprocessed any spent fuel; and although a limited number of countries have decided to reprocess all their spent fuel, many countries have not committed to either the reprocessing or the direct disposal of spent fuel. Currently, direct disposal appears to be gaining favor. Because the fabrication, irradiation, handling, storage, possible fuel reprocessing, and long-term management of spent fuel are all integral parts of the nuclear fuel cycle, these topics are discussed in more detail in NUCLEAR FUELS AND ISOTOPES.

2.1 Spent-Fuel Storage

Storage sites for spent fuel usually consist of deep-water pools; however, many of these pools are rapidly reaching capacity. Utilities in the United States are currently dealing with this problem by reracking spent-fuel storage modules in existing pools, by shipping the spent fuel to other reactor sites that have surplus storage capacity; and by studying alternative storage options, including the use of dry storage casks for the on-site storage of spent fuel. It may also prove feasible to reuse these casks for the future shipment of spent fuel to a centralized storage facility or repository if one becomes available. The pros and cons of on-site storage vs a centralized storage facility or repository are actively being debated in the United States and in many other international communities.

2.2 Spent-Fuel Packaging and Transportation

Because spent fuel might not be reprocessed and because, even if it is to be reprocessed, it is unlikely to be reprocessed at the generation site, the transportation of spent fuel is inevitable. Because of the great deal of attention directed to the shipping of spent fuel, the shipping casks or packages used to transport it must satisfy a variety of societal, political, and technical requirements. Foremost among the latter are requirements that will prevent the release of any radioactive material into the environment and that will provide for radiation and criticality protection. Because the construction of nuclear facilities, fuel fabrication, and shipment of spent fuel are international businesses, the rules and regulations affecting the shipment of it throughout the world are quite similar.

As spent-fuel packages must withstand serious accidents, the criteria of no loss of shielding and no loss of containment have been taken by the international community to mean that certain test conditions must be met by any package designed to transport spent fuel. These mandated requirements are remarkably similar throughout the world. For the United States, the U.S. Nuclear Regulatory Commission (NRC) has determined that spent-fuel packages must experience no loss of integrity upon

1. a 30-ft free-fall drop onto an unyielding surface;
2. a puncture test of at least a 40-in. free-fall drop onto a 6-in.-diameter steel pin;
3. exposure to a thermal environment of 1475 °F for 30 min; and
4. immersion in water for 8 h.

Because of the various regulations and design requirements, spent-fuel shipping casks are invariably made from steel or steel composite (with lead or uranium) thick enough to meet structural and gamma-shielding requirements. Additional elastomer or resin material may also be included for neutron shielding. An appropriately designed liner, specific to the spent fuel being transported, holds the assemblies in place and prevents damage during transport. These casks typically weigh between 25 and 100 metric tons with rail, barge, or ship transportation being required for the larger casks.

In deference to the current uncertainties of whether reprocessing will occur and to the uncertainties of on- or off-site storage of the waste, a number of spent-fuel casks are being designed to meet both storage and transport requirements. These casks are basically similar to the transportation casks described previously, but they have been modified as necessary to provide longer storage life.

2.3 Spent-Fuel Disposal

If the direct disposal of spent fuel is eventually determined to be the disposal method of choice, the fuel will be sent either immediately or after some period of interim storage to a geological repository. For those countries that must dispose of both spent fuel and high-level waste, these materials will be handled in a common repository with possible differences only in specific handling methods and the final repository cells. The differences are usually trivial. The following discussion pertains to both.

Inherently, all proposals for the safe disposal of spent fuel require the safe storage of radioactive isotopes until they decay to nonradioactive elements or to nonhazardous levels of radioactivity (as defined by the host country). Depending on the specific materials and radionuclides present, this requirement mandates storage times of thousands to millions of years. Because these times are much greater than the design lifetimes of conventional manufactured structures, alternative methods of disposal are often required. The obvious method of choice is a deep geological repository, especially in underground rock formations that have not changed for millions of years and thus are considered inherently stable.

Although candidate geological formations have isolated material for sufficiently long periods of time, representative repository designs generally include additional engineered barriers that add greater long-term assurances that material will not migrate out of the formation. These barriers may include long-lived container compositions, incorporation of the spent fuel into inert waste forms, and special backfill material in completed waste cells.

Similar geological repositories have already been used for low-level and hazardous waste. However, the disposal of spent fuel differs considerably in that the heat content of the waste packages (due to radioactive decay) may damage both the package and the structural integrity of the geological formation. Thus, spent-fuel repository designs call for the spreading out of the packages over large areas of the repository. In contrast, low-level or transuranic repository designs call for relatively large rooms filled with waste packages.

Once a suitable geological formation has been selected, underground space needs to be excavated along with suitable access shafts or tunnels. The excavation of the final waste storage areas may occur before storage or may occur simultaneously with storage, with new excavation occurring in areas remote from ongoing waste emplacement. Throughout the world, a number of different rock types are being considered for individual geological repositories; examples include salt, clay, crystalline granites, and tuff. None of these rock types can be called a perfect choice, because each type has its own inherent advantages and disadvantages. There are difficulties in mining, in isolating the waste from groundwater, and in the long-term stability of the formation factor in the choice of geologic formation. Salt is generally considered the easiest and fastest material to excavate, and granite, the slowest. Granite, however, is more stable and allows also for deeper repositories. None of the rock types is overwhelmingly superior for waste isolation. The total effectiveness of a repository is determined by the combination of a favorable geology and an engineering design that mitigates any disadvantages.

Before the emplacement of spent fuel within the repository, the waste will have to be packaged in final canisters or packages. Various options are being considered for the required packages. One option consists of having the spent fuel shipped to the repository in typical spent-fuel shipping casks and transferred to the final disposal package at the repository. Other designs incorporate the use of the actual shipping container as a self-shielded waste package for direct emplacement within the underground repository. The packaging of the spent fuel can be done at the repository, at the reactor before shipment, or at a centralized spent-fuel storage facility where the economics of scale may make packaging more cost effective.

The time interval from spent-fuel generation to actual emplacement within a geological repository may be short or may encompass several decades. No specific requirements determine the time frame involved, although interim storage costs may dictate shorter time intervals, while the desirability of taking advantage of the drop-off in decay heat with time favors longer times.

2.4 Representative Spent-Fuel Repository Designs

Although, currently, no country has an operating geological repository for spent fuel, a number of countries have repositories either under construction or far enough along in their design to permit a discussion of the proposed repositories. Several, though not all, of the various international designs are discussed to present some indication of the similarities and differences among the various designs. The information presented here is as reported in the open literature and is therefore not definitive, but rather gives a working understanding of the proposed designs (Forsberg, 1991). Several countries with major nuclear programs (e.g., France, the United Kingdom, and Japan) have not yet published any detailed plans on their respective repository programs. In a majority of countries, the final decision whether to reprocess spent fuel has not been made. Thus, most of the repository designs are flexible enough to allow for the disposal of spent fuel or high-level waste.

2.4.1 United States The United States is considering building its first repository for both spent fuel and high-level waste in a tuff (fused volcanic deposits) formation at the Yucca Mountain Repository Site in Nevada. The current design includes provisions for disposing of commercial and defense-related spent fuel, high-level waste from defense activities, and a small amount of high-level waste from the historical commercial reprocessing of spent fuel. This repository will have a capacity of some 70 000 metric tons initial heavy-metal equivalent (MTIHM). Typical depths for placement of packages into this repository will be 300 m. The spent-fuel or high-level waste packages (identical in outer dimensions) are to be placed in widely separated bore holes placed in the floor of the disposal tunnels. These tunnels are to be arranged in a series of panels (compartments) with one panel receiving waste, a second ready to receive waste, and a third under construction. Because of heat dissipation requirements, the bore holes are to be widely spaced. The U.S. design calls for the potential retrieval of the waste if the repository does not prove suitable. This requirement has resulted in engineered designs for bore-hole liners and other handling and emplacement components to allow for future retrieval.

2.4.2 Sweden The Swedish design for the final disposal of spent fuel is unique in that it relies heavily on the waste package to provide the primary barrier to environmental releases. The reference waste package design consists of a solid copper package with the spent-fuel assemblies embedded within it. These packages are to be placed 500 m underground into crystalline rock (granite, gneiss, or gabbro). This unique design is based on the knowledge that native copper in granitic formations is quite stable for long geological periods of time. Copper can deform over time; therefore, the package fabrication procedure involves embedding the spent-fuel assemblies within a solid copper cylinder, filling the remaining void spaces with copper powder, and hot-pressing the entire package to produce a single solid copper cylinder. Because copper in nature has been shown to be stable at relatively low temperatures, current plans call for a minimum of 30 to 40 years of interim storage before final packaging to allow for the drop-off in decay heat. Operation is expected around the year 2020.

2.4.3 Germany The German design calls for the joint disposal of high-level waste and spent fuel from reactors of western design at a depth of some 870 m in the Gorleben salt dome. The high-level waste will result from the reprocessing of German spent fuel in France and Great Britain. Direct emplacement of spent fuel will result from unique situations that would make reprocessing difficult or very expensive. Although current German law calls for the reprocessing of spent fuel, direct spent-fuel emplacement will also occur if the reprocessing of reactor fuel is terminated. For spent fuel generated at Soviet-designed reactors within Germany, the preferred option is to return the spent fuel to Russia for reprocessing. The German design calls for the use of the Pollux cask concept, which includes the option for use as a transport cask, for long-term interim storage, or as a final disposal package. The Pollux design provides excellent radiation shielding, thus permitting the direct emplacement of packages at the end of tunnels, backfilling around the package with salt, and repeating the process until the tunnel is full. Salt slowly creeps (deforms) with time and, thus, over tens of years, the tunnels will be self-sealing. Current plans call for initial emplacement of material in the year 2008.

2.4.4 Canada One Canadian design for a spent-fuel repository is based on the direct disposal of spent fuel 500 to 1000 m underground in plutonic formations sometime after the year 2025. Because the Canadian commercial reactor program is based on CANDU reactors that use natural uranium fuel, several unique factors are involved in the Canadian repository design. The low burnup of CANDU fuel implies very large volumes of spent fuel with low decay-heat releases from the spent-fuel packages. The combination of these factors is a reference Canadian repository design of over 190 000 MTIHM capacity, but with larger spent-fuel waste packages and closer spacing of waste packages in the repository than occur with other countries' repository designs.

3. HIGH-LEVEL WASTE MANAGEMENT

High-level waste, which is generated by the reprocessing of spent nuclear fuel and irradiated targets, generally contains more than 99% of the nonvolatile fission products produced in the fuel or targets during reactor operation. The high-level waste from a facility that recovers uranium and plutonium contains about 0.5% of these elements, while the high-level waste from a facility that recovers only uranium contains about 0.5% of the uranium and essentially all of the plutonium. Most of the current U.S. inventory of high-level waste is the result of defense-related programs and is stored at DOE sites. A small amount of commercial high-level waste was generated during the period 1966–1972. Other countries that have or plan to have a significant commercial fuel reprocessing capability (i.e., France and Great Britain with the world's only commercial reprocessing facilities) might well have a different mix of commercial and defense-program-related high-level waste. The production of high-level waste as a waste product is an inherent part of the nuclear fuel cycle, and, as such, the various spent-fuel reprocessing technologies that generate high-level waste are discussed in detail in NUCLEAR FUELS AND ISOTOPES.

3.1 High-Level Waste Treatment

A number of highly publicized recent events in the United States concerning the existence of leaking liquid high-level waste storage tanks highlight the potential limitations and inherent difficulties in the long-term storage of liquid high-level waste. Although the tanks in question were of the old single-shell design, a number of countries (e.g., France, Australia, and the United States) have embarked on vigorous research and development efforts to stabilize high-level waste safely (American Nuclear Society, Inc., and American Society of Civil Engineers, 1992). These efforts are directed toward the conversion of liquid high-level waste to a form that simplifies the long-range waste management problems and often includes a major reduction in waste volumes. In the United States, high-level wastes are currently stored as neutralized sludge, salt, acid liquid, alkaline liquid, and calcine. Only the calcine is a form that can be stored safely in stainless steel bins in concrete vaults. Current plans call for all of the U.S. high-level waste eventually to be incorporated into a stable matrix using borosilicate glass in several different melters and processes. The French use a closely coupled calcination and borosilicate glass vitrification process that appears to be relatively flexible and inexpensive. Several other processes have also gathered attention on an international basis, including the Australian SYNROC process. SYNROC is basically a synthetic rock that consists of a number of titanate mineral phases. The main benefit of this process is that it offers exceptionally high resistance to leaching by groundwater. Although a number of countries have shown interest in alternative waste forms, only the borosilicate matrix has been, and is being, developed commercially.

3.2 High-Level Waste Disposal

To date, it appears that none of the major producers of high-level waste have directly disposed of any of this material. In numerous cases, this liquid waste has been stabilized and solidified by a number of processes, including evaporation, calcination, and vitrification of the waste into a glass matrix. Ultimately, high-level waste probably will be disposed of similarly to spent fuel in a geologic repository. Although a number of countries, including France and the United States, have some of their high-level waste in a form ready to be disposed of, none has apparently done so. The final repository designs generally call for the emplacement of high-level waste and spent fuel depending on each country's decision whether to reprocess spent fuel. These designs are discussed in Sec. 2.4.

4. TRANSURANIC WASTE MANAGEMENT

4.1 Processing and Handling of Transuranic Waste

Transuranic waste is generated primarily by activities associated with research and development, spent-fuel reprocessing, plutonium recovery, weapons manufacturing, environmental restoration, and decontamination and decommissioning projects. About half of the countries having nuclear reactors produce transuranic waste from at least one of these sources. Most transuranic waste exists in solid form (e.g., protective clothing, paper trash, rags, glass, miscellaneous tools, and equipment). However, some transuranic waste is in liquid form (sludges), the result of the chemical processing for recovery of plutonium or other transuranic elements. Before 1970, all U.S. DOE–generated transuranic waste was disposed of on-site in shallow landfill-type configurations. In 1970, DOE concluded that waste containing long-lived alpha-emitting radionuclides should have greater confinement from the environment. Thus, all transuranic waste generated in the United States since the early 1970s has been segregated from other waste types and placed in retrievable storage pending shipment and final disposal in a permanent geologic repository. This retrievable stored transuranic waste is contained in a variety of packages (metal drums and wooden and metal boxes) in earth-mounded berms, concrete culverts, or other types of facilities.

The majority (>90%) of transuranic waste contains primarily plutonium, which emits alpha particles and low-energy photons. Therefore, the packaging is designed to provide sufficient containment and shielding to minimize personnel exposure problems. This waste form is referred to as "contact handled." Less than 3% of transuranic waste contains activation materials and fission products that decay by beta emission and produce penetrating gamma and x-ray radiation. This waste is referred to as "remote handled" if the radiation level at the surface of the packaging exceeds 200 mrem/h.

It is estimated that as much as 50 to 60% of the transuranic waste is also mixed waste in that it contains hazardous constituents defined and regulated by the U.S. Environmental Protection Agency (EPA). Examples of transuranic mixed waste are radionuclide-contaminated spent solvents, discarded materials contaminated with both solvents and radioactive materials, scintillation fluids, and discarded contaminated lead shielding. However, the proposed disposal plans for transuranic waste are such that any concerns about the management of the hazard constituents should be minimal.

Current plans call for the retrievable stored transuranic waste and newly generated transuranic waste from U.S. defense-related activities to be shipped to the Waste Isolation Pilot Plant (WIPP), located near Carlsbad, New Mexico. The disposition of buried transuranic wastes and transuranic waste generated from nondefense activities is uncertain at this time.

4.2 Waste Isolation Pilot Plant (WIPP)

Except for those countries that manage transuranic or transuranic-like waste as low-level waste, most transuranic-waste–generating countries have adopted an interim storage concept with the final disposal as yet to be decided upon. In the past, Germany disposed of transuranic waste in the Asse salt mine, but it has discontinued that operation. Other countries are considering repository projects; for example, the United States is proceeding with the WIPP. The WIPP has been designed as a facility for the permanent isolation of U.S. defense-generated transuranic wastes, but it will also provide an underground test facility in which the safe disposal of high-level waste in salt can be demonstrated. Initial construction of the underground facility was begun in 1981. Currently, the WIPP facility is fully prepared to receive some transuranic waste to conduct various experiments related to regulatory compliance of the repository. The final decisions permitting the initial emplacement of transuranic waste have not yet been made.

Because of the public's and regulators' strong interest in the initial disposal of transuranic waste, a detailed set of waste acceptance criteria has been drafted. These rules are concerned with a wide variety of issues, including gas generation, combustibility, toxic and corrosive compounds, surface dose rate, surface contamination, and criticality. Generator, interim storage, and shipping sites must maintain detailed documentation to meet these criteria and be allowed to ship material to the WIPP.

Contact-handled transuranic waste will be transferred to the WIPP in specially designed and constructed packaging containers referred to as TRUPACT-II containers. Although designed for easily shielded contact-handled transuranic waste, the container consists of several sealed containment vessels and a sandwichlike foam and stainless steel shell that increases the package strength and safety to withstand postulated accidents associated with transport. TRUPACT-II has a capacity of 14 standard 55-gal drums and is about 3 m in diameter and 3 m tall. Three TRUPACT-IIs can be carried on a flatbed truck trailer. Shipment of the remote-handled transuranic waste will take place in a special shipping container that is somewhat similar to the various designs for a spent-fuel cask.

The WIPP site, which is located in the Permian Basin deposits of the southwestern United States, contains salt formations that are about 900 m thick, some of the thickest formations in the United States. Present mining activities take place 650 m below the surface near the middle of the salt bed. This formation was chosen because the area appears to be geologically stable with little earthquake activity, salt deposits demonstrate the absence of any circulating groundwater, salt is relatively easy to mine, and the salt has the ability to heal fractures and creep to fill voids and seal a waste repository. Aboveground facilities house the site personnel and equipment needed for WIPP operations and research activities. Included are separate areas for the contact- and remote-handled transuranic wastes. A series of four shafts connect the surface facilities to the underground area, making it possible to lower transuranic waste to its destination and to transport workers, equipment, mined salt, and fresh air.

Underground WIPP facilities consist of transuranic waste storage rooms 4 m high, 10 m wide, and 90 m long; these rooms are separated from each other by 30-m pillars. As one room is filled with waste, the next room is being excavated, and some of the salt rubble is used to backfill the voids in the room that is being filled. Contact-handled transuranic waste containers will be removed from the TRUPACT-II transporter and transferred to the underground storage area. There they will be moved to and stacked in the appropriate storage room. Remote-handled transuranic waste, however, will need to be handled by specially designed and shielded handling equipment. Actual waste containers will be remotely emplaced within predrilled holes in the storage room wall and immediately plugged. Other nonstorage rooms have been excavated for experimental high-level waste heat-dissipation tests and as shop and maintenance areas.

Near the end of the five-year demonstration and evaluation period, a decision will be made regarding permanent disposal of transuranic wastes at the WIPP. If a decision for permanent disposal is made, the facility will operate as a repository for an additional 20 years. The total anticipated volume of transuranic waste to be stored at the WIPP is about 200 000 m^3. Remote-handled transuranic waste is expected to require only 5000 m^3 of the total available volume.

Plans are to use both a traditional cement-based grout and natural salt plugs to cap the waste-filled underground rooms and to seal the vertical shafts. The cement grout provides a well-characterized short-term seal, and the salt plugs provide a deformable seal that will fuse with the surrounding formation. Plans are in place for the final decommissioning of the WIPP, including decontaminating the surface areas and dismantling of the surface facilities. Permanent surface markers will be placed on the site, and a long-term monitoring program will be conducted.

5. LOW-LEVEL WASTE MANAGEMENT

5.1 Low-Level Waste Generation

As indicated in the classification section, the usual way of determining what is included in low-level waste is to describe what it is not. In most countries, low-level waste is that radioactively contaminated material that is not covered by the definitions for spent fuel, high-level waste, transuranic waste, uranium mill tailings, or any other form of waste. Generally, low-level waste contains relatively small amounts of radioactivity, but occasionally it does have a level of radioactivity high enough to warrant special treatment and disposal. Principal generators of low-level waste include academic and medical institutions, nuclear power plants, and other industries. Of obvious importance is the generation of low-level waste in defense-related programs for those countries having such programs. A majority of low-level waste contains very low levels of radioactivity and generally requires no shielding to protect workers or the general public and decays in fewer than 100 years to levels that are generally considered acceptable. The remainder (3–5%) requires some degree of shielding and takes longer to decay to acceptable levels of radioactivity. This material may not be acceptable for near-surface disposal without including additional engineering barriers. The highest-activity low-level waste is often slated for disposal in a geologic repository along with spent fuel and high-level waste.

The types of low-level waste being generated include the widest range of materials, including contaminated trash, paper, glass, clothing, plastics, equipment, tools, sludges and slurries, and organic and aqueous liquids. Solids, liquids, or gases can all be included as low-level waste. Normally liquid wastes are stabilized or solidified before disposal, and gaseous wastes need to be filtered or scrubbed to remove contaminants before discharge to the environment.

5.2 Low-Level Waste Treatment

The best way to manage low-level waste is not to generate it. The use of substitute materials or good housekeeping practices can go a long way toward eliminating, or at least minimizing, the generation of low-level waste. Sometimes, however, it is not possible to eliminate a particular low-level waste; then various treatment methods have to be relied upon to reduce the volume or simplify the handling of the low-level waste. Numerous such technologies are available, and it would be impossible to describe all of them in detail. Generally, they can be grouped according to their principal objectives: dewatering, thermal transformation, sorting and segregation, decontamination, mechanical volume reduction, and stabilization and solidification.

5.2.1 Dewatering Low-Level Waste Liquid wastes can be concentrated and, thus, their volumes reduced by evaporation, incineration, ion exchange, filtration, reverse osmosis, and precipitation. Other technologies (e.g., distillation, ultrafiltration, centrifugation, and crystallization) can be and probably have been used to treat low-level waste, but the former are more commonly called upon.

5.2.2 Thermal Transformation Incineration of low-level waste is one of the two most widely used technologies for the volume reduction of solid low-level waste; the other technology is compaction. Incineration is also heavily used for a number of liquid low-level waste streams, especially those involving combustible organic materials. Some incineration of noncombustible liquid streams can be handled by mixing these streams with combustible low-level waste or by using a supplemental fuel. Although highly efficient (with reduction ratios of 100 to 1 being achieved for liquid low-level wastes), the capital costs are significant, and secondary waste streams are produced that have to be disposed of safely. These wastes include waste gases that need to be monitored and, if necessary, scrubbed. Fly ash and bottom ash are produced. The radioactivity present in the liquid low-level waste tends to concentrate in the bottom ash, and this material will need to be stabilized and disposed of safely.

5.2.3 Sorting and Segregation Sorting and segregation processes can be highly cost effective when the disposal costs for low-level waste are relatively high. The sorting process can take place either before the discarded material is labeled "low-level" waste or before actual disposal of the material. The effective use of sorting of radioactively contaminated items (and parts of items) from the bulk of the discarded material has been shown to cut down drastically on waste volumes. Alternatively, known contaminated material can be sorted into combustible material, waste suitable for decontamination, compactable waste, and noncompactable waste.

5.2.4 Decontamination Decontamination is the process whereby the surface contamination of solid low-level waste is either removed or reduced. The ultimate goal is to reduce the contamination to a level whereby reuse or nonradioactive waste disposal is feasible. Decontamination methods include mechanical (steam, water, or sand blasting), chemical (acids, alkalies), and ultrasonic (vibrating liquid baths). In some cases, the reuse or recycle of the decontaminated material is possible. Surface-contaminated scrap metal is often reclaimed by smelting. In some cases, minimally contaminated metal ingots that can be used in the production of shielding for spent fuel and high-level waste storage, shipping, and disposal casks are produced.

5.2.5 Mechanical Volume Reduction Numerous mechanical volume-reduction techniques [baling, shredding, and compaction (both conventional and supercompaction)] are available for use on dry low-level waste. Volume reduction values of 3 to 10 are not unusual. Mechanical volume reduction and other forms of volume reduction are heavily used when the disposal costs are high. Often, the final products are high-density disks that can be repacked in standard barrels to facilitate handling and disposal.

5.2.6 Stabilization and Solidification Solidification is generally used to convert low-level waste to a form that, upon its disposal, resists degradation and any release of contaminants to the environment. The waste to be treated can be liquid, slurry, sludge, wet solid, or dry solid. In most cases, the material to be stabilized is simply mixed with an appropriate solidification agent and allowed to solidify in the final disposal container. Some of the most widely used solidification agents are cements, asphalt, polymers, and molten glass. The form of the waste (liquid or solid) and the chemical and thermal stability of the waste determine the optimal solidification agent.

5.3 Low-Level Waste Disposal Methods

The various methods for the final disposal of low-level waste can be grouped into a number of generic categories: above-ground disposal, near-surface underground disposal, intermediate-depth disposal, deep disposal in geologic repositories, and ocean disposal. All specific methods for the disposal of low-level waste have their own advantages and disadvantages. All the low-level waste-producing countries have assumed the responsibility of disposing of their own low-level waste (i.e., very little, if any, transferring of low-level waste from one country to another exists) and, thus, need to optimize the cost-benefit tradeoffs (including safety) of the various options under their particular set of circumstances.

5.3.1 Above-Ground Disposal For above-ground disposal, reinforced concrete vaults or buildings are constructed directly on the surface. Any waste stored in the vault will be isolated from the environment as long as the integrity of the building is maintained. Above-ground disposal vaults are relatively inexpensive and can be easily located and monitored. However, they do lack the environmental protection and the barrier to radionuclide migration that any surrounding soil would offer. This type of disposal is often used for both short- and long-term interim storage of low-level waste when permanent disposal is to occur at a later time.

5.3.2 Near-Surface Underground Disposal Technologies fitting this category have historically been used for the disposal of the vast majority of low-level waste throughout the world. Various modifications of this category are generally the current method of choice for most countries that generate low-level waste because of the low cost and adequate isolation of the low-level waste. For most of these technologies, the waste is simply emplaced within about the first 10 m of the surface and then capped with a layer of soil. The most common near-surface disposal methods include trenches and below-grade or soil-mounded vaults or bunkers. In the past, water infiltration into near-surface disposal units has been linked to the loss of integrity in the overlying cap caused by the compaction and settling of the waste. Regulations requiring the compaction of the low-level waste before its emplacement, along with the use of high-integrity containers and concrete overpacks, help prevent many of these problems. In addition, a number of designs call for the stabilization of the emplaced waste with either a loose soil, sand, or gravel fill, or an injected concrete grout around, and in some cases into, the waste packages. After a disposal unit is filled, a cap composed of single or multiple layers of soil or impermeable synthetic membranes is used to seal the unit from precipitation and ground-water runoff. Although most low-level waste disposal units have been the below-grade type, where the elevation of the surface drainage is above the buried waste, a number of countries have used above-grade facilities, where the surface drainage elevation is below the lowest waste level. Earth-covered bunkers have been used successfully in France for over 20 years, and above-grade tumuli are currently being evaluated for some of the new generation of low-level waste disposal units being considered for use in the United States (Fig. 1).

5.3.3 Intermediate-Depth Disposal Augered holes in the earth's surface have been successfully used for the emplacement of low-level waste at a number of DOE sites (Fig. 2). This method involves the construction of concrete- or metal-lined holes, up to 3 m in diameter and up to 20 m or more in depth, in suitable soil. After the emplacement of the low-level waste, the holes are typically filled with a cement or concrete grout, and a concrete cap is added. Although this is a possibly acceptable method for the disposal of low-level waste, the difficulty in locating and monitoring suitable sites will generally favor other disposal methods. Also included in this category are the use of deep trenches and old pit mines. Unless readily available, these methods are costlier than shallow trenches and yet do not add any protection against releases to the environment.

5.3.4 Deep Disposal in Geologic Repositories Geologic repositories located up to 1500 m below the surface are generally being considered as sites for the disposal of most of the world's high-level waste. These deep repositories, although expensive, generally provide excellent barriers to the migration of radionuclides into the environment and to human intrusion into the disposal unit. A number of European countries are also planning to use such repositories for the disposal of low-level waste. Germany disposed of low-level waste in the Asse salt mine from 1967 to 1978. Sweden has built, and the United Kingdom plans to develop, geologic repositories for low-level waste. The United States is considering

such repositories only for spent fuel, high-level waste, and transuranic waste. In most cases, deep geologic repositories are not considered cost-effective for disposing of low-level waste. The additional protection gained by disposing of material at such depths is often not necessary, and locating such repositories can be difficult and time-consuming.

5.3.5 Ocean Disposal In the 1950s and 1960s, the United States disposed of about 90 000 containers of low-level waste at various depths and distances from shore at several Atlantic and Pacific Ocean sites. Since 1967, a number of European countries have cooperated in a joint disposal of some 36 000 containers off the English coast. Although this is not currently practiced in the United States, several other countries do practice limited ocean disposal of radioactive waste, including low-level waste, without a great deal of publicity.

5.4 Low-Level Waste Disposal in the United States

The disposal of commercial low-level waste in the United States dates back to 1962 with the opening of the Beatty, Nevada, disposal site. Since then, a number of other sites have been opened and subsequently closed; only two (Hanford, Washington, and Barnwell, South Carolina) are still accepting low-level waste. The shipping of the country's waste to the two remaining sites developed into a general concern that the responsibility for accepting low-level waste for disposal should not rest with only a few states and that a coordinated national plan was needed. In response, in 1982, the U.S. Congress passed an act (the Low-Level Radioactive Waste Policy

Act) making each state responsible for its own low-level waste and encouraging the formation of regional interstate compacts to deal with the disposal problems. Although the law laid out the milestones leading to the operation of new regional facilities by 1 January 1993, none have been built, and it remains to be seen what the full impact of the law will be on those industries producing low-level waste.

6. MIXED-WASTE MANAGEMENT

Because mixed waste contains both radioactive materials and nonradioactive hazardous chemicals, it raises a number of legal, regulatory, institutional, and management issues that are unique. All radioactive waste types may, in part, contain some mixed wastes. However, the dominating radioactive characteristics of spent fuel, high-level waste, and transuranic waste generally dictate the methods by which these materials need to be treated, handled, stored, and disposed of. Thus, only mixed low-level waste is generally considered for mixed-waste management.

While low-level waste is somewhat ill-defined throughout the world, the definition of what constitutes a hazardous material is even less exact. Thus, the combination of the two definitions can be either extremely specific or quite confusing, or there may not be a definition at all. A majority of countries consider the low-level components to be of dominant concern and treat their low-level mixed waste as if it were only a radioactive waste. Other countries highlight the hazardous chemicals and manage the waste primarily on the basis of its hazardous components.

In the United States, the radioactive components of mixed waste are subject to the Atomic Energy Act, which, for government sources, is administered by DOE. Commercial sources are administered by the Nuclear Regulatory Commission (NRC) (unless a state has obtained agreement-state status). The hazardous components of all mixed wastes in the United States are subject to two federal statutes that are administered by the Environmental Protection Agency (EPA) (unless a state has obtained an authorization status): the Resource Conservation and Recovery Act [RCRA (1976, 1984)] and the Toxic Substances Control Act [TSCA (1976)]. Thus, the treatment, handling, and disposal of mixed wastes are subject to the regulations of the EPA and NRC (or the authorized and agreement states) or DOE.

Typically, mixed waste includes a variety of contaminated materials—for example, liquid scintillation fluids, air filters, cleaning materials, engine oils and grease, chlorinated or fluorinated organics, pesticides, lead wastes, mercury wastes, other toxic metals, paint residues, photographic materials, soils, building materials, and decommissioned plant equipment. It has been estimated that about 5 to 10% of U.S. low-level waste may, in fact, be properly classified as mixed waste. The characterization as mixed wastes is often quite difficult because such wastes may have different blends of hazardous (chemical or physical) and radioactive components that preclude accurate characterization. In addition, several processes may be involved in generating the wastes, including accidents that may not be amenable to characterization. Further complicating the issue is the fact that regulatory procedures for determining the hazardous components and their toxicities are rapidly changing.

6.1 Availability of Mixed-Waste Treatment Facilities

If, in a particular country, mixed waste is to be treated as either low-level waste or hazardous waste, then the treatment facilities or methods used for disposal are somewhat well defined. If, however, the mixed waste is jointly regulated—both as a radioactive material and as a hazardous waste (as in the United States)—then the nature and availability of mixed waste treatment and disposal facilities become much more difficult to assess.

In most cases, the usual procedure is to treat or remove the hazardous component by the most expeditious and effective treatment technology. The resulting treated waste, residue, or immobilized material can then be managed as if it were a low-level waste. In some cases, such as waste being held for the decay of radioactive isotopes or the presence of low concentrations of certain isotopes such as 0.05 μCi/g or less of ^{3}H or ^{14}C in the United States, the waste may be managed as if it were a hazardous material. The meager number of waste management facilities that meet all the technical requirements to handle both hazardous and radioactive materials and that have all the necessary permits and licenses to do so limits the availability of mixed-waste management facilities to the generators of this waste. In the United States, the nonavailability of licensed or permitted facilities to treat certain categories of mixed waste and the general prohibition on the long-term storage of hazardous wastes have placed numerous mixed-waste generators in a difficult position.

7. URANIUM MILL TAILINGS MANAGEMENT

Uranium mill tailings are the residual wastes of milled ore that remain after the uranium values have been recovered. Depending on the ores' chemical characteristics, uranium mills use either an acid or alkaline leach process to recover uranium. Currently, mills having more than 96% of the U.S. milling capacity use the acid leach process; the rest use the alkaline process or a number of nonconventional methods. Acid leaching is preferred for ores with low lime content. Those with high lime content require excessive quantities of acid for neutralization and, for economic reasons, are best treated by alkaline leaching. In either leach process, most of the uranium is dissolved together with other materials present in the ore (e.g., iron, aluminum, and other impurities). After the ore is leached, the uranium-laden leach liquor is removed from the tailings solid by decantation. Mill tailings from both processes consist of slurries of sands and claylike particles called slimes.

Because the amount of uranium (by weight) extracted from the ore during milling is relatively small, the dry weight of the tailings produced is nearly equal to the dry weight of ore processed. Typically, dry tailings are composed of 70 to 80 wt % sand-sized particles and 20 to 30 wt % finer-sized particles. The tailings contain other naturally radioactive substances (e.g., radium) that are responsible for more than three-fourths of the radioactivity that was originally present in the ore. After thorough washing, the tailings are pumped as a slurry to a tailings pond where the emplaced waste is drained and the water evaporated.

Because huge amounts of tailings are produced from even a modest uranium mill industry, large tailings have historically been produced. In the United States, over 100×10^6 m^3 of commercial uranium mill tailings are distributed over about 24 tailings sites. An equal number of DOE sites possess an estimated additional 30×10^6 m^3 of mill tailings. Several of the largest commercial sites contain over 10×10^6 m^3 of tailings, in piles covering over 100 ha each. Only two of these are currently active, adding some 360 000 m^3 of tailings in 1991. Of the inactive sites, their respective status ranges from unstabilized, to covered with wood chips, to partially stabilized, to fully stabilized with soil and surface plantings. In the future, most of the U.S. production of uranium is expected to come from nonconventional extraction operations (*in situ*, by-product, etc.) with imports and U.S. inventory drawdown projected to make up 80% of U.S. requirements through the year 2005. On a worldwide basis, at least 200×10^6 m^3 of tailings exist, with an additional $(10\text{–}20) \times 10^6$ m^3 of tailings being added each year.

In the past, failures of the holding dams at mill tailings impoundments have occurred. In addition, there was the historical use of the easy-to-handle, readily available, and expensive mill tailings as a source of landfill. Individuals and institutions used the mill tailings in the construction of homes, commercial buildings, and even schools. Because of such events and situations, the creation of large tailings piles is now widely regarded by the public and various regulators as unacceptable. Alternative disposal practices are being actively pursued. The obvious solution is to require the burial of tailings below grade in specially excavated pits or as backfill in deep pit and underground mines so as to reduce radioactive exposure levels to natural background levels. Use of cost-benefit, as low as reasonably achievable (ALARA), and sound engineering analyses leads to the conclusion that the various uncertainties in the predicted values of collective doses to the surrounding population and the costs associated with various waste management options often make sound choices for the future management of mill tailings quite difficult.

In the United States in 1986, the EPA issued rules on ^{222}Rn emissions from tailings piles. Mill owners will have to phase out the use of large existing tailings piles. New tailing piles must be contained in small (i.e., less than 16 ha) impoundments or disposed of by continuous dewatering and burial with no more than 4 ha uncovered at any one time.

8. QUANTITIES OF RADIOACTIVE WASTE

8.1 International Radioactive Waste Generation

Information on the quantities of radioactive waste being managed by the various international waste producers is often difficult or impossible to obtain. Accurate numbers for only spent fuel are available for most countries. Table 1 presents data on the amount of spent fuel generated through 1991 (The Uranium Institute, 1992). A comment needs to be made that some of this quantity has been reprocessed in France, Great Britain, and the United States and that additional material may be reprocessed in the future. Thus, these numbers represent total generation, not material in storage awaiting disposal. Additional quantities of spent fuel have been produced in Soviet-supplied reactors, but these numbers are not included.

Table 1. Spent-fuel production through 1991.

Country	MTIHM
Argentina	1 800
Belgium	1 400
Brazil	150
Canada	15 000
Finland	450
France	16 000
Germany	4 000
India	1 800
Italy	2 000
Japan	9 000
Netherlands	250
Slovenia	140
South Africa	400
South Korea	1 200
Spain	3 300
Sweden	3 000
Switzerland	1 200
Taiwan	1 200
United Kingdom	34 000
United States	24 000

8.2 U.S. Radioactive Waste Generation

The DOE annually publishes a reference document that quantifies the inventories of all radioactive material being generated, stored, or disposed of in the United States (Martin Marietta Energy Systems, Inc., 1994). Table 2 provides a summary of the quantities of radioactive waste being stored in the United States as of 31 December 1993. It must be noted that some differences in definitions for the various waste categories exist between the commercial and the DOE waste-generating industries. In the United States, low-level waste accounts for over 85% of the stored radioactive waste but less than 1% of the radioactivity.

Table 2. Radioactive waste inventories as of 31 December 1993.

Waste category	Total amount in storage	Comment
Spent fuel	28 000 MTIHM[a]	Does not include approximately 2500 MTHM of DOE-owned spent fuel
High-level waste	403 500 m^3	Material predominantly unsolidified waste
Transuranic waste	232 600 m^3	Includes both buried material and waste to be sent to WIPP
Low-level waste	4 561 400 m^3	Includes both commercial and defense material
Uranium mill tailings	118 600 000 m^3	Includes only commercial tailings.
Mixed waste	190 700 m^3	Does not include 2,100 m^3 of commercial mixed waste as of 31 December 1990

---

[a] Metric tons initial heavy-metal equivalent.

GLOSSARY

Activation Product: A radioactive material produced by bombardment with neutrons, protons, or other nuclear particles.

Burnup (Spent Fuel): The total energy released per initial unit mass of reactor fuel as a result of fission.

Calcine: A form of high-level waste produced from spent-fuel reprocessing waste by heating to a temperature below the melting point to bring about a loss of moisture and oxidation to a chemically stable form.

Canister: A metal container used for the storage or disposal of heat-producing solid radioactive waste.

Contact-Handled Waste: Radioactive waste with a low surface dose rate and minimal heat generation that permits handling by contact methods.

Decay, Radioactive: The transition of a nucleus from one energy state to a lower one, usually involving the emission of a photon, an electron, or a neutron.

Enrichment (Reactor Fuel): A nuclear fuel cycle process in which the concentration of fissionable uranium (i.e., ^{235}U) is increased above its natural level of 0.71%.

Fertile Nuclide: A nuclide capable of being transformed into a fissile nuclide by neutron capture.

Fissile Nuclide: A nuclide capable of undergoing nuclear fission with neutrons.

Fission Products: Nuclides produced either by fission of heavier nuclides or by the subsequent decay of the nuclides thus formed.

Fuel Assembly: A grouping of nuclear fuel rods that remains integral during the charging and discharging of a reactor core.

Geologic Repository: A facility that has an excavated subsurface system for the permanent disposal of spent fuel, high-level waste, and possibly other waste forms.

Half-Life, Radioactive: For a single radioactive decay process, the time required for the activity to decrease to half its initial value.

Heavy Metal: Mass of the fissile and fertile (heavy metal) content of nuclear fuel.

High-Level Waste: Generally, the highly radioactive material resulting from the reprocessing of spent nuclear fuel, including the liquid waste produced directly in reprocessing and the solid material derived from such liquid waste.

Intermediate-Level Waste: Radioactive waste that contains higher levels of radioactive than most low-level waste.

Low-Level Waste: For most countries, radioactive waste not classified as spent fuel, high-level waste, transuranic waste, or any other specific category of radioactive waste. Radiation levels are usually quite low, but occasionally the radiation levels may be high enough to require shielding.

Mixed Waste: Waste that includes concentrations of both radionuclides and hazardous chemicals.

Nuclear Fuel Cycle: The complete series of steps involved in supplying fuel for nuclear reactors. It includes mining, refining, enrichment, fabrication of fuel elements, use in a reactor, chemical processing to recover the fissionable material in the spent fuel, reenrichment of the fuel material, refabrication of new fuel elements, and management of radioactive waste.

Remote-Handled Waste: Radioactive waste with a high surface dose rate and/or heat generation that requires remote handling and/or shielding.

Reprocessing, Fuel: The chemical/mechanical processing of irradiated nuclear reactor fuel to remove fission products and recover fissile and fertile material.

Spent Fuel: Nuclear fuel that has been permanently discharged from a reactor after it has been irradiated.

Transuranic Waste: Radioactive waste that contains elevated concentrations of alpha-emitting isotopes with atomic numbers greater than 92. Some countries (e.g., the United States) may have a more specific definition.

Uranium Mill Tailings: Earthen residues that remain after the extraction of uranium from its ores.

Vitrification: The conversion of radioactive waste materials into a glassy or noncrystalline solid for subsequent disposal.

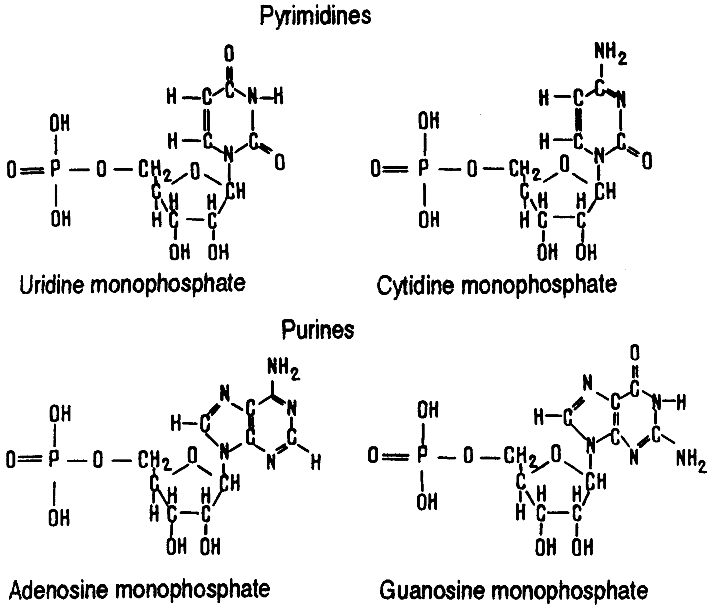

FIG. 1. Chemical formulas of residues of RNA, i.e., of nucleotides. At the top are the pyrimidine nucleotides (U and C), and below, the purine nucleotides (A and G). Nucleotides within DNA differ in that, instead of the right-hand lower OH group, they simply have H. In addition, DNA, instead of the uridine nucleotide, includes the thymidine nucleotide whose top C-H group in the ring is replaced by the C-CH_3 group.

INTRODUCTION

Nucleic acids play a crucial role in all living organisms because they are the key molecules responsible for storage, duplication, and realization of genetic information. There are two types of nucleic acids; ribonucleic acid, or RNA, and deoxyribonucleic acid, or DNA. They are both heteropolymeric molecules consisting of residues (nucleotides) of four types. Four RNA nucleotides are shown in Fig. 1. Each consists of a phosphate group, sugar (these two elements are identical for all four nucleotides), and a nitrous base, which determines the type of the nucleotide. DNA nucleotides are very similar to RNA nucleotides. The main difference is that the right-hand OH group in the sugar is replaced with just H (hence, "deoxy"). Three bases (A,G, and C) are the same for DNA and RNA. Only the fourth base is different: Instead of uracil (U), DNA carries thymine, T (see Fig. 2). The DNA chain is shown in Fig. 3.

In living nature, as we observe it today, DNA plays the most important role because genetic information is stored and duplicated in the form of DNA in all living cells and organisms, without any exceptions. Only in some viruses, which are not living creatures because they cannot reproduce themselves outside cells, is genetic information carried in the form of RNA molecules. The most notable class of such viruses are retroviruses, which include many cancer-inducing viruses as well as HIV, the AIDS virus.

The genetic message is "written down" in the form of continuous text consisting of four letters (DNA nucleotides A, G, T, and C). This continuous text, however, is subdivided, in its biological meaning, into sections. The most significant sections are genes, parts of DNA, which carry information about the amino-acid sequences of proteins. Whereas DNA stores

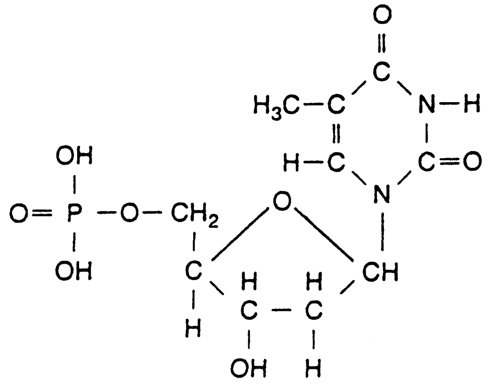

FIG. 2. Thymidine monophosphate is a thymine nucleotide that is part of DNA. The remaining three DNA nucleotides have similar structure, but each has a nitrous base of its own (the top group). These three bases (adenine, guanine, and cytosine) are similar in DNA and RNA (see Fig. 1).

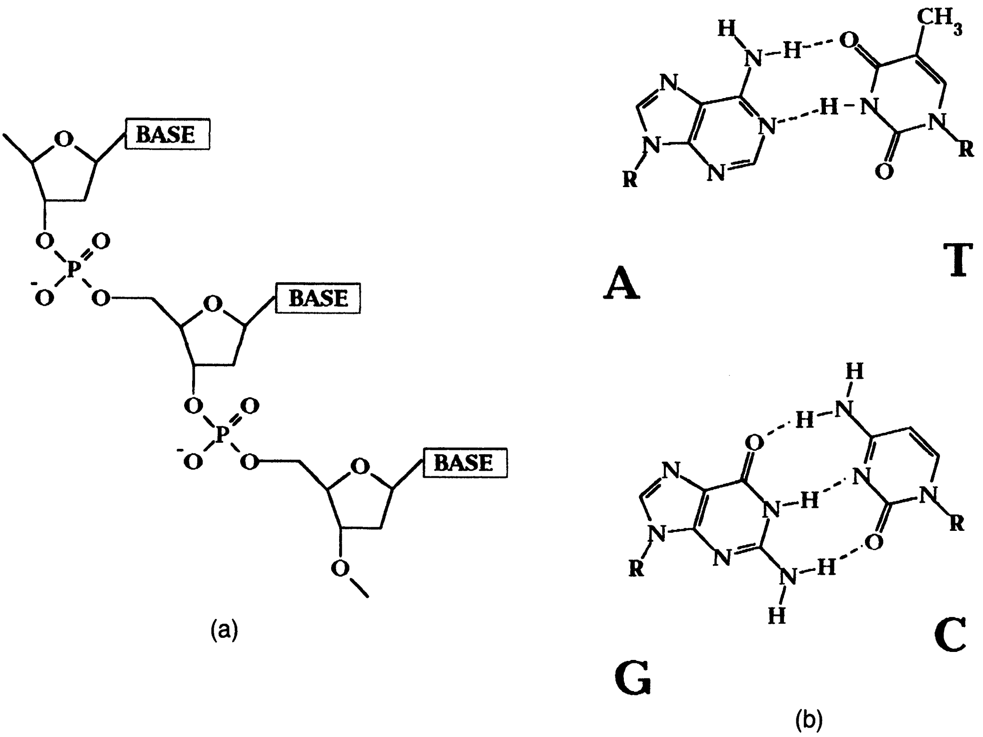

(a)

(b)

FIG. 3. (a) The DNA single strand and (b) the Watson–Crick complementary base pairs.

and duplicates genetic information, RNA plays a key role in its realization, i.e., in the process of synthesis of a protein molecule in accordance with the nucleotide sequence of the corresponding gene.

This process consists of two major steps. First, a RNA copy of the gene is made with the help of a special enzyme, RNA polymerase. The process is called transcription, and the RNA copy of the gene is called messenger RNA (mRNA). Messenger RNA is an exact copy of the gene, in which all thymines (T) are replaced with uracils (U). In the second step, called translation, mRNA is used as a template for protein synthesis in a special cell machinery, the ribosome. The ribosome is a complex aggregate of special ribosomal RNA (rRNA) and a number of proteins. It translates the nucleic-acid text into amino-acid language. In so doing, it uses a special dictionary, the genetic code. In the process of translation, an additional very important class of small RNA molecules plays a crucial role. These RNA molecules consist of about a hundred nucleotides each and are called transfer RNA (tRNA).

The above scheme, known as the central dogma of molecular biology, gives a very general description of how the nucleotide sequence of a gene is realized in the form of the amino-acid sequence of a protein molecule. The scheme is really very general because, for instance, it does not show any difference between prokaryotes, unicellular organisms carrying no cell nucleus, and eukaryotes, complex organisms that have cell nuclei. In practice, however, these two major classes of living organisms significantly differ in the organization of their genomes and its functioning. This difference manifested itself most vividly during the advent of the applied branch of molecular biology, genetic engineering. When pieces of DNA from eukaryotes were incorporated into prokaryotic DNA, they failed to produce any proteins. Only after the fundamental difference was realized in the genome organization of simple microorganisms on the one hand and of complex higher organisms on the other were methods developed that permitted genes of eukaryotes to be expressed in prokaryotes. This opened the way for innumerable applications of molecular biology and marked the beginning of a new era of technological revolution—the era of biotechnology.

The following are the objectives of this article:

Provide an overview of our present knowledge of physical structures of nucleic acids. We describe the most common structures, as well as some new structures discovered recently. The most important structural transitions, such as DNA melting and the B–Z transition, are explained. Special attention is paid to topological properties of DNA, which play a significant role in its functioning within the cell.

Describe some of the major experimental methods used to study nucleic acids, including x-ray diffraction, nuclear magnetic resonance (NMR), electron microscopy, spectroscopic methods, gel electrophoresis, and chemical, photochemical, and enzymatic probing. The potencies of the methods are compared and their advantages and disadvantages discussed.

Describe major biological phenomena where nucleic acids play a crucial role, DNA replication, transcription, and translation. We describe these processes not only in bacteria, where they obey the central dogma of molecular biology, but also in higher organisms and their viruses, for which significant deviations from the central dogma are common, such as RNA splicing, synthesis of DNA on the RNA template, etc.

Provide the background of biotechnology and its prospective. We give the basic ideas for breakthrough discoveries that led to the advent of biotechnology, including restriction enzymes and DNA cloning, DNA sequencing methods, and the polymerase chain reaction (PCR).

1. NUCLEIC ACID STRUCTURES

Traditionally, nucleic acids' structural versatility was considered much narrower than the structural versatility of proteins. This viewpoint well fitted "the division of power" between nucleic acids and proteins in the present-day living creatures. The major function of nucleic acids is to store and reproduce genetic information, while proteins perform an innumerable variety of reactions within the cell and also are its main construction blocks. Major discoveries of the last two decades, however, have significantly changed this attitude. The structural and functional versatility of nucleic acids have proved to be much greater than anybody anticipated before. This is especially true for RNA, which not only adopts extremely complex spatial structures, rivaling the complexity of proteins' spatial structures, but can perform catalytic functions. Such catalytically active RNA molecules have received the special name of ribozymes. The discovery of ribozymes and of the remarkable versatility of RNA structure completely changed the attitude toward the pivotal question of which type of major biopolymers, proteins or nucleic acids, had been the prebiotic molecule, the forefather of the living cell. Before, everybody believed that only protein could fulfill this function. Now, the common view is that this should be the RNA molecule.

However, in the present-day cell, RNA plays just an auxiliary role. The major nucleic acid now is DNA. As a result, DNA structures attract the most attention.

1.1. Major Helical Structures of DNA

In spite of the enormous versatility of living creatures and, accordingly, variability of genetic texts that DNA molecules in different organisms carry, they all have virtually identical physical, spatial structure: the double-helical B form discovered by Watson and Crick (1953). Sequences of the two strands of the double helix obey the complementary principle. This principle is the most important law in the field of nucleic acids, and, probably, is the most important law of the living nature. It declares that, in the double helix, A always opposes T and vice versa, whereas G always opposes C and vice versa.

1.1.1 B-DNA B-DNA (see Fig. 4) consists of two helically twisted sugar-phosphate backbones stuffed with base pairs of two types, AT and GC. The helix is right-handed with ten base pairs per turn. The base pairs are isomorphous: The distances between glycosidic bonds, which attach bases to sugar, are virtually identical for AT and GC pairs. Because of this isomorphism, the regular double helix is formed for an arbitrary sequence of nucleotides, and the fact that DNA should form a double helix imposes no lim-

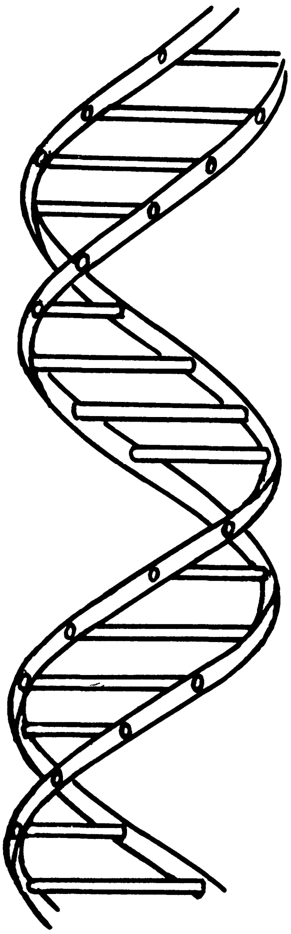

FIG. 4. The double helix.

itations on DNA texts. The surface of the double helix is by no means cylindrical. It has two very distinct grooves: the major groove and the minor groove. These grooves are extremely important for DNA functioning because, in the cell, numerous proteins recognize specific sites on DNA via binding with the grooves.

Each nucleotide has direction: If we treat the sugar as a ring lying in the plane, then the CH_2 group will be above the plane. This carbon is designated as 5′, whereas the carbon atom connecting the sugar to the next nucleotide in the polynucleotide chain is designated as 3′. Thus, the chemical direction is inherent in a single-stranded nucleic acid. In the DNA double helix, the two strands have opposite directions. In B-DNA, base pairs are planar and perpendicular to the axis of the double helix.

Under normal conditions in solution, often referred to as "physiological" (neutral pH, room temperature, about 200 mM NaCl), DNA adopts the B form. All available data indicate that the same is true for the totality of DNA within the cell. It does not exclude, however, the possibility that separate stretches of DNA carrying special nucleotide sequences would adopt other conformations.

1.1.2 B'-DNA Up to now, only one such conformation is demonstrated, beyond any doubts, to exist under physiological conditions. When several A residues in one strand (and, accordingly, several T in the other DNA strand) occur, they adopt the B′ form. In many respects, the B′ form is similar to the classical B form, but there are also significant differences. The main difference consists in the fact that base pairs in B'-DNA are not planar: They form a kind of propeller with the propeller twist of 20°.

Stretches of A residues produce bends in the double helix. Such bends play a very important role in DNA functioning. Although the structural basis of these bends is not fully understood the involvement of the B′ form in the DNA bending is very probable. In spite of its importance, the B′ form does not differ dramatically from the B conformation. Other helical conformations have been found in solution that are significantly different from B-DNA.

1.1.3 A-DNA Similarly to B-DNA, the A form can be adopted by an arbitrary sequence of nucleotides. As in B-DNA, in A-DNA the two complementary strands are antiparallel and form right-handed helices. Normal DNA undergoes a transition from the B to A form under drying. In A-DNA, the base pairs are planar, but their planes form a considerable angle with the axis of the double helix. In so doing, the base pairs shift from the center of the duplex, forming a channel in the center.

If any, A-DNA plays a rather modest role in DNA functioning. There are data indicating that some proteins induce the transition from B to A form. The reason for this remains to be elucidated.

1.1.4 Z-DNA Z-DNA presents the most striking example of how different from the B form the DNA double helix can be. Although in Z-DNA the complementary strands are antiparallel as in B-DNA, unlike in B-DNA, they form left-handed, rather than right-handed, helices. There are many other dramatic differences between Z- and B-DNA.

Not any sequence can adopt the Z form. To adopt the Z form, the regular alternation of purines (A or G) and pyrimidines (T or C) along one strand is strongly preferred. However, even this is not enough for Z-DNA to be formed under physiological conditions. Nevertheless, Z-DNA can be adopted by DNA stretches in a cell as a result of DNA supercoiling (see below). The biological significance of Z-DNA, however, remains to be elucidated.

1.1.5 psDNA The complementary strands in a DNA duplex can be parallel. Such parallel-stranded (ps) DNA is formed most readily if both strands carry only adenines and thymines, and their sequence excludes formation of the ordinary antiparallel duplex. If these requirements are met, the parallel duplex is formed under quite normal conditions. It is right-handed, but the AT pairs are not regular, Watson–Crick ones, but rather so-called reverse Watson–Crick.

1.2 RNA Structure

Quite naturally, similarity between DNA and RNA in their chemical nature entails significant similarity in structures they adopt. RNA can also form the double helix with complementary base pairs AU and GC. However, the major RNA duplex conformation resembles A-DNA rather than B-DNA. In general, because of the bulkier OH group in the sugar ring, the versatility of RNA duplexes is rather narrower than those of DNA.

In the cell, different types of RNA molecules (mRNA, rRNA, tRNA, etc.) exist as single strands. Of course, these strands are not unfolded but fold into complex spatial structures. Mutually complementary stretches of the same molecules form numerous short duplexes, which are the major structural motif of RNA molecules. Single-stranded regions form loops of different types. Sometimes, very complex folding patterns occur, called pseudoknots.

Spatial structure plays an important role in RNA functioning. For instance, rRNA organized in a complex spatial structure forms a scaffolding to which numerous ribosomal proteins attach to form the functional ribosome. The spatial structure of tRNA molecules is specially designed to permit them to fulfill the central role in realization of the genetic code. One part of tRNA carries an anticodon, a trinucleotide complementary to a codon (a trinucleotide corresponding to one amino acid in the genetic code), whereas the amino acid that corresponds to the codon in the genetic code is attached to one terminus of the molecule.

1.3 DNA Topology

DNA very often operates within the cell in the form of a closed circular molecule in which both strands form closed circles (Fig. 5). The closed circular state of DNA is extremely important because, even if DNA is linear as a whole, like the chromosomal DNA of eukaryotes, its parts are organized in closed domains, the closure being fulfilled by proteins. The physical properties and physiological behavior of closed circular (cc) DNA are different in many respects from those of linear DNA molecules. These differences stem from the fact that ccDNA acquires, as compared to linear DNA, a new fundamental feature, topology. There are two levels of DNA topology.

1.3.1 Knots of DNA The double helix as a whole may form a simple circle (i.e., a trivial knot) or be knotted (see Fig. 6). The knotting of DNA may be accomplished by ran-

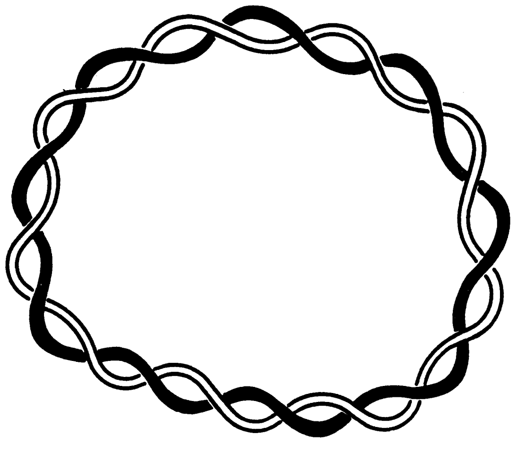

FIG. 5. In a circular closed DNA, two complementary strands form linkage of a high order.

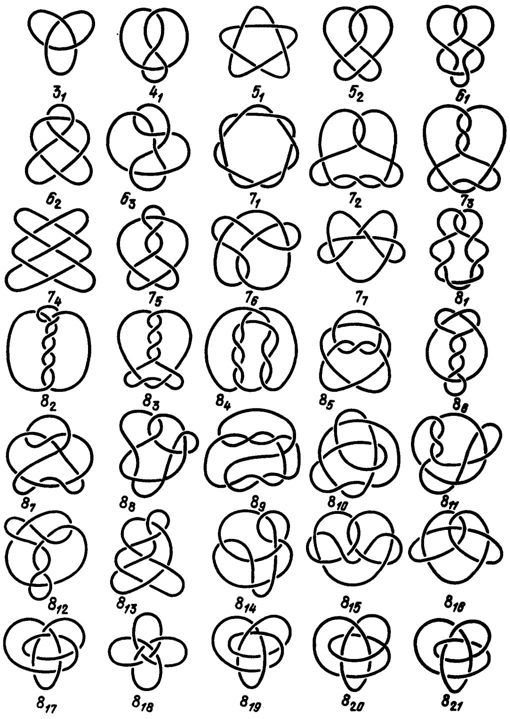

FIG. 6. Knots.

dom closure of linear molecules with "cohesive" ends (mutually complementary single-stranded overhangs). There are also various enzymes that do the job. The most important class of such enzymes is known as DNA topoisomerases II. The type of knot is a topological invariant; i.e., it cannot be changed (converted to another type of knot) without breakage of both DNA strands. As a result, identical ccDNA molecules belonging to different knot types may be separated in gel (Shaw and Wang, 1993).

1.3.2 DNA Supercoiling The two complementary strands in ccDNA are topologically linked with one another (see Fig. 5). The degree of linkage, which is designated as *Lk*, the DNA linking number, is a topological invariant, which cannot be changed by any deformation of the DNA strands without strand breaks. The *Lk* value is easily calculated as the number of times one strand pierces the surface bounded by the other strand. If N is the number of base pairs in DNA and Γ_0 is the number of base pairs per turn of the double helix under given ambient conditions, then the difference

$$\tau = Lk - N/\Gamma_0 \tag{1}$$

is the number of superhelical turns in ccDNA under given conditions. If $\tau \neq 0$, then ccDNA cannot form a planar ring with the helical twist corresponding to the Γ_0 value. Either the helical twist should change, or the DNA molecule as a whole should writhe in space. Actually, with $\tau \neq 0$, both things happen: DNA adopts writhe, and its twist changes. The distribution of energy associated with DNA supercoiling (i.e., with $\tau \neq 0$) between twist and writhe is determined by the torsional and bending rigidities, which have been measured with good accuracy (Frank-Kamenetskii, 1990a). As a result, theoretical knowledge of DNA supercoiling is fairly accurate (Vologodskii *et al.*, 1992).

Closed circular DNA molecules extracted from cells of eukaryotes are always negatively supercoiled ($\tau < 0$; the double helix is "underwound"). Usually, superhelicity is characterized by superhelical density:

$$\sigma = \tau\Gamma_0/N. \tag{2}$$

Special enzymes, topoisomerases, regulate DNA superhelicity in the cell. Supercoiling is also significantly affected by replication and transcription. DNA topology plays an extremely important role in DNA functioning (Cozzarelli and Wang, 1990).

1.4 Unusual Structures and Structural Transitions

If negative supercoiling in ccDNA becomes too high, the bending and torsional degrees of freedom may become insufficient to accommodate the superhelical energy. Under these circumstances, the integrity of the DNA double helix breaks down in its most "weak" sites. These sites, which have the potential to adopt structures significantly different from B-DNA, can undergo structural transitions into unusual (non-B-DNA) structures.

1.4.1 Melting of DNA On heating or under superhelical stress, the DNA complementary strands separate, forming single-stranded loops. In the case of linear duplex molecules, the process ends up, at sufficiently high temperature, with complete separation of the two strands. The process has been comprehensively studied both experimentally and theoretically (Wada and Suyama, 1986) and is known as DNA melting (the terms denaturation or helix-coil transition can be also found in the literature). AT pairs have significantly lower stability than GC pairs.

With increasing temperature, long DNA sections melt out. The melting of each such section is a cooperative, all-or-none phenomenon. However, the melting of a long enough molecule becomes a series of such cooperative processes, each occurring at its own temperature (Fig. 7). Roughly speaking, sections more enriched with CG pairs melt out at higher temperatures. Thus, DNA melting is not a classical phase transition because two different "phases," helical and melted, coexist with each other in one and the same molecule.

When two mutually complementary single-stranded DNA molecules are mixed, the process reverse to melting occurs. It is called renaturation or annealing.

DNA melting is an exceptionally important phenomenon. It occurs in the cell when DNA replicates and when DNA polymerase "reads" the mRNA copy of the gene. Cycles of melting and annealing are utilized in PCR machines, the most remarkable tools of the current biotechnological revolution (see Sec. 4.1.5).

Melting of AT-rich regions in ccDNA may occur with increasing negative supercoiling. However, this does not happen often because other unusual structures defeat melting in competition for the energy of supercoiling.

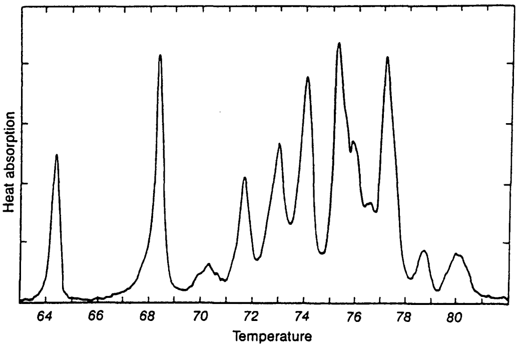

FIG. 7. Melting of DNA. This curve is also often called the differential melting curve. The curve was obtained for DNA that has the code name of ColEI and contains about 6500 nucleotide pairs.

1.4.2 B–Z Transition Negative supercoiling most favors formation of Z-DNA because, in this case, the maximal release of superhelical stress per base pair adopting a non-B-DNA structure is achieved. As a result, although under physiological conditions the Z form is energetically very unfavorable as compared with B-DNA, it is easily adopted in negatively supercoiled DNA by appropriate DNA sequences (with alternating purines and pyrimidines).

Linear DNA with the appropriate sequence adopts the Z conformation at a very high salt concentration (about 3 M NaCl).

1.4.3 Cruciforms Another structure readily formed under negative supercoiling is cruciform, which requires palindromic regions (see Fig. 8). To form a cruciform, a palindromic region must be longer than a certain minimum. For example, six–base-pair–long palindromes recognized by restriction en-

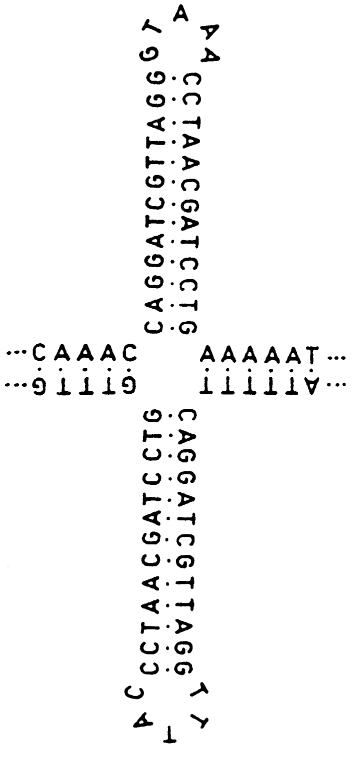

FIG. 8. A cruciform formed in ColEI DNA when the molecule is in a superhelical state.

zymes do not form cruciforms under any conditions.

1.4.4 H-DNA H-DNA forms a special class of unusual structures, which are adopted under superhelical stress by sequences carrying purines (A and G) in one strand and pyrimidines (T and C) in the other, i.e., homopurine-homopyrimidine sequences (Frank-Kamenetskii, 1990b). The major element of H-DNA is a triplex formed by one half of the insert adopting the H form and by one of two strands of the second half of the insert (Fig. 9). Two major classes of triplexes are known—pyrimidine-purine-pyrimidine (PyPuPy) and pyrimidine-purine-purine (PyPuPu). Figure 10 shows the canonical base triads entering these triplexes.

Always two isomeric forms of H-DNA are possible, which are designated as H-y3, H-y5, H-r3, and H-r5, depending on which kind of triplex is formed and which half of the insert forms the triplex (see Fig. 9). H-DNA may be considered as an intramolecular triplex (it is often referred to in this way). Its formation under physiological conditions occurs only under superhelical stress.

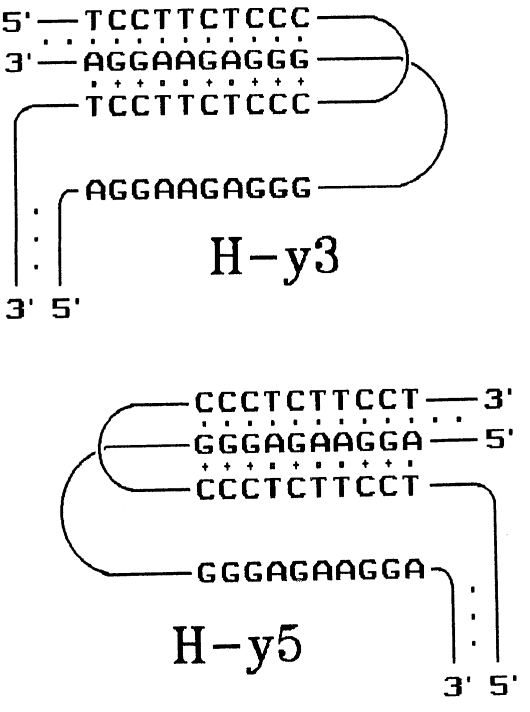

FIG. 9. DNA's H-form structure. Two possible "isomeric" variants of the structure are shown. The Watson–Crick pairing is designated by filled circles, while the GC Hoogsteen pairing, involving the presence of an extra proton, is designated by plus symbols.

The discovery of H-DNA stimulated studies of intermolecular triplexes, which may be formed between homopurine-homopyrimidine regions of duplex DNA and corresponding pyrimidine or purine oligonucleotides. These studies have led to the development of very promising approaches to sequence-specific targeting of duplex DNA (Cherny *et al.*, 1993).

1.4.5 Quadruplexes Of all nucleotides, guanines are the most versatile in forming different structures. They may form GG pairs, but the most stable structure, which is formed in the presence of monovalent cations (especially potassium), is the G4 quadruplex (see Fig. 11). G quadruplexes may exist in a variety of modifications: all-parallel, all-antiparallel, and others. As a result, G quadruplexes are easily formed both intermolecularly and intramolecularly, again with a variety of modifications.

A totally unusual quadruplex was discovered by Gehring *et al.* (1993). It contains two hemiprotonated parallel-stranded duplexes consisting of unusual CC^+ pairs. The two parallel-stranded duplexes are associated in a mutually antiparallel manner so that CC^+ base pairs from one duplex are "layered" by CC^+ pairs from the other duplex, thus alternating along the structure.

1.4.6 RNA Unusual Structures Most DNA unusual structures have their analogs in the RNA world. Specifically, the formation of triplexes was first demonstrated by Felsenfeld *et al.* (1957) for artificial RNA chains. Solitary RNA base triads are often met in tRNA structures. Triplexes are formed by mixed DNA-RNA hybrids, and some of them are rather stable (Roberts and Crothers, 1992).

RNA molecules form G quadruplexes, and there are exciting data indicating that RNA G quadruplexes could be an important element in the structure of HIV RNA. However, in general, studies of RNA unusual structures lag behind the corresponding DNA structures because methods to study unusual structures are much better developed in the case of DNA than in the case of RNA.

2. METHODS TO STUDY NUCLEIC ACID STRUCTURES

The number of methods that are used to study the structure of nucleic acids is truly enormous. Methods to study DNA alone occupy two volumes of the Methods in Enzymology series (Lilley and Dahlberg, 1992a,b). We survey only those of them that are most informative and are widely used. Along with general methods to study molecular structures, a number of special methods have been elaborated to study nucleic acids. But even the regular methods, such as x-ray analysis or electron microscopy, are often significantly modified to fit the needs of studying such complex molecules as nucleic acids.

2.1 General Methods

In this section, we discuss methods that are generally used to study molecular structures. We do not describe the background of

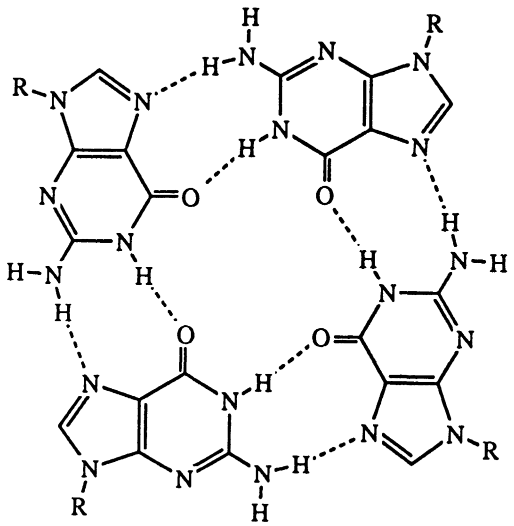

FIG. 11. G quadruplex.

the methods, because they are widely known, but rather concentrate on specific questions of their application to studing nucleic acids.

2.1.1 X-Ray Analysis As in other fields where molecular structure is essential, x-ray analysis occupies a unique position among methods of studying nucleic acid structure as the only direct method that permits elucidation of the structure in all details. X-ray crystallography is absolutely indispensable in the study of the detailed structure of complexes of nucleic acids with proteins, which is most essential for understanding how nucleic acids function in the cell.

However, for a long period of time, the whole edifice of molecular biology relied on one of the indirect versions of x-ray analysis, fiber diffraction, rather than on classical x-ray crystallography.

2.1.1.1 Fiber Diffraction. Long molecules of nucleic acids cannot be crystallized. As a result, from the early 1950s till the mid-1970s, only x-ray diffraction from nucleic acid fibers was used to elucidate the structure of nucleic acids. Such data were used by Watson and Crick (1953) to propose structures for B- and A-DNA. Fiber diffraction is an essentially indirect method, and, to elucidate structure from the data on fibers, one must heavily rely on theoretical approaches, such as conformational analysis.

2.1.1.2 X-Ray Crystallography. The first good crystals of nucleic acids were obtained for the case of relatively short nucleic acids, the tRNA molecules, and those were the first nucleic acids for which structure was solved by classical x-ray crystallography.

The first DNA crystals became available only in the late 1970s, after remarkable progress in chemical synthesis of short DNA pieces had been achieved. This led to many discoveries, first of all of left-handed Z-DNA by Rich and co-workers (Wang *et al.*, 1979).

In recent years, a lot of very detailed data on the structure of DNA have been obtained by x-ray crystallography, including detailed study of the B, B′, A, and Z forms (Dickerson, 1992). Among the most recent achievements of the method is solution of the structure of the G quadruplex (Kang *et al.*, 1992).

In spite of remarkable accomplishments, serious limitations are inherent in the method. It is extremely hard to obtain good crystals of a nucleic acid even if it adopts only a unique structure. For instance, for DNA or RNA triplexes, sufficiently good crystals are still unavailable. Even if this difficulty is overcome, it sometimes appears that the structure in a crystal is significantly perturbed by interaction with neighboring molecules. It is especially true of such subtle, but very important from a biological viewpoint, deformations as bending of the double helix. Thus, the data obtained by the methods of x-ray crystallography should always be correlated with the results of indirect methods, which permit the study of nucleic acid in solution. X-ray crystallography is totally useless for studying such biologically significant problems as DNA supercoiling or the structure of large RNA molecules.

2.1.2 Nuclear Magnetic Resonance (NMR) The role of NMR (see MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE, NUCLEAR) constantly increases, and, in recent years, it has even started to compete successfully with x-ray crystallography. This has become possible as a result of the development of two-dimensional proton NMR techniques, especially nuclear Overhauser-effect spectroscopy (NOESY). The great advantage of NMR, as compared with x-ray crystallography, consists in the fact that it does not require crystals. As a result, structures of some nucleic acids that resist crystallization, like triplexes, have become subjects of very fruitful study by NMR (Rajagopal and Feigon, 1989).

A great advantage of NMR consists in the possibility of studying structural fluctuations, or "breathing," of nucleic acids by following proton exchange in nucleic acid bases. Such studies made it possible to find out important characteristics of base-pair fluctuational openings in DNA (Gueron *et al.*, 1987).

Turning to the limitations of the method, it should be emphasized that resolution of even the most powerful NMR spectrometers permits the study of only short nucleic acids containing about a dozen distinguishable nucleotides. Although crystals are not needed, only very concentrated solutions can be studied. Therefore, like x-ray crystallography, NMR is useless for studying many biologically relevant problems of nucleic acid structure. In spite of its limitations, proton NMR has firmly occupied the second position, after x-ray crystallography, among methods to study nucleic acid structure.

2.1.3 Microscopy Although microscopy looks like the most direct way to visualize structure, in application to nucleic acids it has too numerous limitations to occupy a position ahead of x-ray crystallography or NMR. Nevertheless, in recent years, the role of microscopy in the field of nucleic acids has significantly increased as a result of progress in regular electron microscopy of nucleic acids and their complexes and the development of new techniques, cryo-electron microscopy and scanning tunneling microscopy.

2.1.3.1 Regular Electron Microscopy. In regular electron microscopy, nucleic acids are placed on the grid, dried, and contrasted by one or another method. In recent years, the most popular technique of contrasting consists in staining with uranyl acetate. As a result, for instance, duplex DNA molecules are clearly seen (see Fig. 12).

Regular electron microscopy permits one to see complexes of nucleic acids with proteins. Poor resolution usually does not permit one to observe the internal structure of the complex but permits mapping of the location of the protein on DNA (see Fig. 12).

A limitation of regular electron microscopy stems from poor resolution and the possibility of significant perturbation of nucleic acid structure in the process of sample preparation. And still, in many cases, the method provides the most convincing evidence.

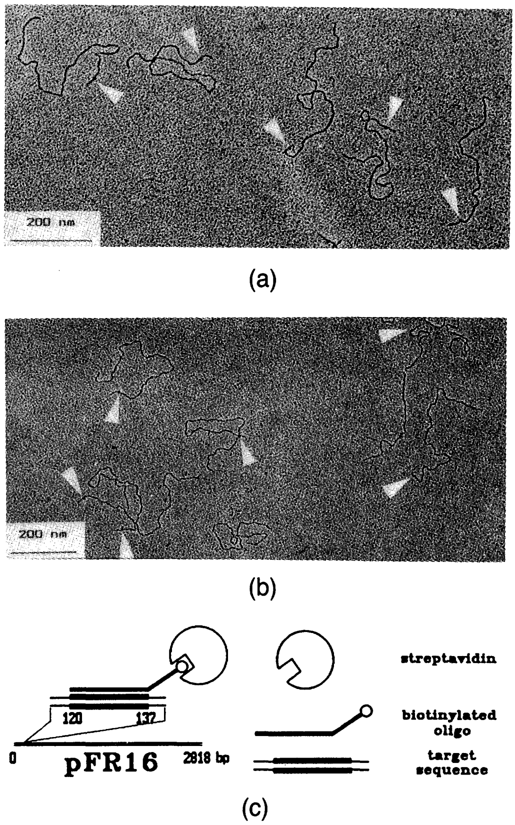

FIG. 12. Electron-microscopy visualization of triplexes formed between duplex DNA and corresponding oligonucleotides [(a) pyrimidine or (b) purine]. The oligonucleotides were chemically tagged by biotin molecules, and then the protein streptavidin was added, which strongly binds to biotin [see the chart, (c)]. The sites of triplex formation are seen as "beads" due to streptavidin molecules and are indicated by the white arrowheads. The data are from Cherny *et al.* (1993).

2.1.3.2 Cryo-Electron Microscopy. The method is based on obtaining vitrified water solutions via very quick cooling of an extremely thin (in the micron range) sample. As a result, the molecule is "frozen" in the state it adopted in solution before cooling. In recent years, the method has received numerous applications in molecular biology in general and in the field of nucleic acids and their complexes with proteins in particular (Dubochet *et al.*, 1992).

The great advantage over regular electron microscopy consists in avoiding the harsh procedures of sample preparation, which strongly limit the value of the data obtained by regular electron microscopy.

The major problem of cryo-electron microscopy stems from the low contrast of biological molecules. Without staining or other contrasting, they are barely visible in an electron microscope. Nevertheless, DNA molecules and their complexes with proteins are extensively studied by the method (Dubochet *et al.*, 1992).

2.1.3.3 Scanning Tunneling and Force Microscopy. These are very new methods in general and in the field of nucleic acids in particular. Spectacular images of DNA helices and even bases obtained by scanning tunneling microscopy (STM) have been widely publicized and created great excitement. However, the nature of these images remains obscure because DNA molecules are not conductors and are not expected to be seen in STM. The recent data of Dunlap *et al.* (1993) strongly indicate that the STM images of DNA could be artifacts.

By contrast, scanning force microscopy (SFM) provides reliable images of DNA molecules and their complexes with proteins (Bustamante *et al.*, 1993). At present, the resolution of this method is not much higher than that of regular electron microscopy. However, there are reasonable hopes that the resolution will be significantly improved in the course of further development of the method.

2.1.4 Optical Methods All optical methods that are traditionally applied to study molecular structures are widely used to study nucleic acids. They are indispensable in routine investigations because they are cheap and quick. The great advantage of those that use light in the visible and UV region consists in the possibility of study of very dilute solutions of nucleic acids, for which intermolecular interaction can be completely neglected. On the other hand, all these methods are essentially indirect and provide any structural information only after careful assignment of particular spectra or special changes with the help of more direct methods described above.

2.1.4.1 UV Spectroscopy. Nucleic acid bases absorb UV radiation around 260 nm. The intensity of this absorption, which is easy to measure with regular spectrophotometers, changes when, for instance, the DNA double helix melts. Hence, UV spectroscopy has been extensively applied to study DNA melting. In application to RNA, the method is not very informative because, in single-stranded RNA molecules, the variety of structures is too large to be elucidated by this method. Changes of UV absorption are too small for B-to-A and B-to-Z transitions.

2.1.4.2 Circular Dichroism (CD). CD spectra in the vicinity of 260 nm are much more sensitive to DNA helical structure than UV absorption. B-DNA, A-DNA, and Z-DNA have characteristic and very different CD spectra (Johnson, 1990), and this fact is extensively used in the study of structural transitions in DNA between different helical structures (Ivanov and Krylov, 1992). As with UV spectra, CD spectra are much less informative in the case of RNA than in the case of DNA.

2.1.4.3 Infrared and Raman Spectroscopy. Infrared and Raman spectra are sensitive to nucleic acid structure. Correspondingly, IR and Raman spectroscopies are used to study nucleic acids. However, the main limitation of these methods stems from the fact that they require high concentrations of nucleic acids. As a result, these methods are much less popular than UV and CD spectroscopies.

2.1.4.4 Fluorescence. Nucleic acids practically do not emit absorbed radiation. However, some RNA molecules, along with the four canonical bases, contain unusual bases, and some of them are fluorescent. This fact is extensively used to study the RNA molecules that carry such bases. Regularly, fluorescence methods are used via binding to nucleic acids of strongly fluorescent dye molecules, such as ethydium.

Fluorescence sensitization and quenching due to excitation energy transfer between the donor molecule of electronic excitation and the acceptor molecule of the excitation are also used. For instance, to check the polarity of strands the donor molecule is tagged to, say, 3'-end of one strand, whereas the acceptor molecule is tagged to the 3' end of the complementary strand. Then the two strands anneal, forming a duplex. Strong excitation energy transfer and acceptor indicates that a parallel-stranded duplex is formed.

2.1.5 Theoretical Methods The paper that signified the beginning of extensive studies of nucleic acids and their biological role was purely theoretical (Watson and Crick, 1953). Since then, theory has been playing a very important role in study of nucleic acids.

2.1.5.1 Conformational Analysis. Conformational analysis was especially important during the era of fiber diffraction. In fact, what Watson and Crick did in their classical paper (Watson and Crick, 1953) was a very simple, but exceptionally efficient, variety of conformational analysis. Since then, the method has been extensively used to refine structures solved by x-ray crystallography (Dickerson, 1992). The method is also often used to predict new structures. For instance, parallel-stranded DNA duplexes were first predicted theoretically and then found experimentally.

2.1.5.2 Theoretical Models. As in the study of any important physical object, a number of simplified theoretical models of nucleic acids exist, different models being used to analyze different properties. Figure 13 presents schematics of some of these models.

The DNA double helix may be treated as an isotropic elastic rod [Fig. 13(a)]. In the framework of this model, the DNA molecule is described by only three parameters: bending and torsional rigidities and the diameter. The model has proved to be extremely useful to analyze hydrodynamics and other properties of linear DNA, when it behaves as a usual polymeric molecule. It also permitted provision of the comprehensive theoretical treatment of DNA topology of both levels, knotting (Klenin *et al.*, 1988; Shaw and Wang, 1993) and supercoiling (Vologodskii *et al.*, 1992).

A quite different, but also very successful, model treats the DNA double helix as consisting of base pairs of two types: closed and open [Fig. 13(b)]. This is the helix-coil model, which has permitted quantitative explanation of all major features of DNA melting (Wada and Suyama, 1986).

The polyelectrolyte model [Fig. 13(c)] treats DNA itself just as a charged cylinder but allows for mobile counterions surrounding the double helix (Frank-Kamenetskii *et al.*, 1987).

To predict RNA structure, a simplified model of RNA folding is widely used [Fig. 13(d)].

There are many other theoretical models of DNA and RNA. Usually, the theoretical models are treated within the framework of statistical mechanics. However, in many cases, such consideration has proved to be insufficient because very slow relaxation is rather typical for nucleic acids. Such slow relaxational processes were very thoroughly studied both theoretically and experimentally in the case of DNA melting (Anshelevich *et al.*, 1984). One cannot correctly describe RNA folding without allowance for slow relaxational processes. Such processes are very essential in many cases of formation of DNA

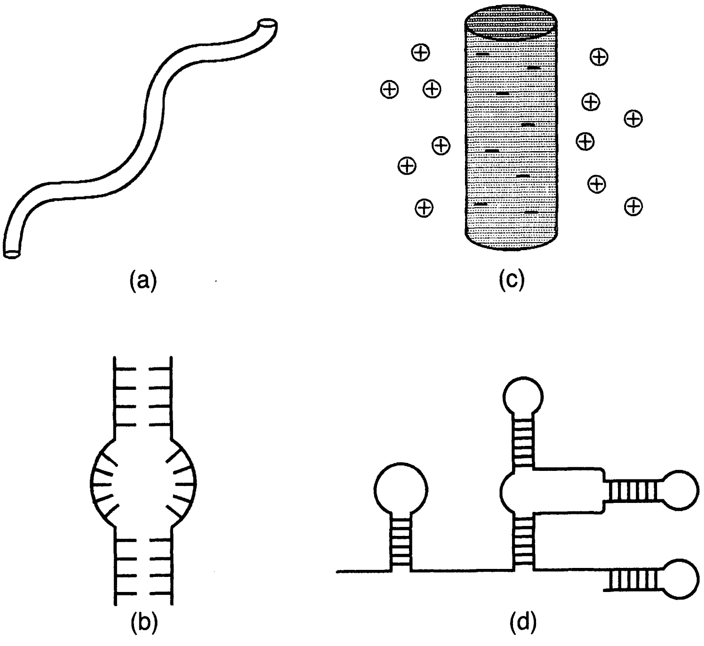

FIG. 13. Theoretical models of nucleic acids: (a) elastic-rod model, (b) helix-coil model, (c) polyelectrolyte model, (d) model of RNA folding.

unusual structures under negative superhelical stress.

2.2 Special Methods

In this section, we consider the most important methods specially developed to study nucleic acids. These methods have been introduced relatively recently (in the past 20 years), but, in many cases, they have pushed aside the traditional methods.

2.2.1 Gel Electrophoresis Gel electrophoresis is a simple technique, introduced in the early 1970s, which truly revolutionized the study of nucleic acids and, subsequently, the whole field of molecular biology. All developments in this field in the past 20 years are connected, directly or indirectly, with the gel electrophoresis method. Gel electrophoresis has pushed aside ultracentrifugation as the method used to separate nucleic acids.

2.2.1.1 Background. Gel electrophoresis differs from electrophoresis in solution only in the nature of the medium in which molecules are separated in the electric field. In the case of gel electrophoresis, the medium is a gel, a polymer network. The most popular in the field of nucleic acids are gels made of polyacrylamide or agarose. Originally, the great advantage of gels in the separation of nucleic acids was discovered purely empirically. The understanding came later after some ideas of P.-G. De Gennes were borrowed from polymer physics, namely the notion of reptation of polymer molecules.

As in regular electrophoresis, the electrophoretic mobility μ is defined as the proportionality coefficient between velocity of movement, v, and the electric field E:

$$v = \mu E. \tag{3}$$

The electric force applied to a nucleic acid of length L is proportional to L (because each residue carries a negative charge). Hence

$$\mu \sim LD, \tag{4}$$

where D is the diffusion coefficient:

$$D = \langle x^2 \rangle / \tau, \tag{5}$$

where τ is the characteristic time for a nucleic acid molecule to go out of its original "tube" and $\langle x^2 \rangle$ is the mean-square shift of the molecule after it leaves the tube.

All movements other than within the "tube" are forbidden in the gel. As a result, the molecule experiences Brownian motion only along its own axis (i.e., within the "tube"). Because the friction in the course of such movement is proportional to L,

$$\tau \sim LL^2 = L^3. \tag{6}$$

For the ideal polymer coil,

$$\langle x^2 \rangle \sim L,$$

and we finally obtain

$$\mu \sim 1/L, \tag{7}$$

whereas, without the gel, similar considerations would lead to the lack of dependence of μ on L. Equation (7) explains why the gel is so efficient a medium to separate molecules of nucleic acids according to their lengths during electrophoresis.

The consequences of Eq. (7) are really far-reaching. The entire idea of genetic engineering, i.e., reshuffling of DNA pieces extracted from different organisms, became feasible only after two major breakthroughs: the discovery of restriction enzymes, which cut long DNA molecules into shorter pieces recognizing special short nucleotide sequences, and the implementation of gel electrophoresis to separate the pieces obtained after cutting. Each piece forms its own band in the gel after the electric field is switched off. Then the gel is cut by an ordinary razor to obtain one unique piece of DNA.

2.2.1.2 Regular Gel Electrophoresis and DNA Sequencing. Gel electrophoresis is indispensable in all methods of DNA sequencing, which have revolutionized the entire field of biology. We explain the basic idea of application of regular gel electrophoresis to DNA sequencing using the chemical method of Maxam and Gilbert (1977) as an example. We explain the essence of the techniques using the example of single-stranded DNA fragments. The technique also happens to be applicable to double-stranded DNA fragments.

So, suppose we have a sample consisting of identical single-stranded DNA fragments of an unknown sequence. First, using a specific enzyme, radioactive phosphorus ^{32}P is attached to one (particular) end of the fragment. We shall refer to the molecule's labeled end as the beginning, the other end being unlabeled. The sample is then divided into four parts.

Then a substance which breaks the DNA strand after an adenine nucleotide (A) is added to the first fraction. In so doing, the reaction conditions are chosen in such a way that, on the average, about one A per fragment will be attacked during the reaction. The reagent will transform the original mixture of uniform-length fragments into one of fragments of varying length. In the process, we are concerned solely with the labeled fragments. If, say, adenines occupy positions 1, 3, 7, 13, 21, 25, and 26 on the original fragment, we may assume that the reagent is added to result in the appearance of labeled fragments with lengths of 1, 3, 7, 13, 21, 25, and 26 nucleotides. Not a single fragment of a different length is expected to appear.

Similarly, the three other parts of the original solution are treated with substances breaking the chain after T, G, and C. After this, all four samples are separated in a parallel manner in the same apparatus for gel electrophoresis. After the electric field is cut off, a photographic plate is placed on the gel's surface to imprint on it the labeled bands in the gel.

The experiment's result is diagrammed in Fig. 14. The sequence that can be read directly on the electrophoregram is shown to the left. (Actually, three, rather than four, different reagents are sufficient.)

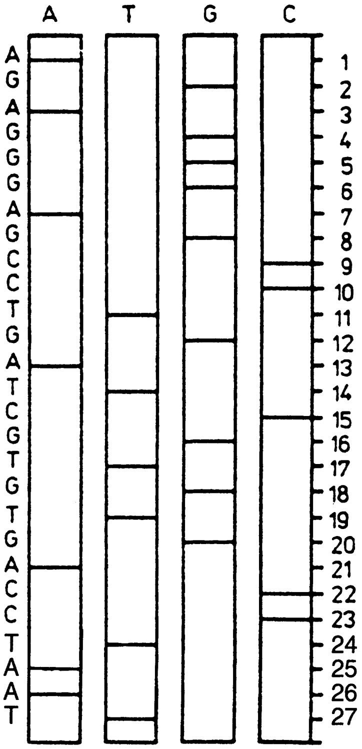

FIG. 14. The Maxam–Gilbert method (chart).

The DNA sequencing techniques have been developed to perfection, based on different conceptual approaches. The most fertile approach proved to be that of Sanger *et al.* (1977), who developed a method of DNA sequencing that uses enzymes working on DNA. Instead of radioactive labels, the approach uses nucleotide analogs linked to different dyes, which makes sequencing an ecologically much cleaner technique.

2.2.1.3 Pulse Electrophoresis. Even gel electrophoresis has its limitations. According to Eq. (7), with increasing length of molecules, their electrophoretic mobility decreases. Therefore, to separate very long molecules in a practically acceptable time scale, one needs to increase the electric field. However, the treatment in Sec. 2.2.1.1 is valid for the case of very small electric fields, which do not deform the molecules [otherwise Eq. (4) would not be valid]. At high fields, the DNA molecule (we talk about DNA because only DNA molecules could be so long that the problems arise) straightens along the electric field. As a result, it moves not like a polymer coil but like a rodlike, straight object. The electrophoretic mobility of such a molecule does not depend on its length independently of whether it moves in pure solvent or in gel, because, in this case, the friction and the driving force are both proportional to L. Thus, in a strong field, separation with respect to length occurs only for a short time before the DNA molecules are straightened. It is totally senseless to conduct electrophoresis longer than this time because all molecules, independently of their length, will just shift by the same distance. Does this mean that long DNA molecules cannot be separated in gel?

Schwartz and Cantor (1984) found a simple way out of the deadlock. If, soon after the molecules are straightened, the direction of the electric field is significantly changed, say by 90°, then, before the molecules will be straightened in the new direction, they assume again the shape of a polymer coil and will be separated for the same short time as while moving in the first direction. After straightening in the second direction, the field again is switched to the first direction, etc. As a result of such cycles or pulses, the molecules effectively move in the diagonal direction, and the separation takes place throughout the duration of the experiment.

Pulse electrophoresis dramatically increased the range of lengths of DNA molecules that can be separated in gels. The method permits separation of entire chromosomal DNA molecules. Implementation of this method opened the way to such ambitious projects as the Human Genome Project, which is designed to sequence the entire human genome (see Sec. 4.2.6).

2.2.1.4. Separation of DNA Topological Conformers. In the field of DNA topology and supercoiling, gel electrophoresis created a kind of revolution similar to those in other branches of nucleic acid research and applications. Although for a different reason than linear DNA, closed circular DNA molecules belonging to different topological classes move in gel with different velocities. As a result, knots of different types can be separated in gel (Shaw and Wang, 1993). The same is true for different topoisomers, ccDNA molecules differing in the linking number *Lk* (see Fig. 15). There it is not the *Lk* value according to which DNA molecules are actually separated, but the writhing, i.e., the spatial shape of the double helix (see Sec. 1.3.2). More precisely, the mobility depends on the absolute value of writhing.

2.2.1.5. Two-Dimensional Gel Electrophoresis. The regular, one-dimensional gel electrophoresis does not separate supercoiled molecules that have the same absolute value of the number of superhelical turns τ but different sign because those molecules have the same absolute value of writhing. When a structural transition into an unusual structure occurs, although the *Lk* value does not change, both twisting and writhing change (their sum, which is the linking number, remaining unchanged). As a result, a topoisomer carrying an unusual structure may move in gel with the same speed as another topoisomer without an unusual structure. To avoid such confusion, two-dimensional gels are used.

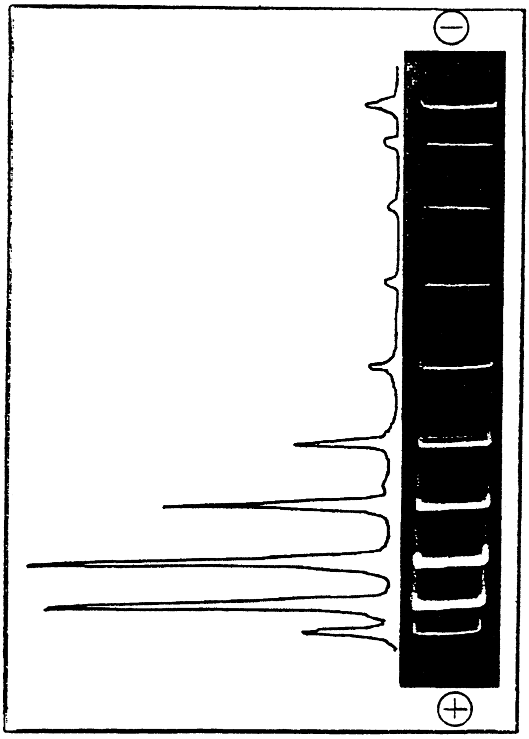

FIG. 15. Separation of DNA molecules differing by the number of superhelical turns, done by the gel electrophoresis technique. The experiment was conducted with DNA of a small pA03 plasmide, containing 1683 nucleotide pairs. Originally, the molecules were inserted at the top, near the negative electrode (the place is not shown in the figure).

A specially prepared mixture of different topoisomers of one and the same DNA, carrying an insert capable of changing into an alternative structure, is placed in the left top angle of a quadrangular gel plate (see Fig. 16). Then an electric field is applied to force DNA molecules to move from top to bottom along the left edge of the plate. Following the separation of topoisomers in the first direction, the gel is saturated with chloroquine molecules, which lessen superhelical stress. The chloroquine concentration is chosen in such a way as to make the superhelical stress insufficient for the formation of an unusual structure. After that, the direction of the electric field is changed to force molecules to move from left to right. As a result, the sequence of spots in the second direction corresponds to the topoisomers' sequence.

The uppermost spot in Fig. 16 corresponds to zero topoisomer, i.e., to a relaxed and nonsuperhelical DNA. The spots coming from that spot clockwise correspond to positive topo-

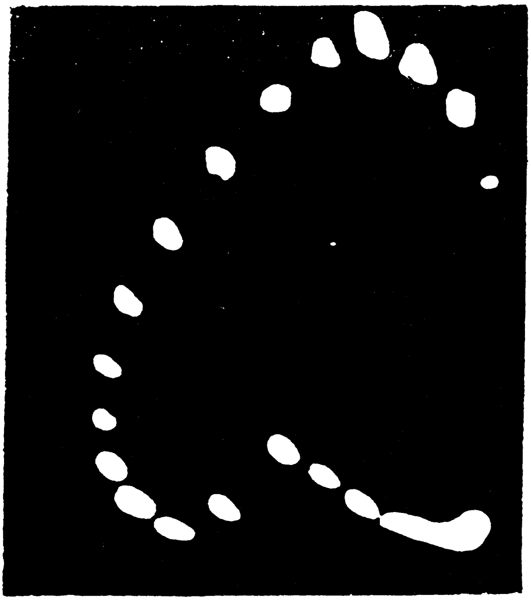

FIG. 16. A typical pattern of two-dimensional gel electrophoresis, observed during formation in DNA of an unusual structure.

isomers; those going anticlockwise, to the negative. One can clearly see the mobility drop, observed in this case between −10 and −12 topoisomers. This means that in topoisomers −12, −13, . . ., an unusual structure is present, while in topoisomers . . ., −9, −10, it is absent. Topoisomer −11 occupies an intermediate position: It carries the unusual structure during, roughly, half the time of its movement in the gel.

2.2.2 Chemical, Photochemical, and Enzymatic Probing A great variety of special approaches have been elaborated to study nucleic acid structures (Lilley and Dahlberg, 1992a,b). They are grounded on the different reactivities of nucleic acids adopting different structures with respect to chemical, photochemical, and enzymatic reactions. In many cases, these methods make it possible to arrive at very specific conclusions about the structure of a particular region of a nucleic acid under conditions that totally exclude application of not only x-ray crystallography or NMR but even spectroscopy and other indirect physical methods. Sometimes, the methods under consideration are applicable even *in vivo*.

To explain the general ideology underlying these methods, let us consider a specific example. In Sec. 1.4.4, we mentioned intermolecular triplexes, which are formed between homopurine-homopyrimidine regions of DNA and corresponding homopurine or homopyrimidine oligonucleotides. If such a complex is actually formed, the reactivity of the N7 position of guanine should dramatically decrease because this nitrogen is sheltered in the triplex by the Hoogsteen pairing (see Fig. 10).

The chemical agent used is dimethyl sulfate (DMS), which reacts with the N7 position of guanine, alkylating it. This alkylation occurs in single-stranded as well as in duplex nucleic acids. However, it cannot take place in triplexes. As a result, in the complex of duplex DNA with an oligonucleotide, which forms a triplex, all guanines in the duplex outside the triplex zone will be alkylated by DMS, whereas guanines within the triplex zone will remain unmodified.

Then the DNA piece under study is end-labeled and subjected to hot piperidine treatment, just as in the Maxam–Gilbert sequencing technique (actually, it is DMS that is used in the Maxam–Gilbert method as a reagent on guanines). Piperidine will convert the sites of alkylated guanines into chain breaks. Such breaks will never occur in the triplex zone. Figure 17 shows the pattern that is obtained after separation of the fragments in gel and radioautography.

The above example is a specific case of the footprinting assay. Such assays can be applied, for instance, to complexes of DNA with proteins to find out which sequences are recognized by the proteins. Instead of DMS, DNAase I, which cuts the uncovered DNA duplex, is often used. The yield of some photoproducts that can also be converted to strand breaks dramatically decreases when a duplex region is covered by a protein or an oligonucleotide. Hence the photo-footprinting assay is useful.

Some chemical reagents, like diethyl pyrocarbonate, potassium permanganate, and osmium tetroxide, do not react with bases in the double helix but react with open bases. The products can be converted into chain breaks. These reagents are widely used to detect open regions. Single-strand–specific nucleases, which digest single strands but do not digest duplex, are used in a similar way.

Chemical, photochemical, and enzymatic

probing are extremely powerful methods of detecting unusual structures, such as Z-DNA, cruciforms, H-DNA, and G quadruplexes (Lilley and Dahlberg, 1992a,b).

3. BIOLOGICAL FUNCTIONS OF NUCLEIC ACIDS

Nucleic acids occupy the most basic position in all living organisms. In this section, we briefly consider how nucleic acids fulfill the most significant of their numerous physiological functions.

3.1 Replication

The most basic function of nucleic acids consists in storage and reproduction of genetic information, which is encoded in the sequence of nucleotides. In principle, one strand of a nucleic acid carries the complete information, and many viruses actually carry only single-stranded DNA or RNA molecules. However, in all living cells, information is stored and reproduced in the form of the DNA double helix.

3.1.1 DNA Replication The ability of nucleic acids to replicate is inherent in the complementary principle. In autonomous living organisms, from unicellular up to the human, genetic information is stored in the form of duplex DNA. Schematically, replication consists in separation of the complementary DNA strands and synthesis on each of the strands of complementary ones (see Fig. 18). In practice, the process is conducted by a special replicating machinery consisting of a number of proteins. The central protein of the machinery is the DNA polymerase enzyme. Other important proteins are single-strand–binding (SSB) and DNA-helicase, which unwind the double helix. Topological problems, which are inevitable because of the necessity of unwinding of the two parent strands, are solved by topoisomerases.

Replication is initiated by binding to the specific sites on DNA of special short RNA oligonucleotides, the primers. On one of the two DNA strands, the synthesis of the complementary strand is carried out continuously. On the opposite strand, the synthesis is often interrupted because the polarity of the second strand is opposite to the direction of movement of the replication machinery along DNA. The gaps between fragments formed on the second strand are filled by DNA ligase.

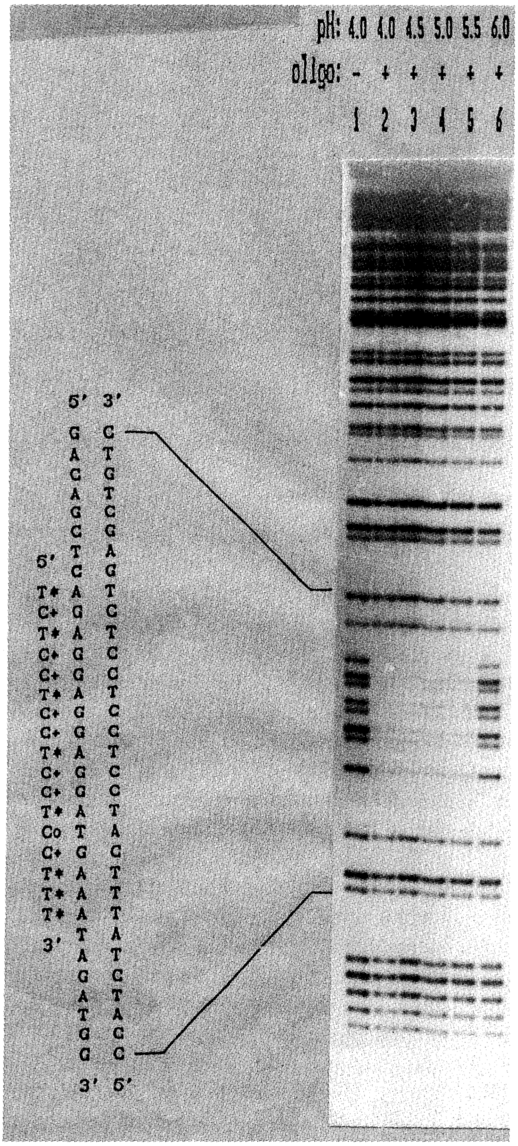

FIG. 17. The result of a footprinting experiment with dimethyl sulfate of a complex of duplex DNA carrying a homopurine-homopyrimidine insert with corresponding pyrimidine oligonucleotide. The data are from Cherny *et al.* (1993).

3.1.2 Replication of Viruses The above scheme is universal for cells. Viruses, the cellular parasites, cannot reproduce themselves autonomously. They penetrate the cell and

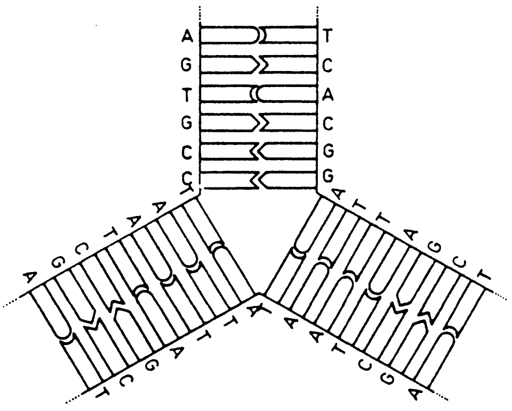

FIG. 18. Replication of duplex DNA.

replicate using the cellular resources. Viruses exhibit extreme versatility in the forms of storage of genetic information and, accordingly, in the fashion of replication. The genetic material of viruses can be in the form of linear duplex DNA, closed circular duplex DNA, linear single-stranded DNA, closed single-stranded DNA, or, last, linear single-stranded RNA.

Some RNA-containing viruses replicate with the help of RNA-dependent RNA polymerase. In many cases, however, first DNA is synthesized on the RNA template by the special enzyme reverse transcriptase, or RNA-dependent DNA polymerase. Then the closed circular double-stranded, so-called replicative, form of DNA is obtained. Then DNA replicates, and, in the final stage, virus RNA is synthesized on the DNA template. This complicated process is typical for retroviruses, the most important class of viruses from the medical viewpoint, which comprises many oncogenic (cancer inducing) viruses and HIV, the AIDS virus.

3.2 Transcription

Genetic information is expressed via the process of protein synthesis. The first step of this process is synthesis of the RNA copy of a gene, i.e., of messenger RNA (mRNA). This process is significantly different for prokaryotes and eukaryotes.

3.2.1 Transcription in Prokaryotes Prokaryotes generally obey the central dogma of molecular biology mentioned in the beginning of this chapter. The special enzyme RNA polymerase recognizes its binding sites on duplex DNA (promoters), binds to them, and synthesizes the full-length copy of the gene. The process is regulated by various mechanisms. Positive regulation occurs either via synthesis of entirely new RNA polymerase, which recognizes other promoters, or via protein factors, which bind with RNA polymerase and change its specificity. Negative regulation occurs via special sites on DNA (operators) to which proteins, called repressors, can bind. This binding prevents RNA polymerase from synthesizing RNA.

Messenger RNA serves as a template for protein synthesis on ribosomes. In prokaryotes, these two processes are coupled (see Fig. 19). The transcription process is often associated with formation of positive supercoils ahead of RNA polymerase and negative supercoils behind it. These topological problems are resolved by topoisomerases (Cozzarelli and Wang, 1990).

3.2.2 Transcription in Eukaryotes In eukaryotes, the process of synthesis of messenger RNA is much more complicated than in prokaryotes. First of all, in eukaryotes, DNA sequences corresponding to protein molecules are not continuous. They are interrupted by other sequences. The pieces corresponding to proteins have been named exons. The interrupting sequences were named introns. The role of introns still remains obscure, although the intron-exon or-

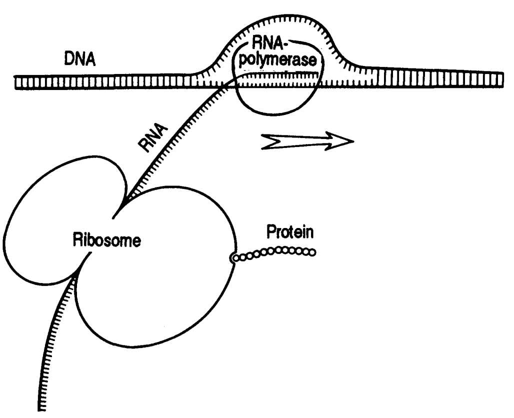

FIG. 19. RNA polymerase moves along DNA, synthesizing RNA. The ribosome copies information from RNA by synthesizing protein, in accordance with the genetic code.

ganization of eukaryotic genes has been known since the late 1970s.

The eukaryotic cell has several different RNA polymerases and numerous proteins (transcription factors) that modulate their activity and specificity. As a result, the mRNA synthesis is carried out by a complicated machinery consisting of many protein molecules.

The full-length copy of the entire sequence of the gene, including all its exons and introns, is synthesized by the transcription machinery. This full-length copy of the gene, which is called pre-mRNA, is converted into mRNA through a special maturation process, or splicing. In the course of splicing, all introns are deleted, and exons are "spliced" to form the maturated molecule of mRNA with the sequence corresponding to the amino-acid sequence of the protein molecule.

This ready-made mRNA is transported, in the form of a complex with special proteins, from the nucleus to the cytoplasm, where it strips the transporting proteins and serves as a template in the process of protein synthesis on ribosomes, i.e., translation. Thus, in contrast to prokaryotes, in eukaryotes transcription and translation are completely separated from each other.

Protein synthesis is extensively regulated on the mRNA level. Special protein factors, which bind with mRNA recognizing its various structural elements, modulate the rate of degradation of mRNA and its affinity to ribosomes. Thus, the yield of a particular protein is regulated the entire way from DNA to the spot where the protein molecule is synthesized, and even beyond this (see the next section).

3.3 Translation Process and Genetic Code

The translation process is the final stage of the protein synthesis. In this process, the genetic code plays the key role. The message brought by mRNA in the form of a nucleotide text is read by a ribosome, and the corresponding protein molecule is synthesized. Because a nucleotide text consists of four different letters, whereas sequences of proteins consist of 20 different amino-acid residues, the genetic code consists of triplets; i.e., one amino acid is encoded by a sequence of three adjacent nucleotides, which are called codons. The entire number of codons is $4^3 = 64$. Therefore, the genetic code is degenerate, several codons corresponding to one amino acid. There are also termination codons. There are no initiation codons, their role under appropriate conditions being played by the codons AUG and GUG, which normally correspond to methionine and valine. Figure 20 shows the genetic code.

In the realization of the translation process, the tRNA molecules play the key role. Each tRNA molecule carries an anticodon, the triplet complementary to the codon. A special enzyme recognizes the particular tRNA molecule and "charges" it with the corresponding amino acid. The ribosome creates conditions for binding (via codon-anticodon complementary recognition) of mRNA codons with the charged tRNA molecules and then adds to the growing protein chain the amino-acid residue brought by the tRNA molecule.

After the protein chain is synthesized, special large protein molecules, called chaperones, create conditions for folding of the chain into a biologically active spatial structure. After this, the protein molecule is ready to fulfill its function. However, even after the protein molecule is ready, its rate of degradation continues to be controlled by the cell.

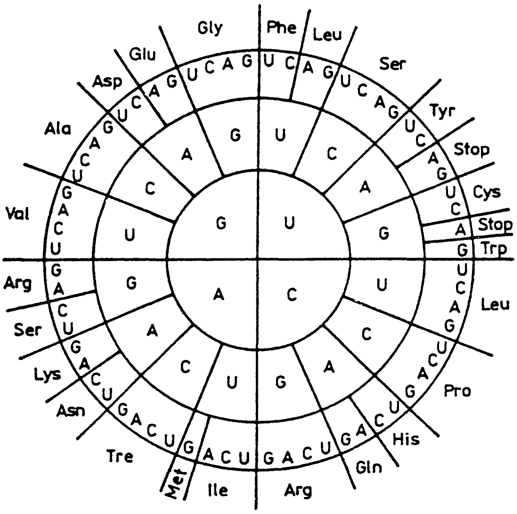

FIG. 20. The genetic code. The first letter of the codon is located in the central ring, the second in the first ring, and the third in the second. Written in the outer ring are the abbreviated designations of amino acids.

4. BIOTECHNOLOGY

The advent of the biotechnology era is the result of the entire accumulated knowledge about nucleic acids and the enzymes working with them. However, among countless achievements that have led to biotechnology and genetic engineering, there are a very few that have most contributed to the elaboration of techniques permitting interference into the most basic processes of life. In this section, we briefly survey these landmarks and then outline the major achievements and prospective of biotechnology.

4.1 Major Tools of Genetic Engineering

The biotechnology revolution is grounded on genetic engineering, a set of relatively simple chemical, biochemical, and biophysical techniques that have been developed during the past two decades. Some of them, like gel electrophoresis, are explained in other sections of this article. In this section, we briefly survey other very significant methods of genetic engineering.

4.1.1 Chemical Synthesis of DNA Achievements in the chemical synthesis of DNA had led, by the early 1980s, to the creation of robots that quickly and efficiently synthesize DNA oligonucleotides containing up to several dozen residues. This opened the way for obtaining synthetic genes. However, the most widespread application of DNA synthesis consists in the creation of so-called DNA probes, relatively short pieces that serve as primers for polymerases in numerous projects, most notably in PCR machines (see below).

4.1.2 Restriction Enzymes These enzymes recognize short sequences of duplex DNA (usually containing six base pairs) and specifically cut the duplex at these sites. Restriction enzymes are, along with gel electrophoresis (see Sec. 2.2.1), the major tools of genetic engineering.

4.1.3 Reverse Transcriptase The intron-exon organization of the genes of eukaryotes prevents their direct utilization in genetic engineering. When transferred to prokaryotes, these genes just do not express because, in prokaryotes, the mRNA maturation process cannot occur. Therefore, eukaryotic genes suitable for transfer to prokaryotes should not contain introns. This is often achieved by extracting maturated mRNA and synthesizing on it the corresponding DNA with the help of reverse transcriptase (RNA-dependent DNA-polymerase).

4.1.4 Plasmids Usually, alien genes are introduced not into the chromosome of a prokaryotic cell but into special small circular molecules, plasmids, which multiply together with the cell. Genetic engineers have constructed many artificial plasmids, which carry multiple recognition sites for restriction enzymes. When DNA fragments obtained as the result of cutting by a restriction enzyme are mixed with a plasmid cut with the same enzyme, the result is new plasmids carrying the fragments inserted into them. This is most common way of obtaining recombinant DNA molecules.

4.1.5 Polymerase Chain Reaction (PCR) This technique has revolutionized genetic engineering in recent years and had an impact comparable to that of the discovery of restriction enzymes and the implementation DNA sequencing methods. It makes it possible to multiply pieces of DNA starting from literally a single DNA copy.

The amplification is performed in a special PCR machine. The machine is loaded with the DNA molecule containing the piece to be amplified (it could be really only *one* DNA molecule to begin with), thermally stable *Taq* DNA-polymerase, and two DNA primers specially synthesized for the particular piece. One primer is complementary to the left-hand flanking sequence of the piece, the second one to the right-hand flanking sequence, but to the opposite strand. The PCR machine works as a cycler, each cycle consisting in heating the sample up to subboiling temperature (94 °C) with subsequent cooling down to 72 °C (the optimal temperature for *Taq* polymerase isolated from thermophilic bacteria). As a result of the first heating, the original DNA molecule melts, and the two strands separate (see Sec. 1.4.1). The subsequent cooling entails the binding of the primers, which are present in macroscopic quantity, to the complementary sites on the two single-stranded DNA molecules. The polymerase immediately starts to extend the primers from their 3′ ends using the complementary strands as the templates. Thus, the first cycle ends up with two partially double-stranded DNA molecules. The common duplex part of these two molecules encompasses only the piece to be amplified plus the two flanking primers. In the subsequent heating-cooling cycles, only this common part is amplified. After *n* cycles, one obtains 2^n duplex molecules corresponding to the piece flanked by the two primers.

4.2 The Coming of the Biotechnology Age

Biotechnology applications of the methods of genetic engineering are truly breathtaking and hardly embraceable. We provide a very brief survey of only some of them.

4.2.1 Protein Superproduction By incorporating genes of virtually any organism into bacteria, genetic engineers have made it possible to produce any protein in considerable quantities. On the one hand, this has enormously stimulated basic research on proteins and their functions, and, on the other hand, it has opened fantastic opportunities for producing proteins for medicine.

4.2.2 Protein Engineering A special technique has been elaborated to substitute nucleotides in cloned genes. The method consists in synthesis of a DNA probe that embraces the site to be changed and carries the desired substitution. This oligonucleotide is annealed with the single-stranded copy of the gene cloned in a special vector DNA. Then DNA polymerase is used to synthesize the double-stranded DNA, which will carry a mismatch in the site of substitution. After replication of the vector within the cell, two versions of the gene are obtained: the original, wild-type copy and the changed, mutant copy. The mutant copy is selected by special technique, again using the DNA probe.

As a result of the advent of protein engineering, unprecedented opportunities have appeared to change purposefully the amino-acid sequences of proteins. This has completely changed the way to study protein structure and function.

4.2.3 New Pharmacology Genetic engineering has made it possible to obtain in large quantities any proteins, even those that are present in the entire human body in very few copies. This opportunity is widely used by pharmaceutical companies to produce a rapidly increasing variety of biologically active proteins unavailable before, such as human growth hormone, human insulin, human interferon, etc.

4.2.4 Forensic Applications The implementation of PCR and other routine techniques of manipulation with DNA promises to revolutionize forensic science. Indeed, all people, with the exception of identical twins, differ from each other in a significant part of their DNA texts. So if a criminal left a tiny portion of his cells in any form (blood, sperm, etc), his DNA can be multiplied by PCR and then analyzed and compared with the DNA analysis of suspects. Although the new DNA forensic methods still need development in order to be widely applied, there is no doubt that they will become very useful in the nearest future.

4.2.5 Transgenic Animals Using microinjections of alien DNA into the cell nucleus and other methods, researchers routinely modify cells' genetic material. If cells are modified at the early stage of their differentiation, entire animals with directionally changed genomes can be produced. This has opened breathtaking opportunities for studying the role of separate genes on the level of the entire organism. Special laboratory animals with significant modifications of heredity, which are not encountered in natural animals, have been engineered. This can lead to a revolution in methods of creation of new species of domestic animals.

4.2.6 Human Genome Project The most ambitious idea that has emerged from achievements in nucleic acid research was sequencing the entire human genome, i.e., the Human Genome Project. The Human Genome Project is expected to be completed in the very early years of the next century. This landmark achievement will undoubtedly lead to a new revolution in medicine.

4.2.7 Diagnostics and Correction of Genetic Defects As a result of the Human Genome Project and related studies on human genetics, remarkable progress is underway in the tracing and sequencing of genes responsible for various hereditary diseases. In parallel, more data have been accumulating about a substantial genetic component in such very common diseases as cancer and atherosclerosis. As a result, the coming revolution in medicine is foreseen as the development and implementation in humans of methods of diagnosis and correction of wrong genes. Very efficient diagnostic methods have been developed and implemented for some genetic defects—for instance, in the case of sickle-cell anemia.

However, efficient methods to correct the established genetic defects are still lacking. Their development is the most challenging unsolved problem in the field of nucleic acids.

GLOSSARY

Adenine: A chemical group that is part of DNA and RNA. It is one of the four bases of nucleic acids. The abbreviated designation is A.

Amino Acid: A chemical compound with the structure $H_2N–CHR–COOH$, where R is any radical. Amino acid is the starting product for protein synthesis.

Amino-Acid Residue: A chemical group with the structure $–HN–CHR–CO–$, which is a residue of protein chain. It is what remains of an amino acid when it is built into the protein chain.

Base (Nucleic or Nitrous): A class of chemical compounds that includes adenine, guanine, thymine, cytosine, and uracil.

Chaperones: Specialized proteins that carry out inside the cell the folding of a polyamino-acid chain, newly synthesized on a ribosome, into a native protein molecule.

Chimerical DNA: An artificial molecule, put together by genetic engineering techniques with sections of different natural DNA. The terms "hybrid" and "recombinant" DNA have the same meaning.

Codon: A term connected with the genetic code. Denotes a trinucleotide corresponding to one amino-acid residue. There are several meaningless (nonsense) codons not corresponding to any amino acid. They play the role of stop signals during protein synthesis by mRNA on ribosomes. They are called terminating codons. Initiating codons serve as signals for starting protein synthesis.

Coil (Polymer): A notion of polymer physics. Serves to denote the form a polymer molecule assumes in space. In consequence of thermal motion, the form of a polymer coil constantly changes.

Cruciform: A DNA structure that can be formed in palindrome sequences.

Cytosine: A chemical group that is part of DNA and RNA. One of the four bases of nucleic acids. The abbreviated designation is C.

Degeneracy of the Code: One of the properties of the genetic code, which is that several codons may correspond to the same amino acid.

Deoxyribonucleic Acid: The full name of the DNA molecule.

DNA-Polymerase: An enzyme responsible for DNA synthesis on a DNA template. The process is called DNA replication.

Eukaryotes: Organisms provided with a cell nucleus.

Exon: A DNA segment that stores information about a part of the amino-acid sequence of protein.

Gel: A polymer network saturated with a solvent.

Gene: The principal notion of classical genetics which for a long time understood the term to mean an indivisible particle of heredity. During the 1950s and 1960s, the word "gene" was taken to mean a continuous DNA section, recorded on which, in the form of a nucleotide sequence, is information about the amino-acid sequence of one protein. The word is still used as the name for a DNA segment. But in some cases, it denotes a continuous segment that corresponds to only a part of the protein chain, while in others, it means a set of segments corresponding to a complete protein molecule. And it may well be that the same DNA segment simultaneously belongs to two and even three genes.

Genome: The entirety of genetic information of the organism.

Guanine: A chemical group that is part of DNA and RNA. It is one of the four nucleic acid bases. The abbreviated designation is G.

Hybrid DNA: An artificial molecule put together through genetic engineering techniques with segments of different natural DNA. The terms "recombinant" and "chimerical" DNA have the same meaning.

Intron: A DNA section dividing exons.

Ligase: An enzyme curing ruptures in DNA.

Linking Number: A quantitative characteristic of the degree to which two contours are linked. The linking number equals the number of times that one contour pierces the surface spread tightly across the other contour. It is denoted by *Lk*.

Nuclease: An enzyme that splits DNA or RNA.

Nucleotide: A residue of DNA and RNA.

Oligonucleotide: A short single-stranded piece of nucleic acid.

Oncogene: A gene causing cancer.

Palindrome: A phrase that reads the same from left to right or from right to left. In the context of DNA texts, such palindromes are called "mirror repeats." A real DNA palindrome is a segment of double helix that has the same sequence when reading either strand in the same direction, dictated by the chemical structure of DNA strands—for example,

→
ATGCGCAT
....
TACGCGTA
←

Plasmid: A circular DNA molecule multiplying together with bacteria and capable of passing from cell to cell.

Primer: A single-stranded oligonucleotide that binds, via complementary pairing, to DNA or RNA and serves for the priming of polymerases working on both DNA and RNA.

Prokaryotes: Single-cell organisms with no cell nuclei.

Promoter: A DNA segment with which RNA polymerase binds to set in motion mRNA synthesis.

Purine: A class of chemical compounds that includes adenine and guanine.

Pyrimidine: A class of chemical compounds that includes thymine, uracil, and cytosine.

Recombinant DNA: An artificial molecule put together by genetic engineering techniques from segments of different natural DNA. The terms "hybrid" and "chimeric" DNA have the same meaning.

Replication: Doubling of genetic material. DNA synthesis on DNA.

Repressor: A protein binding very strongly with an appropriate DNA segment between the promoter and the gene itself. By associating with DNA, repressor prevents the progress of RNA polymerase from promoter to gene and thus blocks mRNA synthesis. Serves to regulate transcription.

Reptation: Snakelike movement of a polymer molecule through the polymer network. The notion is crucial for the theoretical understanding of DNA separation in gel.

Restriction Endonuclease: An enzyme cutting the double helix in places with a definite nucleotide sequence. It is the chief instrument of genetic engineering, and often is called just restriction enzyme.

Restriction Fragment: A piece of DNA cut out of the molecule with the help of restriction endonucleases.

Reverse Transcriptase: An enzyme responsible for DNA synthesis on an RNA template. The process is called reverse transcription.

Ribosome: An involved complex of RNA and proteins, which is responsible for the translation process in the cell.

RNA Polymerase: An enzyme synthesizing mRNA on a DNA template. Carries out the transcription process.

Splicing: The process of mRNA maturing in eukaryotes, which results in the discharge of introns, while exons combine into one RNA chain.

Superhelicity: A characteristic of a circular closed DNA. Superhelicity arises when the linking number Lk in the DNA differs from the value N/Γ_0, where N is the number of base pairs in the DNA and Γ_0 is the number of base pairs per turn of double helix in linear DNA placed in the same conditions.

Template: A polymer molecule whose sequence is used for charting a sequence for another polymer molecule. DNA serves as a template for DNA synthesis during replication and for RNA during transcription. RNA serves as a template for protein synthesis during translation and for DNA during reverse transcription.

Topoisomerases: A class of enzymes that change the topology of a circular closed DNA.

Topoisomers: DNA molecules identical in chemical terms but different in topology (by the type of knot, or by the linking number).

Transcription: RNA synthesis on a DNA template. Reverse transcription is DNA synthesis on a RNA template.

Translation: Protein synthesis by an mRNA template on ribosome.

Thymine: A chemical group that is part of DNA. Is one of four DNA bases. The abbreviated name is T.

Uracil: A chemical group that is part of RNA. It is one of four RNA bases. The abbreviated designation is U.

Vector: A genetic engineering term. This is the name of a carrier DNA molecule (plasmid, virus, and so on), within which the desired gene is cloned.

Virus: A cellular parasite, one of the simplest objects of living nature. Outside the cell, a virus is a molecular complex consisting of nucleic acid (DNA, sometimes RNA) and several proteins forming the virus membrane. The cell's penetration by a virus (or its nucleic acid) switches the resources of the cell over to synthesizing the virus nucleic acid and proteins. When the cell's resources are exhausted, its membrane bursts, spilling out "ready-made" virus particles. Animals' viruses have a much simpler structure than bacteria viruses (bacteriophages). Animal viruses are incapable of injecting their nucleic acid into the cell, and they get inside the cell together with food. Viruses cause many infectious diseases, such as the grippe, smallpox, poliomyelitis, hepatitis, and AIDS. In some cases, finding itself inside the cell, the virus does not undo it but builds its DNA into that of the cell, after which the virus DNA begins to multiply together with the cell DNA. The behavior of the cell itself may, however, undergo a sharp change in the process.

INTRODUCTION

Oceanography deals with the application of fundamental scientific principles to the ocean environment. This results in a variety of subfields in oceanography (physical, chemical, and biological oceanography and marine geology), which must often be integrated to understand ocean processes. This report will focus on physical oceanography. Physical oceanography is the study of the physical structure, motion, and mixing of ocean waters.

The two traditional approaches used in

digital Encyclopedia of Applied Physics

physical oceanography are the descriptive approach and the theoretical approach. The descriptive approach uses observations to determine the structure of the ocean while the theoretical approach applies Newton's laws of motion and thermodynamical laws to understand how forces affect the structure of the ocean. These two approaches complement one another.

As a recognizable scientific discipline, oceanography is young, beginning with the voyage of *HMS Challenger* from 1872 to 1876. The first systematic large-scale expedition to study primarily the physical aspects of the ocean circulation was the German *Meteor* expedition to study the South Atlantic from 1925 to 1927. Worldwide surveys of the ocean were conducted during the International Geophysical Year in 1957–1958, and the first satellite mission that was dedicated to studies of the ocean was *Seasat*, which observed the oceans for 100 days in 1978.

This report is organized into nine sections. First, we describe the physical characteristics of seawater, then the character of the ocean's waters and currents, and then the instruments used in the practice of physical oceanography. Next, we introduce marine hydrodynamics and then develop the physics of the mean ocean circulation. Ocean waves are then described. The final sections deal with mesoscale motions, small-scale processes, and concluding remarks. A list of references and additional reading is provided for those who need more detailed information.

1. PHYSICAL CHARACTERISTICS OF SEAWATER

The density of water is determined by the temperature T, salinity S, and pressure p. Temperature is measured in degrees Celsius. Salinity represents the weight of dissolved solids (in grams) in a kilogram of seawater. In 1978, oceanographers adopted the Practical Salinity Scale, which defined a practical salinity unit (psu) in terms of the conductivity of seawater at 15 °C referenced to the conductivity of a potassium chloride solution at 15 °C (see UNESCO, 1981). This provided an accurate, reproducible primary standard and a better measure of the effect of the dissolved solids on density, and supported *in situ* measurement methods. The unit of pressure used by oceanographers is the decibar, db, where 1 db = 10 000 Pa.

In addition to modifying the conductivity of water, salt modifies the physical characteristics of water in another important way. The temperature of maximum density of seawater decreases with increasing salinity at a rate greater than the freezing point, so that for salinity greater than 24.7 psu, seawater freezes before the maximum density is reached. Other physical properties of water, e.g., viscosity, surface tension, and thermal conductivity, are also modified.

Typical ranges of salinity and temperature found at the sea surface in the open ocean are 32–37 psu and −1 to 29 °C, respectively. Salinities lower than these values are associated with melting ice, rivers, or intense rainstorms. Larger salinities are encountered in semienclosed evaporative basins such as the Red Sea or Mediterranean. Since water is slightly compressible, *in situ* temperature increases below about 3500 db because of adiabatic effects. These adiabatic changes can be taken into account by using a potential temperature, θ, which nominally uses the sea surface as a reference pressure. The mean temperature and salinity for the world ocean are 3.5 °C and 34.7 psu.

1.1 Equation of State

The equation relating density to temperature, salinity, and pressure is called the *equation of state*. The equation of state in current use, EOS80, was established by the Joint Panel on Oceanographic Tables and Standards (UNESCO, 1981) and uses the functional form

$$\rho(S,T,p) = \frac{\rho(S,T,0)}{1 - p/K(S,T,p)}, \qquad (1)$$

where $\rho(S,T,0)$ is the density of seawater at one standard atmosphere and $K(S,T,p)$ is the bulk modulus, and both are nonlinear functions of S, T, and p. Typical density values for the ocean range from 1020 to 1060 kg/m^3. The density is usually represented by a density anomaly γ:

$$\gamma(S,T,p) = \rho(S,T,p) - 1000\ \mathrm{kg/m^3}. \qquad (2)$$

The nonlinearity of the equation of state has several important properties. These can be deduced from the curved shape of constant-density lines on the *T-S* diagram (Fig. 1). At temperatures close to zero, the constant-density lines become nearly vertical, indicating that salinity changes have a much greater effect on density than they do at warmer temperatures. At warmer temperatures, the slope of these constant-density lines decreases, indicating that temperature changes contribute more to density variability. When two different water masses of the same density but differing temperature and salinity are mixed, temperature and salinity are conserved so that the resulting water mass will lie on a line connecting these two points on the *T-S* diagram; but, as indicated by the curve of the constant-density lines, the resulting mixture will be heavier (more dense) than the original waters. This provides a mechanism of generating internal buoyancy changes that is called either cabelling or thermobaric instability.

1.2 Hydrostatic Equation

In most oceanographic applications, vertical accelerations can be neglected so that pressure and depth z are related by the hydrostatic equation

$$\frac{\partial p}{\partial z} = -\rho g, \tag{3}$$

where g represents gravitational acceleration. Zonal variations of g are usually considered, and g is estimated as follows:

$$g(\phi) = 9.790\,318(1.0 + 5.2788 \times 10^{-3} \sin^2\phi + 2.36 \times 10^{-5} \sin^4\phi)\ \mathrm{m^2s}, \tag{4}$$

where ϕ is latitude (in degrees). Note that 1 db corresponds to about 1 m and that 1010 db is about 1000 m.

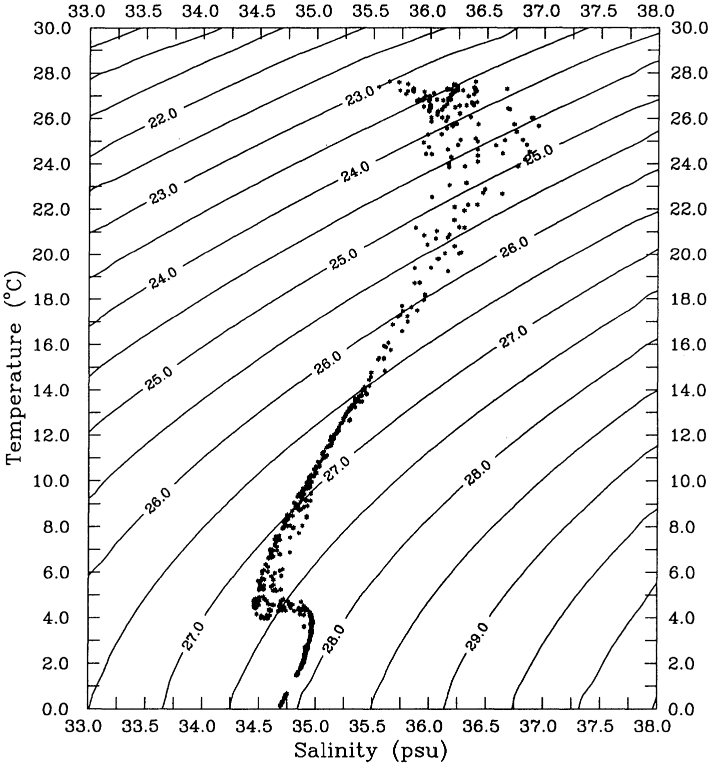

FIG. 1. *T-S* diagram for waters of the Tropical Atlantic along 23° W from 6° N to 9° S. Readily identifiable water masses include subtropical subsurface water at 26 °C, 36.5 psu, Antarctic intermediate water at 4 °C, 34.5 psu, North Atlantic deep water at 4 °C, 35 psu, and Antarctic bottom water at 2 °C, 35 psu. The curved lines are contours of a density anomaly, γ_t which is referenced to atmospheric pressure and has units of kg/m^3.

1.3 Sound in the Ocean

The speed of sound in seawater, U_a, in units of m/s, is given by

$$U_a^2 = \left(\frac{\partial p}{\partial \rho}\right)_a, \tag{5}$$

where $(\partial p/\partial \rho)_a$ is the reverse adiabatic density gradient. In practice, the speed of sound is usually not computed in this manner; instead, empirical formulas are used that express sound velocity as a function of S, T, and p and that are derived from laboratory measurements. Typical sound-speed values range from 1400 to 1700 m/s. To a first approximation, sound is nondispersive in the ocean. Refraction of sound is important, creating both convergence and shadow zones. A simple model for the attenuation of sound (which does not take into account geometric spreading, refractive loss, and volume and boundary scattering loss) is

$$I(x) = I_0 e^{-\kappa x}, \tag{6}$$

where $I(x)$ is the intensity of sound at distance x from the source and I_0 is the intensity of sound at the same frequency at the location of the source. The attenuation coefficient κ, in units of dB/m, is given as

$$\kappa = 4.343\left[\frac{1.7 \times 10^8(\frac{4}{3}\mu_F + \mu_F')f^2}{\rho_F c_F^3} + \left(\frac{SA'f_{rm}f^2}{f^2 + f_{rm}^2}\right)(1 - 1.25 \times 10^{-2}p) + \frac{A''f_{ra}f^2}{f^2 + f_{ra}^2}\right],$$

where μ_F is the dynamic coefficient of shear viscosity for fresh water, μ_F' is the dynamic coefficient of bulk viscosity for fresh water, f_{rm} is the relaxation frequency (kHz) for magnesium sulfate, f_{ra} is the relaxation frequency (kHz) for boric acid, A' is 2.03×10^{-5} dB/(kHz psu m), A'' is 1.2×10^{-4} dB/(kHz m), S is salinity (psu), and f is the frequency in kHz. At intermediate frequencies (100–1000 kHz), absorption is mainly due to boric acid and magnesium sulfate chemical relaxation processes. At low frequencies (below 100 Hz), attenuation is almost independent of frequency, and the attenuation coefficient is about 0.003 dB/km. This means that low frequencies can easily insonify the ocean, i.e., 15 W of transmitted power can be detected at a distance of 2000 km. In part, this is because sound speed increases with increasing pressure, creating a duct that focuses acoustic energy (called the SOund Fixing And Ranging or SOFAR channel) at about 1-km depth.

Current applications include not only finding submarines and fish, and mapping the seafloor, but inverse problems including acoustic tomography and ocean acoustic thermometry. The latter application may lead to the first quantitative measure of "greenhouse" warming of the ocean.

1.4 Light in the Ocean

The behavior of light in the ocean affects not only the heating of the upper layer but also the growth of plants (and hence the oceanic food chain). Light also has marine applications for charting, and finding fish, submarines, and mines, or measuring bioluminescence.

Seawater has both inherent and apparent optical properties (see OPTICS, UNDERWATER). Inherent properties can be measured on a seawater sample in the laboratory (if, of course, suspended particles, etc., were not affected by removal from the sea). Apparent properties must be measured *in situ*. The inherent properties include the beam attenuation coefficient c, the volume absorption coefficient a, and the volume scattering coefficient b, where $c = a + b$. A beam transmissometer is used to measure c (m^{-1}) over a fixed distance, so that for 1 m

$$T = I_1/I_0 = e^{-c}; \tag{7}$$

and c may be written

$$c = c_\lambda = a_{\lambda w} + a_{\lambda d} + a_{\lambda p} + b_{\lambda w} + b_{\lambda d} + b_{\lambda p}, \tag{8}$$

where the subscript λ indicates dependence on wavelength, w indicates pure water, d is dissolved matter, and p is suspended particles.

Apparent properties include the radiance (W m^{-2}) and the diffuse attenuation coefficient for downwelling (indicated by a superscript consisting of an arrow pointing downward) irradiance, $k_\lambda^\downarrow$ (W m^{-2}), which are both strongly λ dependent. Downwelling irradiance attenuation $k_\lambda^\downarrow(z)$, where z is depth, better represents the depth to which a lidar can detect an object than does $c_\lambda(z)$. It is always true that $a_\lambda < k_\lambda < c_\lambda = a_\lambda + b_\lambda$. A good estimate of the upwelling solar irradiance $k_\lambda^\uparrow$ can be obtained from satellite observations of the sea surface (see Sec. 3.4.3). The apparent properties are connected to the inherent ones via the radiative transfer equation [see Eq. (13)].

Within the ocean, light is mostly absorbed but is also scattered, by both seawater and particles within the water including plankton. The absorption results in heating of the water. The euphotic zone refers to the upper layer of the ocean in which the intensity of light is greater than 1% of its value at the sea surface. The attenuation of light with depth depends not only on the wavelength of light but also the clarity of the water. The clarity is mostly controlled by biological activity although at the coast, sediments transported by rivers or resuspended by wave action can strongly attenuate light.

In terms of clarity, waters may be classified according to Jerlov (1976) as coastal (types 1–9) or oceanic (types I–III). For oceanic waters, blue light (400–500 nm) is transmitted to the greatest depth, while coastal waters favor transmission of green-yellow light (650–580 nm) because plankton and organic compounds absorb blue light. Diffuse attenuation coefficients may vary from 0.01 to 1 m^{-1} for the oceanic and coastal regimes, respectively, in the latter case limiting light to the upper few meters.

2. OCEAN STRUCTURE

The physical structure of the ocean is largely governed by the shape of the ocean basins and atmospheric forcing and to a lesser extent by mixing and internal dynamic processes. Continents prevent ocean waters from freely circulating around the Earth except in the Southern Ocean between 56° S and 63° S. A system of midocean ridges splits the major oceans (Pacific, Atlantic, Southern, and Indian) into a series of smaller basins. In addition to these ridges, major topographic features include abyssal plains, trenches, submarine canyons, seamounts, and islands. The mean depth of the ocean is 3.8 km; the greatest depth, 12 km, is found in Marianas Trench. Note that these dimensions, e.g., 4 km in the vertical and 4000 km or more in the horizontal, imply aspect ratios of 1/1000 for vertical sections presented in an atlas or report. Semienclosed seas such as the Mediterranean, Red, Black, Baltic, Arctic, Japan, and Bering Seas or gulfs such as the Persian, Mexico, or California exchange water with adjacent oceans to varying degrees, often introducing waters of distinct characteristics.

Next to the coast, shallower waters overlie the continental shelf. The continental shelf is found inshore of a sharp break in topography that occurs at an average depth of 130 m. Continental shelves are regions of high fishery productivity, oil production, and recreational boating. Because of the shallow water, circulation on the continental shelf can have a different character from that found offshore. Oceanographers refer to the region that is found further inshore, where ocean swell begins to feel the bottom in about 10 m of water, as the "nearshore." Here surf forms, and waves run up onto the beach. Other distinct geographical features along the coast include bays, estuaries, fjords, and river mouths. Note that continental shelves are separated from deep ocean basins by a region where depth increases rapidly, which is called the continental slope.

The atmosphere drives the ocean both through the stress that the winds exert upon the water and through the buoyancy effects of heat, evaporation, and rainfall. Over much of the globe, the atmosphere has a distinct meridional character consisting of trade winds in the tropics and westerlies in the midlatitudes. In the Indian Ocean, these are modified by the Southwest Monsoon, which begins in late May, and the Northeast Monsoon, which begins in October. Continents serve to modify air masses further in such a way that cold, dry air may be found over the ocean off east coasts during the winter.

2.1 Vertical Structure

A major feature of the ocean is its layered structure. Radiation impinging on the ocean surface heats both the ocean surface and the lower atmosphere. As noted above, seawater is a good absorber of radiation, so that typically 60% of the penetrated radiation is absorbed within the first meter of the ocean, around 80% is absorbed within 10 m, and only about 1% of the entering radiation remains at 140-m depth in the clearest tropical ocean waters. The turbulent fluxes of heat, water, and momentum across the ocean surface result in vigorous mixing in the uppermost layer of the ocean. The turbulent kinetic energy generation by the wind stress and the upward buoyancy flux will mix the seawater vertically, eventually forming a vertically uniform layer called the upper mixed layer.

Below the upper mixed layer, the water can be divided into two zones in terms of the rate at which temperature decreases with depth: a region of rapid change of temperature with depth, called the thermocline, and a region where temperature changes slowly with depth, called the deep zone (Fig. 2). In mid- and high latitudes, the thermocline can be subdivided into an upper or seasonal thermocline and a lower or permanent thermocline.

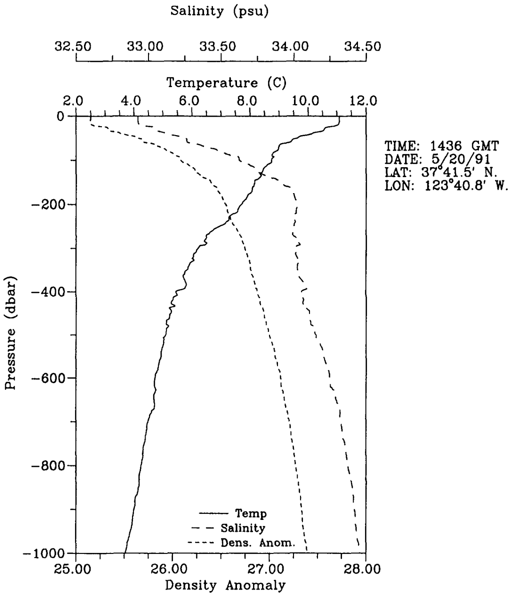

FIG. 2. Vertical profiles of temperature, salinity, and density for an oceanographic station off San Francisco, California. An oceanographic station consists of observations of temperature and salinity at a fixed location. Data were obtained by lowering an instrument that measures conductivity, temperature, and pressure (or depth), called a CTD, from the *R/V Pt. Sur* on May 20, 1991. The mixed layer is confined to the upper 15 m, and the seasonal thermocline/halocline/pycnocline extends to a depth of 80–100 m at this location.

At low and mid latitudes, despite a steady input of heat and downward mixing by eddy diffusion, the depth of the thermocline does not appear to change at any given location. It has been postulated that this is due to upward advection of water of the order of cm/day due to sinking of water at high latitudes.

Density increases with depth and has the same kind of vertical zonation as temperature. The zone of rapid density increase is called the pycnocline. The stability E is defined as

$$E = -\frac{1}{\rho}\frac{\partial \rho}{\partial z} - \frac{g}{U_a^2}. \tag{9}$$

The first term is the *in situ* vertical density gradient and the second term the adiabatic gradient ($\simeq 400 \times 10^{-8}$ m^{-1}). The requirement of static stability means that E must be positive. Situations where E is negative and the water column is not stable can exist, e.g., convection due to surface cooling or subsurface hot springs; when using a surface reference pressure, deep densities (below 4 or 5 km) can appear to be less than those at shallower depths, but this is due to inaccuracy of EOS80 and the situation is corrected by using a reference pressure that is near the observed density inversion. Equation (9) can be expanded to include vertical gradients of temperature and salinity:

$$E = \alpha\left(\frac{\partial T}{\partial z} + \Gamma\right) - \tilde{\beta}\frac{\partial S}{\partial z}, \tag{10}$$

where $\alpha = -\rho^{-1}\partial\rho/\partial T$ is the thermal expansion coefficient of seawater at the surface, $\tilde{\beta} = \rho^{-1}\partial\rho/\partial S$ is the haline contraction coefficient, and Γ is the adiabatic temperature gradient. This indicates that subsurface warming (called a temperature inversion) does not violate the requirement for stability if it is less than the adiabatic gradient or the salinity increases sufficiently.

The vertical distribution of salinity cannot be summarized as easily as that for density and temperature. Upper-layer salinity tends to be high in low to mid latitudes, decreasing to subsurface minimum at 600–1000 m. In the tropics, a shallow salinity maximum is usually found at about 100-m depth.

At high latitudes, upper ocean waters are fresher than those at depth. The region of rapid salinity change with depth is called the halocline. Since salinity usually does not dominate density changes, it can be used to trace the horizontal flow pattern.

2.2 T-S Diagram

The temperature-salinity (*T-S* or *θ-S*) diagram is used as a characteristic diagram by oceanographers. This is because temperature and salinity are conservative properties when a water mass is not in the mixed layer. This means that water masses must acquire temperature and salinity properties at the ocean surface and that these properties are determined by the local climate; when the water later sinks along density surfaces, it carries these properties with it. As a consequence, only a limited number of temperature and salinity combinations occur. These can be recognized by plotting observations for a series of oceanographic stations as a function of temperature and salinity.

A water type appears as a point on a *T-S* diagram, and a water mass is represented by a line and is formed from the mixing of water types. Using this representation, the global ocean has a distinct geography with specific regions readily identifiable by their *T-S* characteristics (Fig. 1).

2.3 Ocean Currents

In the mean, a steady ocean circulation exists. This circulation is the result of both thermohaline forcing and forcing by the wind. Currents are classified by their depth (surface, intermediate, deep, and bottom) or by their forcing mechanism. This is not unambiguous because some currents extend from the surface to the bottom of the ocean. The pattern of surface currents was first studied because of their effect on navigation. Today, the principal focus for such studies is to understand the poleward transport of heat by the ocean.

The steady-state circulation is characterized by subpolar and subtropical gyres with zonal tropical currents and an eastward flow around Antarctica called the Circumpolar Current. The strongest currents occur as poleward flow at the western boundaries of subtropical gyres and include the Gulf Stream in the North Atlantic, the Kuroshio in the North Pacific, and the Agulhas in the South Indian Ocean. The eastern-boundary currents of subtropical gyres are weaker, flow equatorward, and are characterized by upwelling at the coast. These include the California Current in the North Pacific, the Canary Current in the North Atlantic, the Benguela Current in the South Atlantic, and the Humboldt or Peru Current in the South Pacific. In the South Indian Ocean, the eastern boundary current, called the Leeuwin Current, flows poleward.

The system of equatorial currents includes the westward-flowing North and South Equatorial Currents. These currents are separated by the eastward-flowing North Equatorial Counter Current, which, in the Pacific, is found between 4° N and 10° N. At the equator, a strong subsurface eastward flow is usually found between 75 and 200 m depth and is called the Equatorial Undercurrent. It is usually about 400 km wide, and speeds in excess of 1 m/s are not uncommon.

The Indian Ocean circulation is dominated by the monsoons. A strong western-boundary current, the Somali Current, develops in response to the Southwest Monsoon. The monsoon currents in the North Indian Ocean reverse and flow in the direction of the monsoon. When eastward winds occur at the equator, a strong eastward current develops at the surface as well.

Intermediate, deep, and bottom currents are the result of thermohaline processes. These currents are also intensified at western boundaries.

3. OCEAN MEASUREMENTS

The equations of motion and state specify the variables that must be measured experimentally. These include temperature, salinity, and pressure for the equation of state and the velocity of the water. Related variables include the height of sea level and wind stress. Although the ocean environment is hostile, e.g., cold, great pressures, and often large accelerations at the sea surface, recent technical developments have greatly improved our ability to obtain data of the requisite accuracy and precision for study of most physical processes. Our major challenge is to obtain sufficient synoptic data to be able to identify unambiguously the processes that control ocean circulation.

3.1 Shipboard Profiling

Instruments that are routinely used from shipboard include conductivity-temperature-depth (CTD) profilers, expendable bathythermographs (XBT), and acoustic-Doppler current profilers (ADCP). The ship itself is a key element of these systems. Research vessels range in length from 30 to 100 m and have special capability for maneuvering at low speed, maintaining station, and handling equipment over the side. Protection from wind and seas is provided for scientists working on deck, and special electronic, biological, and chemical laboratories are needed. Larger ships must be capable of extended cruises of more than 40 days at sea and 20 000-km ranges.

CTDs are lowered by a winch and conducting cable when the ship is hove to (CTDs can also be towed, cycling up and down through the water column, but depth is limited to about 200 m by cable drag) (Fig. 3). Temperature measurement is by means of a platinum resistance thermometer (PRT) and a faster-response thermistor. Conductivity is measured by means of paired electrodes mounted inside a 4-mm-diam channel that is 30 mm long. Pressure is measured by a strain gauge. Data are sampled at 30 Hz and transmitted up the cable as a FM signal. The fast-response thermistor compensates for the mismatch in time constants of the PRT and the conductivity electrodes, allowing the computation of salinity without severe spikes. The accuracy of the system is 0.005 mS, 0.005 °C, and 0.1 of full scale for pressure. Corresponding precisions are 0.001 mS, 0.005 °C, and 0.1. The CTD is usually attached below a rosette that allows water samples to be collected at discrete depths by Niskin bottles for shipboard analysis. The Niskin bottles are open cylinders with endcaps, which are held together with an elastic band. During descent, the rosette holds the endcaps back, allowing water to flow freely through the bottles. During ascent, the rosette is electrically triggered, releasing the endcaps and closing the bottles. The Niskin bottles shown in Fig. 3 hold 5 L. Salts from these samples are necessary to maintain the accuracy of the CTD conductivity measurements. Final data processing produces a table of temperature and salinity values averaged over successive 2-db intervals. A typical CTD cast takes about 45 minutes per 1000 meters.

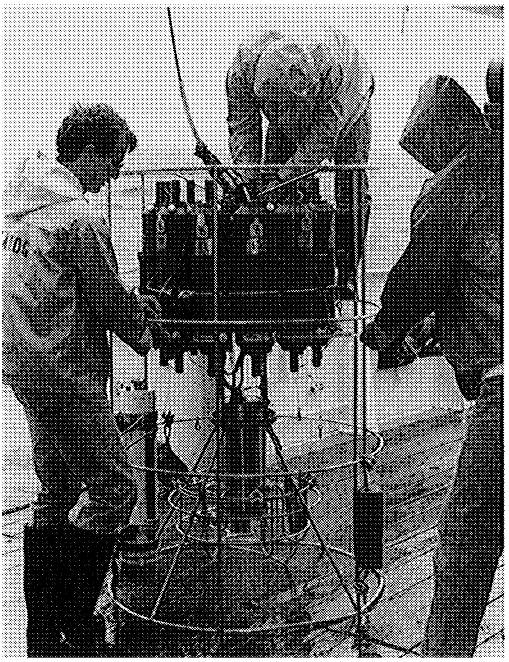

FIG. 3. Ocean profiling system. Vertical profiles of conductivity and temperature are obtained by a conductivity-temperature-depth (CTD) instrument and water sampling bottles. The CTD is the stainless steel cylinder that is mounted in the lower part of the cage. Water sampling (Niskin) bottles are held by a rosette at the top of the cage. The oceanographers standing on deck are filling seawater sample bottles from the Niskin bottles while the oceanographer standing on the cage is resetting the rosette.

XBTs are designed to be launched while a ship is under way. They were originally designed for use in antisubmarine warfare by naval vessels, but the simplicity and reliability have led to widespread use by merchant vessels in climate-related ocean studies. Temperature measurement is by means of a thermistor mounted on the nose of a 1-kg lead weight. Depth is determined by using an empirically determined rate of fall. Data are transmitted back to the ship by means of two-strand copper wire. XBTs are available for 450-m, 750-m, and 1500-m depths. Systematic errors of 0.2–0.4 °C occur in these measurements, and random errors are about half this amount; depth accuracy ranges from 2% to 10%, depending on the type (depth) of probe used (the increase with depth is due to errors in fall rate and microscopic leaks in wire insulation). Expendable probes that measure sound velocity and velocity shear are also available.

ADCPs are mounted in the hull of a ship, run continuously, look downward, and in good weather allow sampling to 400-m depth. Paired transducers look fore–aft and port–starboard, and the Doppler shift in gated returns (caused by plankton drifting in the water) is transformed to horizontal velocity. Typically, a pulse repetition rate of 1 Hz is used, and data are resolved in 8-m depth bins. Averaging over 3-min intervals reduces random errors to 1 cm/s. Current velocities are obtained by removing the ship's motion from ADCP output. ADCPs can also be lowered on a wire with a CTD, yielding velocity profiles that extend throughout the entire water column. The Global Positioning System (GPS) provides accurate navigational data for ADCP operation, including ship's heading.

3.2 Moored Instruments

Current measurements that are made at a fixed point in space are called "Eulerian" measurements. Eulerian measurements are made by mooring current meters. Currents are measured either

1. mechanically by means of orthogonal rotors or a rotor and vane,
2. acoustically using changes in travel time or an ADCP, or
3. electromagnetically in higher flow regimes associated with waves and surf.

In deep-sea applications, the mooring may be 4–6 km long, and is held to an anchor by means of a release that is interrogated acoustically from shipboard. A deep-sea mooring is typically left in place for two years.

Temperature and pressure measurements are easily made from moorings, but conductivity measurements of the precision and accuracy required for most deep-sea applications are not, because of problems of biological growth and electrode oxidation.

3.3 Lagrangian Measurements

Measurements that are of quantities that are traveling with the fluid are called "Lagrangian" measurements. Lagrangian measurement systems include surface (called drifters) and subsurface (called floats) drifting buoys. Surface drifting buoys must be properly coupled to the surface layer of the ocean, requiring a subsurface drogue that has a drag that is at least 40 times that exerted on the surface float. Drifter positions are currently determined by satellite at least six times per day with position accuracy (2σ) of 600 m. Future applications will use GPS with continuous position keeping of 100-m accuracy. Observations of near-surface temperature and vertical temperature gradients can also be made from drifters.

Subsurface floats are positioned acoustically. Floats that signal are called SOFAR floats while those that listen are called RAFOS floats. These floats may be isobaric or isopycnal or profile a short distance above and below these levels to measure potential vorticity. Moored autonomous listening stations (sound sources) or fixed Navy listening stations provide the requisite positioning network for SOFAR (RAFOS) floats. RAFOS floats surface when their mission is completed, relaying data via satellite.

A new system of Autonomous Lagrangian Circulation Explorer (ALACE) floats is currently being developed. These floats drift at depth but surface at regular intervals so that their position can be determined by satellite and subsurface ocean observations relayed to shore. Current floats are capable of 50–100 depth cycles. Further developments of this type of float, adding CTD, electromagnetic measurements, and perhaps "wings" to maneuver the float, promise to make ALACE a key component of a global ocean-observing system.

Anthropogenic chemical tracers are also an effective Lagrangian technique for determining ocean circulation. Tritium, produced by atmospheric atomic bomb testing, and cesium-137 and strontium-90, associated with nuclear power plant operations, have been used to trace horizontal and vertical circulation. Since tritium decays to helium-3 at a known rate, the ratio of tritium to helium-3 can be used to determine the length of time since the water parcel was exposed to the ocean surface; the utility of this technique is limited by the introduction of helium-3 into the ocean by submarine vents. Freon compounds (10, 11, 12) can also be used to trace and date ocean waters.

3.4 Satellite Measurements

Satellite techniques promise continuous global coverage. The principal problem with these techniques is that the atmosphere gets in the way and the ocean is nearly opaque to electromagnetic radiation. Satellite applications that we will discuss include satellite altimetry, synthetic-aperture radar, and ocean-surface temperature measurements. Other satellite techniques effectively map ice cover, and new satellite-positioning systems [the Global Positioning System (GPS)] and data relay capabilities are essential for modern experimental programs. Two kinds of sensors (active and passive) are available for measurements. The active sensors transmit radio signals, comparing the transmitted with the reflected or scattered signals that are received by the sensors from an area on the earth's surface. Passive sensors do not transmit a signal; instead, the emitted radiance from the earth's surface is compared to that received from space or a blackbody. Satellite altimetry and the synthetic-aperture radar are active sensors. Satellite radiometers are passive sensors.

3.4.1 Satellite Altimetry If the ocean were motionless, the shape of its surface would be determined entirely by the gravitational acceleration of the Earth. The spatial variation of the gravity field generates a sea-surface topography with a global range in height of nearly 160 m relative to the center of the earth. But forces associated with ocean currents produce departures from this static topography called *dynamic ocean topography*. The dynamic ocean topography has a global range in height of about 2 m, about 1% of the height range of the static or gravitational topography (Plate 1).

Satellite altimetry maps the dynamic ocean topography in three steps. First, the radar altimeter sends short pulses of microwave energy toward the ocean; the round-trip travel times of the reflected pulses yield the distance between the spacecraft and the sea surface (additionally, the shape of the reflected pulse can be used to determine wave height and sea-surface wind speed). Second, precise determination of satellite orbit permits these distances to be translated into a global map of sea level relative to the center of the Earth. Third, a map of the gravitational sea-surface topography (which must be obtained independently) must be subtracted from the satellite-derived topography, yielding the dynamic ocean topography. Methods for determining ocean current speed and direction from the dynamic ocean topography are described below.

Errors are associated with absorption of microwave energy by atmospheric water vapor and pulse-arrival delays due to electron release by ionization of gases in the ionosphere caused by sunlight. The largest source of error is associated with the determination of satellite orbit.

Satellite altimeter measurements have been made on Skylab (1973), Goes-3 (1975–1978), Seasat, and Geosat (1985–1989), and are currently being made by *Topex/Poseidon*. Topex has an orbital altitude of 1136 km and observes the Earth from 66° N to 66° S. Measurement tracks across the Earth are reproduced within 1 km over every 10-day repeat cycle. Widest spacing between tracks, at the equator, is 315 km. The altimeter operates at dual frequencies, 5.3 and 13.6 GHz, permitting correction for ionospheric electron delays. Topex also carries a microwave radiometer that operates at frequencies of 18, 21, and 37 Ghz to estimate total atmospheric water vapor content. Topex is tracked by three systems: ground-based lasers, measurement of Doppler shifts of microwave frequencies transmitted by a global network of ground-based beacons, and GPS. Sea-level topography is being measured with 2-cm accuracy.

3.4.2 Synthetic-Aperture Radar A synthetic-aperture radar (SAR) is a pulse-Doppler radar that transmits short radio pulses and maps the radar reflectivity of the sea over areas 50–100 km on a side, with a resolution of 10–40 m. From SAR images of ocean surface, we can "see" and study meanders of currents, eddies, storm waves, ice floes, leads, ice ridges, and polynyas. The perturbed sea surface ζ modulates the reflectivity of the radio pulse. The radar cross section becomes

$$\sigma = \langle\sigma\rangle + \delta\sigma, \tag{11}$$

where $\langle\sigma\rangle$ is the spatially averaged cross section per unit area of the sea, and $\delta\sigma$ is the deviation induced by surface long waves. A complex modulation transfer function R is used to link $\delta\sigma$ to ζ:

$$\delta\sigma/\langle\sigma\rangle = R\zeta. \tag{12}$$

When R is determined, the surface fluctuations can be measured by $\delta\sigma$.

Three processes cause variability in radar cross section: surface tilting, hydrodynamic interaction, and velocity bunching. The modulation caused by surface tilting and hydrodynamic interactions depends on the wave direction. Consider a SAR viewing the sea at an incidence angle of 23°: With an amplitude of 3 m and a wavelength of 200 m, the modulation caused by tilting is roughly ±3 dB for waves traveling toward the range direction (detectable by SAR), and nearly ±0.3 dB for waves traveling in the azimuthal direction (not detectable by SAR).

3.4.3 Satellite Radiometer Sea-surface temperature (SST) has a 150-year history of global measurement and is intimately linked with climate and global change. Although historical measurements were made by naval and merchant vessels, space-based measurements of SST have improved remarkably in the past decade and now represent one of our most important data sets for monitoring the global environment. Satellite measurement of SST is made possible by satellite radiometers (Plate 2).

The physical principle for the satellite radiometer is radiative transfer through an emitting and absorbing atmosphere with the absorption coefficient κ_λ, which is depicted by the radiative transfer equation

$$L^\lambda = L_S^\lambda \exp[-\tau(0,H)] + \int_0^H L_B^\lambda(z)\, \kappa_\lambda(z) \exp[-\tau(z,H)]\, dz, \qquad (13)$$

where

$$\tau(z,H) = \int_z^H \kappa_\lambda(z')\, dz'$$

is the optical thickness (or opacity) of the atmospheric layer with thickness H. The superscript λ indicates the wavelength of the radio waves. The terms L_S^λ, L^λ, and L_B^λ are the source radiance, the radiance seen by an observer viewing the source, and the radiance of the blackbody at the same temperature as the absorbing air, respectively. The first term on the right-hand side of Eq. (13) gives the total attenuation due to absorption; the second term gives the emission $L_B^\lambda \kappa_\lambda$ from any point z along the path attenuated by the air along the remainder of the path (Plate 2). The radiative transfer equation is complicated, and one needs to know L_B^λ (or temperature) and κ_λ (or atmospheric constituents) to solve it. At the atmospheric windows, however, the absorption coefficient κ_λ is small such that the second term of the right-hand side of Eq. (13) is negligible. Therefore, the source radiance (or the surface temperature) can be easily determined by the satellite radiometer.

The primary instrument for production of operational satellite-derived SST is the Advanced Very High Resolution Radiometer (AVHRR) carried on two polar-orbiting meteorological satellites. These satellites are sun-synchronous with local equator crossing times of 0730 and 1330 for descending orbits. The AVHRR scans the Earth perpendicular to the satellite direction of travel, providing twice-daily global coverage at 4-km ground resolution. The AVHRR has four or five channels, which use the 3–4-μm or 10–12-μm atmospheric windows, and carries an on-board blackbody viewed by the instrument, and this, along with a view of space, is used to perform a linear calibration. Multichannel observations are used to correct for atmospheric effects to produce a global SST data set. This is done after navigation of the images, land masking, eliminating observations of clouds, and averaging into 8-km areas. The bias and scatter of these data, when compared to drifting buoy measurements, are less than 0.3° and 0.7° C, respectively. Some of this difference is due to the fact that the radiometers measure the skin temperature of the ocean while buoy measurements are made in the upper meter of the ocean.

AVHRR images with 1-km resolution are broadcast directly to ground stations. These high-resolution images are useful for delineating fronts and eddies in the ocean that are associated with biological productivity and that also have tactical significance for naval warfare.

4. MARINE HYDRODYNAMICS

The equations of motion for the ocean are the momentum equations (application of Newton's law to a unit mass of seawater) and the continuity equation indicating conservation of mass per unit volume:

$$\frac{d\mathbf{V}}{dt} = \mathbf{F}_C + \mathbf{F}_p + \mathbf{F}_t + \mathbf{F}_g + \mathbf{F}_v, \tag{14}$$

$$\frac{d\rho}{dt} + \rho\nabla \cdot \mathbf{V} = 0, \tag{15}$$

where **V** is the velocity vector relative to the Earth, ρ is water density, and $\mathbf{F}_C$, $\mathbf{F}_p$, $\mathbf{F}_g$, $\mathbf{F}_t$, and $\mathbf{F}_v$ are various forces (per unit mass) exerted on the water parcels: Coriolis force, pressure-gradient force, gravity, tidal forces, and viscous forces.

4.1 Coriolis Force

The Earth is a rotating planet with the angular velocity of 2π/day. Any water parcel at rest relative to the Earth in fact moves with a velocity of as much as 460 m/s relative to a "fixed" star. Rather than include these velocities and accelerations, a coordinate system is generally chosen that is fixed with respect to the Earth. In this coordinate system, any moving water parcel "feels" an apparent force called the Coriolis force due to the rotation of the Earth:

$$\mathbf{F}_C = -2\mathbf{\Omega} \times \mathbf{V}, \tag{16}$$

where Ω is the angular velocity of the Earth.

4.2 Pressure-Gradient Force

If the pressure (p) on a level surface is inhomogeneous, the pressure gradient leads to a force exerted on the water parcel:

$$\mathbf{F}_p = -(1/\rho)\,\nabla p, \tag{17}$$

which is called pressure-gradient force.

4.3 Tidal Forces

In principle, the ocean responds to all gravitational fields exerted on it, but in practice, except for the Earth's own gravity, only the gravitational forces exerted by sun and moon are strong enough to induce detectable tidal excursions. If the ocean is attracted by the sun or moon, water parcels at different locations experience different forces that lead to a tidal force, which is decomposed into components normal and parallel to the ocean surface

$$\mathbf{F}_t = \frac{GMR}{D^3}\left(3\cos^2\chi - 1,\ -\tfrac{3}{2}\sin 2\chi\right). \tag{18}$$

Here G is the Newtonian gravitational constant, χ is the angle between the local vertical axis and the line between the center of the Earth and the external terrestrial body, M is the mass of the external terrestrial body, D is the distance between the Earth and the external terrestrial body, and R is the radius of the Earth. The 11 most important tides with commonly accepted nomenclature are listed in Table 1.

Table 1. Major tidal modes.

	Tidal mode	Period, T (h)
Semidiurnal Tides		
M_2	principal lunar	12.421
S_2	principal solar	12.000
N_2	elliptical lunar	12.658
K_2	declination luni-solar	11.967
Diurnal Tides		
K_1	declination luni-solar	23.935
O_1	principal lunar	25.819
P_1	principal solar	24.066
Q_1	elliptical lunar	26.868
Long-Period Tides		
Mf	fortnightly lunar	327.86
Mm	monthly lunar	661.31
Ssa	semiannual solar	4383.04

If the Earth were uniformly covered with a fluid envelope, these forces would give rise to an equilibrium tide having a maximum elevation of 0.35 m for the lunar (M2) tide and 0.16 m for the solar (K1) tide. In the ocean, this behavior is considerably modified. The phase speed of the tidal wave is approximated by $(gH)^{0.5}$ (where H is the water depth), ocean basins have natural periods of oscillation, tides are affected by the Coriolis force, and land masses can reflect the tides. A given tidal constituent may have amphidromic points where no vertical displacements occur.

Tides can behave as either standing or progressive waves. Tides are generally amplified in shallow water, and here tides are classified as either diurnal, semidiurnal, or a combination of diurnal and semidiurnal called "mixed." Tidal currents associated with rising sea level are called *flood*, while those associated with falling sea level are called *ebb*. Tides cause considerable mixing in shallow water, can generate internal tidal waves when waters are stratified, and, with the rate of river discharge, serve to control the character of estuaries and bays. Bores occur on some rivers, and, at a few locations, tides are used for power generation.

4.4 Gravity

Gravity is the strongest force acting on the sea. It is a body force exerted on the water column, and is the sum of the Earth's gravitational force and the centrifugal force. It is taken in the vertical direction downward:

$$\mathbf{F}_g = -g\mathbf{k} = \frac{d\Phi}{dz}, \tag{19}$$

where $\mathbf{k}$ is the vertical unit vector (directed positive upward from a level surface), g is the gravitational acceleration given by Eq. (4), and Φ is called the *geopotential*, which has units of $m^2\ s^{-2}$. The geopotential defines a level surface to which a motionless ocean would conform (see discussion in Sec. 3.4.1). Gravity provides the restoring force for sea and swell and the energy for thermohaline circulation. It also acts to compress water at depth.

4.5 Viscous Forces

The molecular viscosity of seawater is the mechanism by which mechanical energy is removed. The viscous force is always a resistance force and is expressed by

$$\mathbf{F}_\nu = \nu\nabla^2\mathbf{V}; \tag{20}$$

here ν is the kinetic molecular viscosity, which is a function of temperature, salinity, and pressure and has a value of about $10^{-6}\ \mathrm{m}^2\ \mathrm{s}^{-1}$ for seawater.

Although damping due to molecular viscosity is small, it is important for small-scale processes, e.g., acoustic and capillary waves. It is neglected for larger-scale processes for which the damping due to eddy mixing and diffusivity is represented by means of eddy viscosity.

4.6 Geostrophic Balance

For the large-scale motions in the ocean, the Coriolis force and the pressure-gradient force are the two dominating forces, and the momentum equation becomes geostrophically balanced. The water moves along isobars.

The pressure-gradient force is estimated through the use of the geopotential. From Eqs. (19) and (3),

$$d\Phi = gdz = -(1/\rho)\,dp = -\alpha dp, \tag{21}$$

and here α is specific volume. Integrated over a given pressure interval, this yields *dynamic height*. In practice, an anomaly δD is used; results are divided by ten, and the resulting unit is called *dynamic meters*. Since currents at depth in the ocean are typically slow, an assumption of a *level of no motion* is made, i.e., the lower-pressure surface is assumed to be parallel with a geopotential surface, and a geostrophic current velocity v_g, normal to two CTD stations, a and b, can be calculated:

$$v_g = (\delta D_a - \delta D_b)/fL, \tag{22}$$

where L is the distance between the stations.

4.7 β Effect

The Coriolis parameter ($f = 2\Omega\ \sin\phi$) depends on latitude. If the latitudinal range of motion exceeds 20°, the Coriolis parameter cannot be treated as a constant. To keep this dependence as simple as possible, a linear function is obtained by expanding f into a Taylor series about $y_0 = a\phi_0$ ($a \sim$ Earth's radius),

$$\begin{aligned} f &= f_0 + \beta(y - y_0) + \cdots \\ &= f_0\left[1 + \frac{\beta}{f_0}(y - y_0) + \cdots\right], \end{aligned} \tag{23}$$

where

$$\beta = \left.\frac{df}{dy}\right|_{\phi_0} = \frac{2\Omega\cos\phi_0}{a}. \tag{24}$$

This linear relationship between f and y is called the β effect. In the equatorial region, $f_0 \simeq 0$, the second term on the left-hand side of Eq. (23) becomes dominant and the β effect is evident. In the polar regions, $\beta \simeq 0$, the β effect is negligible. If the zonal variation is much smaller than the Earth's radius, $|y - y_0 \ll a$, the latitudinal variation of the Coriolis parameter is negligible:

$$|(\beta/f_0)(y - y_0)| \ll 1.$$

Therefore, it is reasonable to replace f by the constant f_0 except where it is differentiated by y and to change df/dy to the constant β. This is called the β-plane approximation.

4.8 Conservation Principles

With neither a heat source nor sink, the second law of thermodynamics requires entropy to be conserved, and therefore the potential temperature θ should also be conserved:

$$\frac{d\theta}{dt} = 0. \tag{25}$$

Similarly, with no source or sink of salt, salt should be conserved, i.e.,

$$\frac{dS}{dt} = 0. \tag{26}$$

Further, if water is incompressible, mass conservation leads to

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0, \tag{27}$$

which indicates that horizontal divergence will induce vertical convergence, and vice versa.

If there are neither heat nor salt sources or sinks, nor friction nor diffusion, a mathematical manipulation of momentum, heat, and continuity equations leads to conservation of potential vorticity (Π),

$$\frac{d\Pi}{dt} = 0. \tag{28}$$

4.9 Topographic Forcing

The ocean has sides (e.g., coasts) as well as a bottom. These boundaries are generally assumed to be rigid,

$$\mathbf{V} \cdot \mathbf{n} = 0, \tag{29}$$

indicating that no water particle can penetrate the boundaries. Here **n** is the unit vector in the outward normal direction to the rigid boundary.

In the open ocean, bathymetry is expressed by a two-dimensional function $z = -H(x,y)$. Therefore, the rigid-bottom boundary condition becomes

$$w = -u\frac{\partial H}{\partial x} - v\frac{\partial H}{\partial y}, \quad \text{at } z = -H(x,y). \tag{30}$$

Vertical motion is then generated by horizontal currents flowing over the bottom. This forced vertical motion is important in studies of deep-water processes.

For coastal regions, the water is generally considered as barotropic. Its potential vorticity is $\Pi = (f + \zeta)/H$, where $\zeta = \partial v/\partial x - \partial u/\partial x$ is the vertical component of the relative vorticity. Since the magnitude of ζ is much smaller than f, $|\zeta| \ll |f|$, potential vorticity conservation becomes

$$\frac{d\Pi}{dt} = u\frac{\partial}{\partial x}\left(\frac{f}{H}\right) + v\frac{\partial}{\partial y}\left(\frac{f}{H}\right) = 0, \tag{31}$$

which means that the current vectors are parallel to the isolines of the f/H field. This forcing is very important for topographic waves in coastal regions.

5. OCEAN CIRCULATION THEORY

Motions are generated both by surface wind stress (the wind-driven circulation) and by buoyancy flux (the thermohaline circulation). While it is difficult to say that one type of forcing is more important than the other, aspects of wind forcing have been easier to treat analytically.

5.1 Wind-Driven Circulation

The atmospheric forcing on the ocean takes two forms. One, called the *inverted barometer effect*, is the force exerted on the irregular ocean surface that is associated with atmospheric-pressure differences. The second is the wind stress. Except for severe weather systems (e.g., typhoons) in which the horizontal pressure gradient is large, wind stress is generally considered the major mechanical forcing of the ocean.

Winds blowing over the ocean surface drive different kinds of motion (gravity and capillary waves, turbulence, circulation, etc.) through frictional effects near the ocean surface. The surface wind stress, defined as the turbulent momentum flux at the ocean surface, is on the order of 1 dyn/cm^2 and is related to the surface wind speed $\mathbf{V}_a$ by the drag law

$$\boldsymbol{\tau} = C_D \rho_a |\mathbf{V}_a| \mathbf{V}_a, \tag{32}$$

where C_D ($\sim 10^{-3}$) is the drag coefficient, whose magnitude is affected by the roughness, the buoyancy flux, and the waves and turbulence near the ocean surface.

5.1.1 Ekman Transport When the wind blows over the ocean surface, the friction between the air and the ocean will slow the wind and cause ripples, waves, and currents in the ocean. The stress of the wind on the water involves a transfer of turbulent fluxes of momentum and kinetic energy from the atmosphere to the ocean. In the ocean, the turbulent kinetic energy transferred from the atmosphere decreases from the surface downward and will vanish at some depths. A depth of 100 m is usually considered the practical lower limit for wind-driven currents. The layer that contains the turbulent flux is called the surface layer, or the Ekman layer.

Imagine that the ocean surface layer is divided into thin horizontal layers. The frictional force (per unit area) exerted between the two neighboring layers is represented by a horizontal stress (X,Y), which is the retarding force for the upper layer and the driving force for the lower layer. At the ocean surface, (X,Y) is the wind stress. If these stresses are balanced by the Coriolis force, the Ekman velocity (u_E,v_E) satisfies

$$\frac{\partial u_E}{\partial t} - f v_E = \frac{1}{\rho}\frac{\partial X}{\partial z}, \tag{33a}$$

$$\frac{\partial v_E}{\partial t} + f u_E = \frac{1}{\rho}\frac{\partial Y}{\partial z} \tag{33b}$$

[this solution was derived by Ekman (1905) to explain why Arctic icebergs drifted 40° to the right of the wind]. Notice that currents driven by the pressure-gradient force are not included in the Ekman flow. For steady state ($\partial/\partial t = 0$), the vertical variation of the Ekman velocity, called the Ekman spiral, shows that the surface current is directed 45° to the right of the wind stress in the Northern Hemisphere and 45° to the left in the Southern Hemisphere. As depth increases, the direction of water transport deviates to the right in the Northern Hemisphere relative to the overlying water in the same fashion as the surface water is transported by the wind. Friction causes each succeeding layer to decrease in speed.

The total water transport in the Ekman layer is calculated by the vertical integration of the Ekman velocity:

$$(U_E,V_E) = \int (u_E,v_E)\,dz,$$

which is also called the Ekman transport. Vertical integration of Eq. (33) leads to

$$\rho\left(\frac{\partial U_E}{\partial t} - fV_E\right) = \tau_x, \quad \rho\left(\frac{\partial V_E}{\partial t} + fU_E\right) = \tau_y, \tag{34}$$

where (τ_x,τ_y) is the surface wind stress. In steady conditions, the Ekman transport is directed 90° to the right (or left) of the surface wind stress in the Northern (or Southern) Hemisphere. The discontinuity of the Ekman transport at the equator results in equatorial upwelling (downwelling) for westward (eastward) winds.

The wind stress varies from place to place, and hence so does the Ekman transport. This leads to convergence or divergence of water mass in the Ekman layer, i.e., causes the water mass to flow horizontally into some regions and out of others. This will result in vertical motion. For example, if the Ekman transport is horizontally convergent in a particular region, vertical downward motion away from the Ekman layer is induced in order to conserve mass. If we assume no significant distortion of the ocean free surface, a vertical integration of the continuity equation across the Ekman layer yields the vertical velocity (called Ekman pumping velocity) at the base of the Ekman layer:

$$w_E = \nabla \cdot \mathbf{U}_E = \mathbf{k} \cdot \mathrm{curl}(\boldsymbol{\tau}/\rho f). \tag{35}$$

This vertical velocity, driven by the surface wind stress, exchanges water between the surface layer (under the direct effect by the atmosphere) and the deeper water. In subtropical gyres (equatorward of 45 deg) w_E is usually negative: The surface water is pumped downward into the deeper layer. In subpolar gyres, w_E is generally positive: The water mass is pumped upward from the interior into the surface layer. Therefore, Ekman pumping is a crucial link between the surface wind forcing and deep-ocean dynamics.

5.1.2 Sverdrup Transport Ekman flow excludes the currents forced by the pressure gradient. The Sverdrup transport includes both the Ekman transport and the geostrophic transport that results from the pressure gradients set up by the convergent or divergent Ekman-layer flow. Let the mass transport function with respect to the ocean bottom (H) and the integrated pressure (P) be defined as

$$\frac{\partial M}{\partial x} = \int_{-H}^{0} v\,dz, \quad \frac{\partial M}{\partial y} = -\int_{-H}^{0} u\,dz,$$
$$P = \int_{-H}^{0} \frac{p}{\rho}\,dz. \tag{36}$$

Vertical integration (from $-H$ to 0) of the momentum equation (14) after neglecting the advection term and the tidal forcing leads to

$$-\frac{\partial^2 M}{\partial t \partial y} - f\frac{\partial M}{\partial x} = -\frac{\partial P}{\partial x} + \tau_x, \tag{37a}$$

$$\frac{\partial^2 M}{\partial t \partial x} + f\frac{\partial M}{\partial y} = -\frac{\partial P}{\partial y} + \tau_y. \tag{37b}$$

Sverdrup (1947) first obtained the steady-state solution of Eq. (37) for the mass transport M under the β-plane approximation:

$$\frac{\partial M}{\partial x} = \frac{1}{\beta}\left(\frac{\partial \tau_y}{\partial x} - \frac{\partial \tau_x}{\partial y}\right), \tag{38}$$

which shows the congruity between the north–south ocean flow and the wind-curl patterns. Note that the Sverdrup transport was obtained only when the zonal dependency of the Coriolis parameter is considered. If the β effect is negligible (f = const), there is no Sverdrup transport. In the low to middle latitudes of the Northern Hemisphere (15°–50° N), the surface wind-stress curl is usually anticyclonic, and drives a southward Sverdrup transport. Sverdrup further showed that if Eq. (38) is integrated for M from an east coast, where the mass transport diminishes, a current counter to the prevailing winds would occur in the Eastern Pacific Ocean under the Inter-Tropical Convergence Zone (ITCZ). Such a current is observed, the North Equatorial Counter Current. (Oceanographers have subsequently defined a unit of transport as a Sverdrup, i.e., 10^6 m^3/s = 1 Sv.)

5.1.3 Westward Intensification If you look at a pilot chart of ocean currents, you immediately notice that the strongest currents (e.g., the Gulf Stream and Kuroshio) appear at the western boundaries of the ocean and that currents elsewhere are noticeably weaker. This east–west asymmetry is called *westward intensification.*

As noted in Sec. 4.7, the zonal change of the Coriolis parameter (β effect) must be taken into account. In low to middle latitudes, the anticyclonic surface wind-stress curl drives equatorward Sverdrup transport. This equatorward flow must return poleward somewhere in order to satisfy continuity. Will this occur at the eastern or western boundary? Because the Coriolis effect causes equatorward flow to turn toward the west, the return flow must take place at the western boundary. Stommel (1948) and Munk (1950) offered theoretical explanations for the westward intensification. Both models are based on potential vorticity conservation,

$$\begin{aligned}\frac{d\Pi}{dt} &= \frac{\partial \Pi}{\partial t} + (\mathbf{V}\cdot\nabla)\Pi \\ &= \frac{1}{\rho h^2}\,\mathbf{k}\cdot(\text{curl } \boldsymbol{\tau}|_0 - \text{curl } \boldsymbol{\tau}|_{-h}) + A\nabla^2\Pi,\end{aligned} \tag{39}$$

which indicates that the time-rate change of the potential vorticity is caused by the surface wind stress ($\boldsymbol{\tau}|_0$), bottom friction ($\boldsymbol{\tau}|_{-h}$), and the horizontal diffusion ($\nabla^2\Pi$). Here, h is the ocean depth and is assumed to be a constant. The magnitude of the relative vorticity (ζ) for large-scale motions in the ocean is much smaller than the magnitude of the planetary vorticity f, so that the advection of the potential vorticity can be linearized:

$$\mathbf{V}\cdot\Pi = (\beta/h)\,v. \tag{40}$$

For the steady state, potential vorticity advection is balanced by friction and diffusion. The difference between the two models is that there is no horizontal diffusion in Stommel's model, and no bottom friction in Munk's theory.

5.1.3.1 Stommel's Model. By neglecting horizontal diffusion and parametrizing the bottom friction by the Rayleigh friction, $\tau_{-h}/\rho = R(u,v)$, the barotropic potential vorticity equation (39) becomes

$$\begin{gathered}\nabla^2\psi + \frac{h}{R}\beta\frac{\partial\psi}{\partial x} = \frac{\mathbf{k}}{\rho R}\,\text{curl } \boldsymbol{\tau}_0, \\ u = -\frac{\partial\psi}{\partial y}, \quad v = \frac{\partial\psi}{\partial x}.\end{gathered} \tag{41}$$

Stommel (1948) applied this model to a rectangular ocean. The shores of the ocean were at $x = 0, L_x$, $y = 0, L_y$. The surface wind stress was chosen as a sinusoidal function $\mathbf{k}\cdot\boldsymbol{\tau}_0/\rho = F\sin(\pi y/L_y)$. The model was integrated for three cases: $f = 0$, $f =$ const, and $f = f_0 + \beta y$. The nonrotating, wind-driven system features a broad circulation exhibiting no tendency toward western boundary intensification. The uniformly rotating, wind-driven system has a similar pattern (i.e., no westward intensification). The final case, which used a β plane, has intense crowding of streamlines toward the western boundary of the ocean.

5.1.3.2 Munk's Model. By neglecting bottom friction, Munk (1950) simplified the barotropic potential vorticity equation (39):

$$\left[-A\nabla^4 + \beta\frac{\partial}{\partial x}\right] = \mathbf{k}\cdot\text{curl } \boldsymbol{\tau}_0. \tag{42}$$

His solutions show westward intensification similar to Stommel's model.

5.2 Thermohaline Circulation

Thermohaline circulation problems have proven more difficult, both theoretically and experimentally. On the experimental side, this has been due to the relatively weak flows and the depth at which they occur, as well as the fact that the polar regions, where much of the convective forcing occurs, are not easily accessible. The two major deep-water masses are the North Atlantic Deep Water and Antarctic Bottom Water. North Atlantic Deep Water is formed at high latitudes in the North Atlantic from overflow waters from the Nordic seas (a production rate of about 6 Sv) and in the Labrador Sea (about 8 Sv). Most Antarctic Bottom Water is formed in the Weddell Sea at a rate of 2–4 Sv.

Stommel (1958) proposed a circulation model for the deep circulation given these two sources of deep water. Upwelling in the interior is fed by slow eastward flow from equatorward-flowing deep western-boundary currents, which carry water from the deep-water formation regions. Measurements subsequently confirmed the deep western-boundary currents.

5.2.1 Thermocline Theory Broecker (1991), Munk (1966), Schmitz and McCartney (1993), and Luyten *et al.* (1983) argue that the difficulty in modeling the thermocline is due to the tendency of the ocean to preserve both density and potential vorticity over great distances from source areas of both fields. The problem of the vertical structure of thermocline must be coupled to the horizontal structure of the ocean circulation.

A thermocline equation can be derived from the geostrophic and hydrostatic balance of the large-scale ocean circulation, and from the advective–diffusive balance of the density field:

$$J\left(\frac{\partial Q}{\partial z}, \frac{\partial^2 Q}{\partial z^2}\right) + \cot\phi \frac{\partial Q}{\partial \lambda}\frac{\partial^3 Q}{\partial z^3} = \mu \frac{\partial^4 Q}{\partial z^4} \cos\phi \sin\phi, \tag{43}$$

where ϕ and λ are latitude and longitude, respectively, $J(F,G)$ is the Jacobian for any two functions F and G; $\mu \equiv \delta_D/\delta_A$ is the ratio of the diffusive to advective length scales; Q is defined as

$$Q(\phi,\lambda,z) = -\int_z^0 p dz' + \sin^2\phi \int_0^\lambda w_E d\lambda'. \tag{44}$$

The thermocline equation (43) is very difficult to solve, although solutions have been obtained for special cases.

5.2.2 Thermohaline Forcing The combined effect of fluxes of heat and salt on the ocean causes buoyancy contrasts, and induces motion called the thermohaline circulation. The most important thermodynamic forcing is the buoyancy flux at the air–ocean interface:

$$B = \alpha(LE + Q)/c_{pw} + \beta(E - Pr)\, S_0 + \beta(F - M)(S_0 - S_f), \tag{45}$$

where Q is the sum of the radiative and turbulent heat fluxes at the air–ocean interface (upward positive), E the evaporation rate, Pr the precipitation rate, F the ice freezing rate, L the latent heat of vaporization, M the ice melting rate, C_{pw} the specific heat of seawater, S_0 the upper-ocean salinity, and S_f the ice salinity ($S_f \sim 0.7$ g/kg). Since $\alpha L/c_{pw} \simeq 0.12$ and $S_0 \simeq 0.03$, the contribution of evaporation rate to the buoyancy flux from the first term on the right-hand side of Eq. (45) is 4 times greater than that from the second term. The values of B are on the order of 10 g/cm^2 yr, which corresponds to a turbulent kinetic energy generation rate of the order of 3×10^{-4} cm^2 s^{-3}. Upward surface buoyancy flux B (heat loss from the ocean surface, or excess evaporation over precipitation, or salt injection due to ice formation) increases the surface density and makes the water parcel descend. The circulation that is driven by the buoyancy flux is called the thermohaline circulation.

5.2.3 Ventilation Ventilation is any process that brings subsurface water to the surface so that heat, momentum, and gases can be exchanged with the atmosphere. Ventilation of deeper water occurs primarily through two processes. The first is the Ekman pumping of water onto density surfaces. The region on an isopycnal surface affected by this process is called the ventilation region. The second process is deep convection. Although a number of estimates of the mean ventilation time for the deep ocean have been proposed, that of about 1400 years, based on radiocarbon, is the most widely quoted. The ventilation time T of the deep ocean is usually measured by the carbon isotope ratios:

$$T = \frac{V_D}{R} = \left[\frac{(^{14}C/C)_S}{(^{14}C/C)_D} - 1\right] T_{^{14}C}, \tag{46}$$

where V_D and R are the volume and the ventilation rate of the deep sea, respectively. Here $(^{14}C/C)_S$ and $(^{14}C/C)_D$ are the carbon isotope ratios for the mean surface and mean deep ocean. The term T_{14_C} is the mean half-life of ^{14}C.

Ventilation is fundamental to understanding the large-scale motion in the deep sea. To understand deep-sea circulation, one needs to answer the dual questions of how a fluid below the surface layer (which is directly driven by the wind) is set into motion, and what determines the depth to which that motion penetrates. Since the ocean has no significant frictional stresses between layers, only the surface water that is immediately acted upon by the wind stress can brought into motion. The existence of subsurface motion therefore requires either ventilation or convective mixing. Ventilation requires the water parcel trajectories to thread back and intersect near-surface regions directly affected by Ekman pumping. Convective mixing leads to momentum transfer between different layers.

This scheme creates at least two regions in the thermocline of the North Atlantic. One region is connected directly to northern latitudes where water is ventilated to the atmosphere and forced downward by Ekman pumping, subsequently being subducted and conserving potential vorticity. Another region is not ventilated to the atmosphere. The unventilated region sweeps across the entire low-latitude North Atlantic from the eastern boundary at the depth of 27.4 kg/m^3 isopycnal. Observed distributions of dissolved oxygen and tritium on this surface are indicative of poor ventilation in this region.

Subduction is a companion concept to ventilation. In the subtropical gyre, surface waters are pumped down into the main thermocline (ventilation) by the action of the prevailing winds. Under mechanical and buoyancy forcing, the mixed layer cools and burrows into the thermocline, entraining thermocline water. Stratification existing in the thermocline determines how the mixed layer responds to the forcing. Alternatively, the mixed layer may warm and retreat, leaving behind newly stratified fluid, which then subducts into the deeper layers.

5.2.4 Convection Generally the ocean is stable, i.e., the lighter water lies over denser water. In polar regions and the Mediterranean Sea, the stratification sometimes becomes quite weak. Slight negative buoyancy in the surface water caused by atmospheric cooling or salt injection will make the water column statically unstable and trigger deep convection. Water columns with vertically homogeneous hydrographic structure (called "chimneys") have been observed in the Arctic, Antarctic, and Mediterranean; they have been observed near ocean boundaries as well as in the open ocean.

Near-boundary convection requires three ingredients:

1. a reservoir,
2. a source of dense water within the reservoir,
3. a reason for the dense water to leave the reservoir and to descend the slope to the deep layer (Killworth, 1983).

Open-ocean convection usually requires a cyclonic gyre and "preconditioning." Upward "doming" of isopycnals in the center of the cyclonic gyre reduces static stability of water column within the gyre. The preconditioning creates a region of very weak static stability within the dome of the gyre where a sufficient surface forcing can drive deep convection. Many processes can be thought of as preconditioning, e.g., topographic forcing, baroclinic instability, etc.

An example of open-ocean convection is a column of water (14-km radius) that was observed within the central region of the Weddell Gyre west of Maud Rise (Gordon, 1978). The normal Antarctic stratification was absent, and the column appeared as a cold, low-salinity, high-oxygen, cyclonic flow (surface velocity about 50 cm/s), which extended to at least 4000 m.

5.2.5 The Conveyor Belt Recent observations and numerical modeling suggest the existence of a "conveyor belt" in the ocean that may serve as a mechanism for long-term climate variability. Deep waters in the northern North Atlantic are convected, sinking to depth and flowing southward along the western boundary of the North and South Atlantic Oceans as the North Atlantic Deep Water (NADW) with high salinity content, hence forming the conveyor belt's lower limb. After passing 30° S, this lower limb of the conveyor joins the Circumpolar Current along the perimeter of the Antarctic continent, along with older deep waters recirculated into the Antarctic from the deep Pacific and Indian Oceans. The lower limb water returns to the surface in the northern Indian and Pacific Oceans, feeding the upper limb of the conveyor. The imported water that feeds the upper limb of the conveyor belt in the Atlantic can have three components: Antarctic surface waters passing through the Drake Passage, Indian surface waters passing around the tip of Africa via the Agulhas Current, and intermediate waters formed at the northern perimeter of the Atlantic segment of the Antarctic. Different conveyors (or climatic regimes) can be envisioned in which only one or two of these three components are active.

6. OCEAN WAVES

An ocean basin filled with slightly compressible and electrically conducting seawater on a weakly magnetized rotating Earth will support a variety of waves. An ocean wave is generally depicted by a periodic function. A one-dimensional wave propagating in the x direction is usually described by a sinusoidal function

$$\zeta = A \cos(kx - \omega t), \tag{47}$$

where ζ is any wave variable, A the wave amplitude, k the wave number, and ω the wave frequency. The quantity $L = 2\pi/k$ is called the wavelength; $T = 2\pi/\omega$ is called the period. The nondimensional quantity $kx - \theta t$ is called the phase angle. The wave propagates with a phase speed

$$C = \omega/k. \tag{48}$$

When the phase speed (C) varies with the wave number (k), the waves with different wavelengths travel with different phase speeds, which is called the wave dispersion. The wave packet, a group of waves with different wavelengths, travels with the group velocity

$$C_g = \frac{\partial \omega}{\partial k}. \tag{49}$$

Hydroelectromagnetic waves (Alfvén waves) are possible in the ocean, but the Earth's magnetic field is so weak that the electromagnetic restoring forces are insignificant compared to other restoring forces; so Alfvén waves are not important in the ocean. Acoustic waves exist as a result of compressibility. Gravity waves arise through the restoring force of gravity. Short, high-frequency capillary waves occur at the interface between air and water through the restoring force of surface tension. Inertial waves appear as a result of the Coriolis force, acting at right angles to the velocity vector. Finally, very slow, planetary waves develop from the variation of quasigeostrophic potential vorticity.

These five basic types of oceanic waves (acoustic, capillary, gravity, inertial, and planetary waves) generally occur together, with five basic restoring forces all acting simultaneously to produce more complicated and mixed waves, such as inertial–gravity waves, mixed Rossby–gravity waves, etc. The effect of the lateral boundary on the inertial–gravity waves leads to a special type of wave named after Lord Kelvin, who first found a solution describing the wave.

6.1 Acoustic Waves

The propagation of sound in the ocean was discussed in Sec. 1.3. The propagation of acoustic waves in the ocean is governed by

$$\nabla^2 p - \frac{1}{U_a^2}\frac{\partial^2 p}{\partial t^2} + \frac{\mu}{\rho U_a^2}\nabla^2\frac{\partial p}{\partial t} = 0, \tag{50}$$

where μ is molecular viscosity of seawater. The ocean surface is a very good reflector/scatterer of sound energy. The ocean bottom, composed of hard rock to soft muds, has large variability in reflection, scattering, and absorption. We usually solve the wave-propagation equation subject to various surface and bottom boundary conditions and obtain information about the propagation and attenuation.

6.2 Gravity and Capillary Waves

The wind generates surface waves. At very low wind speeds, small capillary waves develop on the surface. Surface waves have frequencies ω much higher than the inertial frequency (Coriolis parameter) f and buoyancy frequency N. Therefore, the Coriolis, buoyancy, and viscous terms are usually neglected in the momentum equations. Under these conditions, the fluid motion will be *irrotational.* A scalar velocity potential ϕ can be defined to represent the vector velocity:

$$\mathbf{V} = \nabla\phi. \tag{51}$$

The incompressibility condition, $\nabla \cdot \mathbf{V} = 0$, implies that the velocity potential (ϕ) satisfies Laplace's equation,

$$\nabla^2\phi = 0. \tag{52}$$

To solve this equation, we need surface and bottom boundary conditions. Consider a uniform, frictionless ocean of depth H, whose surface is subject to a small wavelike perturbation

$$\xi(x,y,t) = \xi_0 \cos(kx + ly - \omega t). \tag{53}$$

The pressure across the air–ocean interface should be continuous, i.e.,

$$p = p_a - \tau_s\left(\frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2}\right). \tag{54}$$

Here p and p_a are oceanic and atmospheric pressures at the ocean surface, and τ_s is surface tension. If $\tau_s = 0$, we have the pure gravity waves; if $\tau_s \neq 0$, we have the gravity-capillary waves. Combining these two conditions, the surface boundary ($z = 0$) condition for ϕ can be derived:

$$\frac{\partial^2\phi}{\partial t^2} + \frac{1}{\rho}\left[-\tau_s\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) + \rho g\right]\frac{\partial\phi}{\partial z} = 0, \quad z = 0. \tag{55}$$

The ocean bottom is generally considered a rigid boundary. Since this is a linear system, ϕ should have the same harmonics as ξ, i.e.,

$$\phi = \phi_0(z)\sin(kx + ly - \omega t). \tag{56}$$

Substitution of Eq. (56) into Eq. (55) leads to an ordinary differential equation for ϕ_0 with z. By using the surface and bottom boundary conditions, we will have the dispersion relation

$$\omega^2 = (gk_h + k_h^3\tau_s/\rho)\tanh k_h H, \tag{57}$$

where $k_h = \sqrt{k^2 + l^2}$ is the horizontal wave number. The dispersion relation shows that the gravity-capillary waves are generally dispersive ($c_g = \partial\omega/\partial k \neq 0$).

For the pure gravity waves, $\tau_s = 0$, and therefore, the dispersion relation becomes

$$\omega^2 = gk_h \tanh k_h H. \tag{58}$$

If the horizontal wavelength $L_h = 2\pi/k_h$ is much shorter than the ocean depth (deep water), $k_h H = 2\pi H/L_h \gg 1$ and $\tanh k_h H \simeq 1$, and so the deep-water gravity-wave phase speed becomes

$$c = (g/k_h)^{1/2}, \quad k_h H \gg 1, \tag{59}$$

while the group velocity is

$$c_g = c/2. \tag{60}$$

The deep-water gravity waves are dispersive with the phase speeds depending inversely on the square root of the wave number; therefore, longer waves travel faster than short ones. In addition, the group velocity is $\frac{1}{2}$ of the phase speed, so that within a traveling wave packet, wave crests first appear toward the rear of the group. An initially localized packet consisting of many wave components spreads out in space and time as it propagates.

If the horizontal wavelength is much longer than the ocean depth (shallow water), $k_h H = 2\pi H/L_h \ll 1$ and $\tanh k_h H \simeq k_h H$, and so the shallow-water gravity-wave phase speed becomes

$$c = c_g = (gH)^{1/2}, \quad k_h H \ll 1. \tag{61}$$

Thus, the shallow-water gravity waves are nondispersive. Earthquakes generate a special kind of gravity wave called a tsunami, which behaves as a shallow-water wave even in deep water.

6.3 Rossby Waves

For large-scale motion, departure from geostrophic balance (sometimes called geostrophy) is small. Such flow is called quasigeostrophic flow. The quasigeostrophic potential vorticity (QGPV) Π_{QG} is

$$\Pi_{QG} = f_0 + \beta y + \zeta_g + \Lambda\frac{\partial}{\partial z}\left(\frac{f_0^2}{N^2}\frac{\partial\Phi}{\partial z}\right), \tag{62}$$

where $\zeta_g = (\partial^2/\partial x^2 + \partial^2/\partial y^2)\Phi$ is the geostrophic vorticity, Φ is the geopotential computed by Eq. (19), $N^2 = E$ is the square of the buoyancy frequency, $\Lambda = 0$ refers to the barotropic mode, and $\Lambda = 1$ to the baroclinic mode.

Rossby waves are associated with the β effect. The conservation of quasigeostrophic potential vorticity,

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y}\right)\Pi_{QG} = 0, \tag{63}$$

leads to a special form of oscillation on the planetary scale. An individual water parcel experiences no change in its QGPV. If a water parcel moves poleward, then as f increases, ζ_g has to decrease for the barotropic mode ($\Lambda = 0$) in order to keep Π_{QG} constant. If, furthermore, the geostrophic vorticity is mostly curvature, this means that a poleward-moving water parcel loses cyclonic curvature and ultimately must curve anticyclonically and move equatorward. The converse is true for a water parcel moving equatorward. This mechanism leads to the generation of Rossby waves (Rossby, 1936).

If the disturbances are sufficiently small, the advection terms in the QGPV conservation equation (63) can be neglected,

$$\frac{\partial}{\partial t}\left[f_0 + \beta y + \nabla_H^2 \Phi' + \Lambda \frac{\partial}{\partial z}\left(\frac{f_0^2}{N^2}\frac{\partial \Phi'}{\partial z}\right)\right] = 0, \tag{64}$$

where Φ' is the geopotential perturbation and $\nabla_H^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the horizontal Laplacian. If we assume no vertical velocity at either the surface or bottom, the sinusoidal wave solution has the form (when N = const)

$$\Phi' = \mathrm{Re}\left[\cos\frac{n\pi z}{H}\, e^{i(kx+ly-\omega t)}\right], \tag{65}$$

where H is the ocean depth. Substitution of Eq. (65) into Eq. (64) leads to the Rossby-wave dispersion relation

$$\omega = -\frac{\beta k}{k^2 + l^2 + \Lambda m_n}, \qquad m_n = \frac{n\pi f_0}{NH}, \quad n = 1, 2, \ldots. \tag{66}$$

For baroclinic Rossby waves, $\Lambda = 1$, formula (66) shows the dispersion relation of the nth baroclinic mode. For barotropic Rossby waves, $\Lambda = 0$, the dispersion relation becomes

$$\omega = -\beta k/(k^2 + l^2). \tag{67}$$

Rossby waves are highly dispersive and propagate westward. Rossby-wave phase speed and group velocity can be easily computed from the dispersion relation:

$$\mathbf{C} = \left(\frac{\omega}{k}, \frac{\omega}{l}\right), \quad \mathbf{C}_g = \left(\frac{\partial \omega}{\partial k}, \frac{\partial \omega}{\partial l}\right). \tag{68}$$

If the barotropic Rossby waves propagate only in the x direction ($l = 0$), the phase speed is

$$C_x = \omega/k - \beta/k^2 \tag{69}$$

and group velocity is

$$C_{gx} = \frac{\partial \omega}{\partial k} = \frac{\beta}{k^2}. \tag{70}$$

The highly dispersive nature of these waves is indicated by the fact that the phase speed and group velocity have the same magnitude but opposite directions.

6.4 Solitary Rossby Waves

Rossby waves are usually nonlinear and dispersive. The degree of nonlinearity depends on the amplitude and length of the waves, while the phase dispersion is determined by their length relative to the vertical length scales related to stratification and water depth. In general, these two dynamic effects tend to balance in such a way that nonperiodic, solitary waves emerge from initial disturbances.

Consider barotropic Rossby waves ($\Lambda = 0$) being excited from a zonal basic flow ($\bar{U}$) and propagating in a zonal channel bounded by southern and northern boundaries $y = y_S$, $y = y_N$. Introducing a scaled coordinate $\xi = \epsilon^{1/2}(x - Ct)$ moving with the wave at speed C, we seek a steady solution

$$\Phi = -\frac{1}{f_0}\int_{y_S}^{y} \bar{U}\,dy + \epsilon\Phi_1(\xi,y) + \epsilon^2\Phi_2(\xi,y) + \cdots, \tag{71a}$$

$$C = C_0 + \epsilon C_1 + \epsilon^2 C_2 + \cdots, \tag{71b}$$

where ϵ is a measure of the wave amplitude. Notice that the disturbances are no longer sinusoidal functions. Substitution of Eq. (71) into Eq. (63) leads to nonlinear equations for the components Φ_n, $n = 1, 2, \ldots$. If the first component is separated into

$$\Phi_1 = A(\xi)\psi(y), \tag{72}$$

the function $A(\xi)$ satisfies the steady Korteweg–de Vries (KdV) equation

$$\frac{dA}{d\xi} + rA\frac{dA}{d\xi} + s\frac{d^3A}{d\xi^3} = 0, \tag{73}$$

and solvability to $O(\epsilon^2)$ is insured if r and s satisfy certain conditions.

The soliton solutions are a linear sum of a barotropic soliton and a baroclinic soliton (first baroclinic mode). If a rigid lid is imposed, the barotropic solitary Rossby wave has an eastward phase speed ($c > 0$), and the baroclinic solitary Rossby wave has a phase speed that is either westward with a faster speed than βa_1^2 ($c < -\beta a_1^2$), or eastward ($c > 0$). Here a_1 is the Rossby radius of deformation for the first baroclinic mode. When the barotropic and baroclinic solitons are combined, only the baroclinic part moves west.

6.5 Kelvin Waves

When planetary waves approach the coastal zone, their behavior changes. The lateral boundary supports a different type of wave called a Kelvin wave. Consider a straight coastline, placing the x axis along the coast and the y axis perpendicular to the coast so that offshore is positive. Assume that the offshore variation of wave height and alongshore velocity exponentially decays. Since the coast is a rigid boundary, v vanishes at $y = 0$; therefore, v should vanish for the other values of y as well. Kelvin-wave solutions can be obtained by letting $v = 0$ in the momentum and continuity equations,

$$\frac{\partial u}{\partial t} = -g\frac{\partial \eta}{\partial x}, \tag{74a}$$

$$\frac{\partial \eta}{\partial t} + H\frac{\partial u}{\partial x} = 0, \tag{74b}$$

$$fu = -g\frac{\partial \eta}{\partial y}, \tag{74c}$$

where η is the surface elevation. Solutions of Eq. (74) are

$$\begin{aligned} &\eta = A_\eta e^{-y/a}\cos(kx - \omega t), \\ &u = \eta(g/H)^{1/2}, \quad v = 0, \end{aligned} \tag{75}$$

where A_η is the amplitude for wave variable η, and a is the barotropic Rossby radius of deformation [see Eq. (76)]. The solution shows two important features of coastal trapped Kelvin waves:

1. The amplitude is greatest at the boundary and decreases exponentially away from it, and
2. propagation is with the coast at the right (left) in the Northern (Southern) Hemisphere.

Kelvin waves also occur along the equator where f changes sign, propagating from west to east. Abrupt changes in topography can also support Kelvin waves; in this case, they are called double Kelvin waves because there is motion on both sides of the depth change.

7. INSTABILITIES, EDDIES, AND FRONTS

The kinetic energy of the ocean is dominated by synoptic or mesoscale eddies, rotating about nearly vertical axes and extending throughout the water column. The scale of these eddies is controlled by the baroclinic radius of deformation. Typical scales are 100 km and 100 d with a rotational velocity of about 10 cm/s. Mesoscale eddies are generated by baroclinic and barotropic instabilities.

7.1 Rossby Radius of Deformation

Two fundamentally important frequencies in ocean dynamics are f and N, representing buoyancy and rotational effects. For small-scale motion, buoyancy dominates, while for large-scale motion, the rotational effect is dominant. There must exist a horizontal length scale at which rotation becomes important. This length scale, a, is called the Rossby radius of deformation, and the barotropic mode is given by

$$a = \sqrt{gH}/|f| \tag{76}$$

while the nth baroclinic mode is

$$a_n = \frac{NH/n\pi}{|f|}. \tag{77}$$

If $f = 10^{-4}\ \mathrm{s}^{-1}$ (about 45° N), and $H = 4$ km, then the barotropic Rossby radius $a \simeq 2000$ km. For shallower water on the continental shelf, $H \simeq 40$ m, then $a \simeq 200$ km. The baroclinic Rossby radius is much shorter. The typical value for the first baroclinic mode is 10–30 km, which is a natural scale for the ocean and is often associated with eddies, fronts, and coastal processes.

7.2 Baroclinic Instability

Baroclinic instability originates from the horizontal inhomogeneity of the density field and allows eddies to grow with energy coming from the mean potential energy field. The horizontal density gradient is related to the vertical shear of the geostrophic flow (U_g,V_g) by the *thermal wind* equation:

$$\frac{\partial U_g}{\partial z} = \frac{g}{f\rho}\frac{\partial \rho}{\partial y}, \quad \frac{\partial V_g}{\partial z} = -\frac{g}{f\rho}\frac{\partial \rho}{\partial x}. \tag{78}$$

The existence of vertical shear leads to baroclinic instability and eddy generation. In this instability process, energy is taken from the large-scale potential energy distribution and put into disturbance-scale kinetic and potential energies. Stommel (1965) suggested that the enormous amount of potential energy present in the stratification of the ocean and associated with the mean circulation is a possible source for baroclinic instability.

7.3 Barotropic Instability

Barotropic instability originates from the lateral shear of the flow and is an important mechanism to generate eddies in the tropics. For simplicity, consider a zonal current U that changes with latitude, i.e., $U = U(y)$. If the lateral shear satisfies the condition (Kuo, 1949)

$$\beta - \frac{d^2U}{dy^2} = 0 \tag{79}$$

somewhere in the flow, then the flow U is barotropically unstable. Eddies generated by the shear in the mean flow gain energy from the mean flow kinetic energy.

Within the ocean, eddy generation is the result of a mixture of baroclinic and barotropic instability.

7.4 Mesoscale Eddies

Mesoscale eddies are energetic disturbances of currents and the associated fields of salinity, temperature, and density (Robinson, 1983). More kinetic energy is contained in these features than in any other form of oceanic motion. These eddies are partly organized and yet highly irregular, with spatial scales of 10–100 km and temporal scales of weeks to months. The energy is distributed unevenly in space, with the greatest energy associated with western-boundary currents. Mesoscale eddies provide an important mechanism for the horizontal stirring of the ocean, and for transfers of energy, momentum, and water properties. Numerical model results (Schmitz and Holland, 1986) suggest that these eddies may also drive the recirculation region associated with subtropical gyres. The mesoscale features can also be found from satellite altimetry data. Geostrophic currents are maintained by horizontal pressure gradients and are expressed as sea-surface slopes relative to the level of constant geopotential (the geoid). All mesoscale current systems exhibit high levels of sea-height variability due to meandering, changes in speed or current reversal, vortex shedding, and migration of eddies. For example, western-boundary currents such as Gulf Stream and Kuroshio are characterized by high rms sea-height variability (Plate 3).

An important category of mesoscale eddy is called a *ring*. Rings associated with the Gulf Stream have been well documented (see Plate 2) (Richardson, 1983). These rings appear to form from cut-off Gulf Stream meanders. Two types of rings have been observed, warm-core rings to the north of the Stream and cold-core rings to the south. Cold-core rings are cyclonic, are carried to the west by the Gulf Stream recirculation, and are reabsorbed by the Gulf Stream to the south of Cape Hatteras. A young cold-core ring has rotational velocities of 1.5 m/s and is remarkably similar to a Rankin vortex: Speed increases with distance from the center (a nearly solid rotating core), reaching a maximum near a radius of 30–60 km, and then drops off toward the outer limits of the ring. Ten cold-core rings have been observed at a given time to the south of the Stream.

Warm-core rings are anticyclonic and are formed at a rate of about five per year. They may be reabsorbed by the Gulf Stream, but a few impact the continental shelf/slope where they are the most energetic source of variability on the Slope Water (Joyce, 1991). Rings are also observed in other strong western-boundary currents, most notably the Kuroshio and Agulhas.

7.5 Quasigeostrophic Turbulence

It is possible to extend the concepts of eddies and planetary waves to two-dimensional quasigeostrophic turbulence. Beginning first with an f plane in the absence of friction or forcing, conservation equations for energy E,

$$\frac{\partial E}{\partial t} = 0, \quad E = \int E(k)dk, \tag{80}$$

and for enstrophy Z,

$$\frac{\partial Z}{\partial t} = 0, \quad Z = \int k^2E(k)dk, \tag{81}$$

require an energy transfer to smaller wave numbers and an enstrophy transfer to larger wave numbers. This means that vorticity and eddy fields change with time, with eddies increasing in size and vorticity contours increasing in length. The rate of cascade controls the spectral slope so that for the energy cascading range,

$$E(k < k_0) \sim k^{-3/5}, \qquad (82)$$

and for the enstrophy cascading range,

$$E(k > k_0) \sim k^{-3}. \qquad (83)$$

There is some suggestion that the ocean behaves in this manner, but in numerical models, spectral slope is related to the friction parameterization.

With β, linear Rossby waves will propagate to the west and disperse energy in space, but can also concentrate energy at a specific λ. The transition between turbulence and waves occurs for wave steepness

$$k_\beta = (\beta/2U)^{1/2}, \qquad (84)$$

and energy and enstrophy cascades may be impeded. For a typical midlatitude synoptic motion, $k_\beta \sim 70$ km. This means that eddies in the energy cascade region increase scale to k_β, then propagate as Rossby waves. The waves undergo transition to zonal anisotropy, eventually creating a field of alternating zonal jets with a width scale of $2U_{RMS}/\beta$.

Stratification and topography further modify the behavior of quasigeostrophic turbulence. With stratification, vertical transfers of energy occur through interface vortex stretching and nonlinear modal coupling. Transfer of energy to both smaller and larger scales is possible. The latter occurs through interaction of barotropic and baroclinic wave triads. Barotropic triads involve energy transfer to larger scales only, while for baroclinic triads layers act independently for $k > k_{Rd}$, and energy is transferred to smaller scales for $k < k_{Rd}$, where k_{Rd} is the wave number for the Rossby radius of deformation for the first baroclinic mode.

In general, the effect of topography on two-dimensional turbulence is dependent on the ratio

$$r = \left(\frac{V}{fL}\right)\left(\frac{f}{H}\frac{\partial H}{\partial x}\right)^{-1} \qquad (85)$$

and the amount of energy in each layer. With strong lower-layer flow, cascade occurs until they reach the wavelength of the topography and become locked to f/H.

7.6 Submesoscale Coherent Vortices

Submesoscale coherent vortices are also observed in the ocean (McWilliams, 1985). Lenses of Mediterranean water are observed throughout the Eastern North Atlantic and are readily identified by their water properties and are called *Meddies*. Meddies have diameters of 30–70 km and thicknesses of 0.5–1 km; they are anticyclonic, 15–20 exist at any one time, and they cover about 5% of the area of the Canary Basin. Their core appears to be in solid-body rotation with a period of five days. They appear to erode from their sides and have 2–4-year life-time (Armi *et al.*, 1989). Stratification is minimum in their center, and their motion is primarily through advection by the mean flow. Similar features have been observed in other locations where strong water mass contrasts exist, e.g., the Gulf of California (Bray, 1988).

7.7 Fronts

Fronts are regions with sharp horizontal gradients in temperature, salinity, or density. They occur on a variety of scales: The Antarctic Polar Front circumscribes the Earth at 60° S while in coastal waters fronts associated with internal waves or river plumes may be less than 1 km in length. Fronts may occur in the temperature or salinity field as well as the density field. More generally, fronts are formed by horizontal convergence, by a water-mass boundary, or by coastal upwelling. The Antarctic Polar Front and the Kuroshio/Oyashio Front are regions where intermediate water masses are formed. Surface jets are associated with density fronts.

8. SMALL-SCALE TURBULENCE AND MIXING

Although eddies and quasigeostrophic turbulence serve to stir the ocean horizontally, smaller-scale motions are necessary to connect these scales to scales on which molecular diffusion can act. At the boundaries of the ocean, wind stress and shear provide mechanisms for mixing, while at fronts intrusive features serve to enhance mixing, and within the interior of the ocean, processes associated with internal waves provide energy for mixing. Since turbulence is discussed elsewhere in this Encyclopedia (see TURBULENT FLOWS), we will concentrate on those aspects that are unique to the ocean.

8.1 Instability and Turbulence

There are two major types of instabilities in the ocean relating to the onset of turbulence: static (gravitational) and dynamic. The static stability is given by Eq. (9), so that instability occurs when $E = N^2 < 0$. Dynamic instability usually appears at the interface of two layers moving initially at different velocities. Such an instability is called Kelvin–Helmholtz instability. Two nondimensional numbers, Reynolds number (*Re*) and Richardson number (*Ri*), are used to identify the onset of turbulence in the ocean:

$$Re = LU/\nu, \quad Ri = N^2/U_z, \tag{86}$$

where L, U, and U_z are scales for length, velocity, and vertical gradient of velocity, ν is the kinematic coefficient of molecular viscosity, and N is the buoyancy frequency. If the Reynolds number is greater than some criterion

$$Re > Re_{cr}\,(\sim 10^6), \tag{87a}$$

or if the Richardson number is smaller than some criterion

$$Ri < Ri_{cr}\,(\sim 0.25), \tag{87b}$$

turbulence will occur. These criteria provide useful guidelines for the ocean.

8.2 Generation and Maintenance of Turbulence

The onset of turbulence may occur suddenly through a breakdown of originally nonturbulent flow in certain localized regions. The cause of the breakdown is an instability caused by processes naturally occurring within the ocean, e.g., breaking internal waves, convective overturning, etc. Once turbulence is produced and becomes fully developed in the sense that its statistical properties achieve a steady state, the instability mechanism is no longer required to sustain turbulence. The turbulent kinetic energy (TKE) is converted from the mean flow kinetic energy by the shear production (*S*), and from the potential energy by the buoyancy production (*B*), damped by viscous dissipation (*D*), and transported from or to other regions of flow (*Tr*). This leads to the TKE equation

$$\frac{d(\text{TKE})}{dt} = S + B - D + Tr. \tag{88}$$

Thus, in order to maintain turbulence, one or more generating mechanisms must be active continuously.

8.3 Statistical Characteristics of Turbulence

To describe a turbulent field, it is necessary to know the probability density functions (pdf), which require measurements with sensitive and stable instruments for a sufficiently long period of time and at a fine spatial grid. The problem should become much simpler if the turbulent field could be assumed homogeneous and stationary. In such a case, the turbulent field can be depicted by its spectral density function, $E(k)$, which is generally in power-law form:

$$E(k) \simeq k^{-n}, \tag{89}$$

where k is the wave number. Laboratory results indicate that the exponent n equals 5/3 for the inertial–convective range, and equals 1 in the convective–diffusive range. Oceanic spectra of velocity and temperature appear to behave in this manner.

8.4 Double Diffusion

The ocean generally has a multilayer structure, caused by the stratification of two different components: heat and salt. The rate of molecular diffusion of heat is about 100 times that for salt. Consider a layer of warmer, saltier water above cooler, fresher water, such that the upper layer has the same density as or less density than the lower layer. Then, the saltier water at the interface will lose heat much faster than it will lose salt. If the density difference between the layers is small, the saltier water above may become heavier than the cooler, fresher water below, sink into the lower layer, and form tall thin convective cells, called "fingers." In these cells, descending branches of water diffuse heat horizontally more rapidly than salinity and, therefore, become heavier than surrounding water and continue to sink. A similar mechanism occurs in the rising branch. This process is called double-diffusive convection. The density ratio,

$$R_p = \alpha \Delta T / \tilde{\beta} \Delta S, \qquad (90)$$

is a controlling parameter in the growth rates of salt fingers and the resulting fluxes of heat and salt. The terms ΔT and ΔS are the temperature and salinity jumps between the two layers. There exists a criterion R_{pcr} such that if

$$R_p \leq R_{pcr},$$

double-diffusion takes place. Here R_{pcr} ranges from 1.2 to 2.2. In the laboratory, salt fingers have lengths of 20–30 cm with a spacing between fingers of about 1 cm and a temperature difference of 0.1 °C. In the ocean, this produces a "staircase" structure in temperature, salinity, and density where the steps are meters thick.

Although the occurrence of double diffusion is related to R_{pcr}, the rate of double diffusion has not been parametrized in terms of large-scale oceanic fields. The mass flux associated with double diffusion is downward so that it does not help to maintain the thermocline.

8.5 Microstructure

Bounds for mixing processes can be inferred from large-scale distributions. For example, a vertical advective–diffusive model of the ocean interior,

$$K_v \frac{d^2T}{dz^2} - w \frac{dT}{dz} = 0, \qquad (91)$$

governs the vertical distribution of temperature so that for the vertical velocity $w \simeq 4$ m/yr, the vertical mixing coefficient $K_v = 10^{-4}$ m^2/s provides a bound for other estimates of vertical mixing. The term K_v can be estimated from sufficient measurements of temperature microstructure from free-fall probes. In regions with no lateral gradients, we find

$$K_v = \mu k C, \qquad (92)$$

where the Cox number $C = \overline{(\partial T'/\partial z)}^2 (\partial \bar{T}/\partial z)^2$, and the multiplier μ takes a value between 1 and 3 depending upon layering or isotropy at small scales (Garrett, 1979). Measurements yield $K_v \simeq 10^{-6}$ m^2/s, implying that mixing takes place either at boundaries or water-mass formation regions but at rates that do not seem sustainable. Internal waves or internal tides or biological activity may provide sufficient energy for the missing mixing energy. In general, vertical mixing appears to be inversely proportional to N.

9. CONCLUDING REMARKS

In this review, there were a number of important areas that are normally considered within the purview of physical oceanography that we were unable to describe. These include coastal (Huyer, 1990) and estuarine (Officer, 1976) circulation, sea ice (*q.v.*) and related processes, internal waves, and electromagnetics and associated measurements (Sanford, 1971). The latter may be increasingly important as abandoned submarine cables are provided for research use.

Oceanographers are currently engaged in a number of important programs to understand ocean circulation better. Global surveys using carefully calibrated CTDs and water samplers for collection of nutrient, tritium, radiocarbon, and Freon are underway. These data, with *Topex/Poseidon* altimetric measurements, will provide a better description of thermohaline circulation and poleward transport of heat. They will also serve to constrain numerical ocean circulation models, which in turn can be used to study physical processes and design future experiments. In the Tropical Pacific, moored buoys are providing real-time oceanographic data via satellite, better to understand and predict *El Niño*. Modern supercomputers allow the coupling of global ocean and atmosphere models and hence a better understanding of climate. These computers also allow ocean models to be used for forecasts, which can be substantially improved through better ocean data assimilation techniques.

The ocean dominates the surface of the Earth. It has tremendous capacity for heat, carbon dioxide, and organic waste as well as biological productivity. We need to be able to use this resource in a balanced, ecologically sound manner without inducing anthropogenic change. Toward this end, we need a global ocean-observing system that will allow a continuous quantitative assessment of the state of the ocean.

Ching-Sang Chiu provided valuable comments on Sec. 1.3, and Stevens Tucker assisted with Sec. 1.4. Albert Semtner and Carl Wunsch graciously provided Plates 1 and 3, respectively, and Paul Jessen constructed Figures 1 and 2.

GLOSSARY

Baroclinic: The state of the ocean in which surfaces of constant pressure (isobars) intersect surfaces of constant density (isopycnals).

Baroclinic Instability: A hydrodynamic instability arising from a baroclinic flow and vertical shear, allowing eddies to grow with energy coming from the mean potential energy field.

Barotropic: The state of the ocean in which surfaces of constant pressure (isobars) coincide with surfaces of constant density (isopycnals).

Barotropic Instability: A hydrodynamic instability arising from lateral shear in a current, which allows eddies to grow with energy coming from the mean flow kinetic energy.

Ekman Layer, Ekman Transport, and Ekman Pumping: The Ekman layer is the oceanic planetary boundary layer (typically 100 m thick) through which the stresses exerted on the water surface are transmitted into the ocean. For steady wind stress in the open ocean, the surface wind stress is balanced by the Coriolis force. The Ekman transport is the vertically integrated Ekman-layer currents, and is to the right (left) of the wind in the Northern (Southern) Hemisphere and depends only on the magnitude of the wind stress and the latitude. Ekman pumping is the vertical motion in the Ekman layer forced by convergence and divergence of the surface flow, associated with spatial variability of wind stress.

Convection: Vertical motion caused by dense water lying over lighter water.

CTD: An instrument to measure vertical profiles of conductivity and temperature vs depth (pressure).

Double Diffusion: Convection caused by different diffusion coefficients for heat and salt.

Geostrophic Flow: Flow due to the balance between Coriolis and pressure-gradient forces.

Mesoscale Eddies: Horizontal vortices whose size is controlled by the Rossby radius of deformation, e.g., 10–100 km.

Nutrients: Nonconservative chemicals (phosphate, silicate, nitrate) that identify water properties and are used to trace flow patterns.

Ocean Acoustic Tomography: A technique for determining ocean density and velocity structure by measuring the arrivals of specific acoustic rays.

Potential Density, and Potential Temperature: The density and temperature a water parcel would attain if raised (or lowered) adiabatically to the surface or other specified reference pressure.

Quasigeostrophic Flow: For large-scale motion, departure from geostrophic balance is small. Such flow is called quasigeostrophic flow.

Stratification: The vertical structure of the ocean.

Subduction: Newly stratified water leaving the ocean-surface mixed layer to enter deeper layers.

Subtropical Gyre: A basin-scale subtropical anticyclone.

Sverdrup Transport: The wind-driven meridional transport in the ocean interior. It includes both the Ekman transport and the geostrophic transport caused by Ekman pumping.

Thermohaline Circulation: The flow field associated with the sinking of dense water at high latitudes, its subsequent equatorward flow in deep western-boundary currents, and finally deep flow into the ocean interior and upwelling.

T-S Diagram: A characteristic diagram used to study water properties and to identify water masses and water types.

Ventilation: Any process that brings deep water to the surface so that it exchanges heat, momentum, and gases with the atmosphere.

Western-Boundary Intensification: The appearance of strong currents (e.g., the Gulf Stream and the Kuroshio) along the western boundaries of the oceans, as contrasted to weak currents in the interior and at the eastern boundary. This large-scale east–west asymmetry of the ocean circulation is called western-boundary intensification.

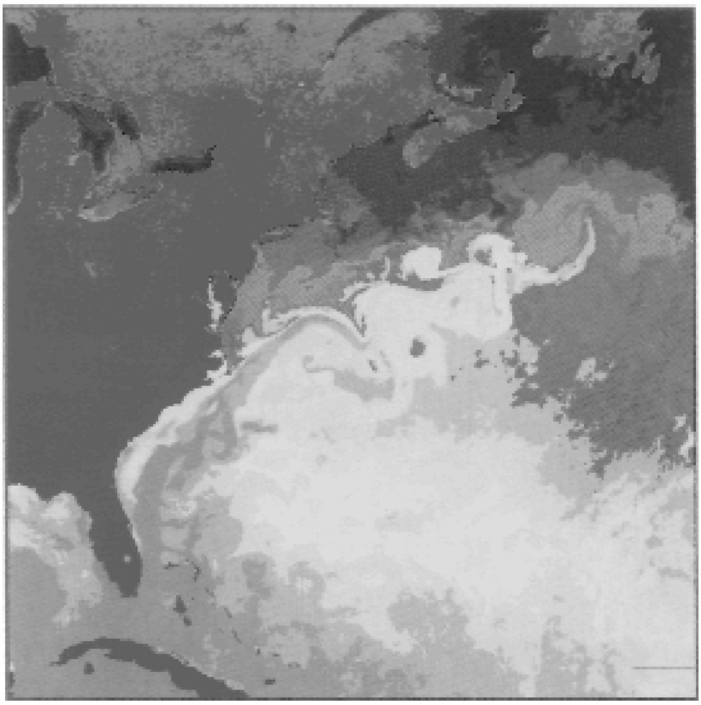
Vol. 12 – PLATE 1. Dynamic topography of an ocean model sea surface. Results were obtained from a global eddy-resolving ocean model. Units are centimeters. (Courtesy A. Semtner.)



Vol. 12 – PLATE 2. Composite Advanced Very High Resolution Radiometer (AVHRR) image of the Western North Atlantic during April 1984. The image was produced by compositing data from 35 satellite passes obtained during the first week in April; this was necessary to remove clouds. The image is printed with an artificial color scale; Reds and oranges are warm, 24°–28° C; yellows and greens 17°–23° C; blues 10°–16° C; and purples are cold, 2°–9° C. The Gulf Stream appears as a band of warm water, originating in the Florida Straits, separating from North America at Cape Hatteras, and thence flowing west in the North Atlantic, developing meanders. Two cold-core rings appear to be almost pinched off from the Stream to the south of the southern tip of Nova Scotia. (Courtesy NASA.)

INTRODUCTION

Oil shale and tar sand are relatively recent terms for rocks containing hydrocarbon materials that are of marginal economic interest to present society but have been used for centuries. Interest in oil shales and tar sands (OS&TS) has declined over the last decade, repeating historic cycles related to oil prices and the prognosis for petroleum supplies. The profile of OS&TS use since prehistoric time reflects widespread availability and relative ease of extraction of useful products from these resources by primitive technologies. Large-scale production of liquid fuel from OS&TS using modern technologies, however, has not generally been competitive with modern petroleum operations. The history of

small-scale operations exploiting these ubiquitous solid hydrocarbons, including asphaltites and lake asphalt, to produce a variety of products has been more stable. The components of the hydrocarbon spectrum, whether progressing from oil shale to petroleum to tar sands or from peat to coals, are formed and transformed under a great variety of conditions from diverse materials. As a result, the hydrocarbon resources found today have an enormous variety of physical properties and compositions. The terminology that has evolved for these resources is inconsistent. Labels, from ancient use of the word "asphalt" to the modern misnomers, oil shale and tar sand, are usually related to first use, discoverer, or location of first discovery rather than to composition. Historically, the efficiency of OS&TS extraction technologies has continually improved, whereas use of these substances has reflected cycles in markets and world economics. Just as OS&TS became important resources when wood and whale oil became scarce, they may become crucial resources as petroleum becomes harder to find and recover. OS&TS are comparable to other natural resources in that the occupational health, environmental, and legal issues associated with their extraction and use are receiving more attention as the world's growing population becomes more sensitive to global health and environmental issues and organizes to deal with them.

1. ORIGIN, PROPERTIES, AND CHARACTERISTICS

OS&TS are important components of the spectrum of hydrocarbon resources found at or near the Earth's surface. Modern geology has established with certainty that these ubiquitous resources are part of a continuum of organic materials and the conversion products thereof present in the Earth's crust. This spectrum of sometimes valuable materials graduates from just-fallen plant, animal, and marine life, to rocks containing the petroleum precursor kerogen, to petroleum (natural bitumens, oil, and natural gas), and on to petroleum degradation products resulting from the varying degrees of geologic processing to which the original buried organic materials were subjected. The resultant resources grade from one to another with great variety depending upon how the important parameters of depositional condition, pressure, temperature, and geochemistry changed over time. This continuum, as currently understood by geologists, is depicted in Fig. 1 with annotations of theoretical estimates of the order of magnitude of kerogen or equivalent energy value present in each of the important hydrocarbon forms (Durand, 1980, p. 29).

1.1 Origin and General Characteristics

Most deposited organic material is initially converted to the solid hydrocarbon called kerogen by diagenesis as the combination of descending mineral and organic materials is transformed into sedimentary rock. A minor portion is converted directly to natural bitumen. Rocks containing significant quantities of kerogen are called oil shales. In addition to being insoluble in most solvents, kerogen does not melt upon heating but is converted to vapors, some of which can be condensed to oil.

Kerogen is widely recognized as the precursor of petroleum. If, however, the host rock is not subsequently subjected to the geologic pressures and temperatures required to convert the kerogen to oil and gas, the oil shale (and coal) remains for man to find and exploit for its hydrocarbon content. All sedimentary rocks laid down since life began on Earth contain some kerogen. In most of the great depositional basins, the processes of deposition, burial, and geologic change continued to the point that some kerogen underwent catagenesis, and great quantities of petroleum were produced. In many cases, the petroleum migrated to the traps that are today's oil and natural gas reservoirs. As petroleum migrated, some of the liquids saturated porous or unconsolidated formations, or filled joints or voids; there the petroleum underwent thermal or biological degradation. The lighter fractions evaporated, leaving the heavy fractions to cool and with their new host material to form a reservoir with zero mobility. These reservoirs that do not produce petroleum by conventional primary methods are now called tar sands.

Most hydrocarbon materials that fit the definition of tar sands are natural asphalts,

which are soluble, melt on heating, vaporize at higher temperatures, and can be cooked out of their host materials in boiling water. In a few cases, nearly pure petroleum moved into joints in adjacent rock and degraded into highly paraffinic material called mineral wax. In other isolated cases, petroleum carrying fine sediment escaped into joints in adjacent rock beds and was converted into solid hydrocarbons called asphaltites. At a few famous locations, such as Pitch Lake on Trinidad Island, a substantial amount of petroleum carrying fine sediment found its way to the surface, where it ponded and cooled to form asphalt lakes. At a few locations, such as New Brunswick, Canada, geologic conditions were such that *insoluble* natural bitumens formed, usually in veins or in voids in rock. These solid hydrocarbons have characteristics much like the kerogen in oil shale or coal and are called pyrobitumens.

As geologists, geophysicists, and geochemists better recognized the differences between kerogen as a precursor of petroleum and the products of petroleum degradation, the latter became known as "asphalts and allied substances." As the term asphalt came to be used for products manufactured from petroleum, the natural products became known as "natural asphalts and related substances." The modern term "tar sands" initially referred to deposits such as those in Canada and Venezuela that are mixtures of natural asphalt and sand, but the definition of tar sands evolved to recognize all host mineral matrices and to rely on viscosity to differentiate tar sands from heavy oil. Whether intended or not, the resultant definition includes all of the solid products of natural petroleum degradation, as well as the natural bitumens left behind in petroleum source rock, petroleum migration paths, and petroleum reservoirs. Tar sands are so delineated in Fig. 1.

In most cases, petroleum lost its mobility by degradation or metamorphosis after moving up along faults and layers of porous materials from where it was formed. Both oil shales and tar sand, therefore, are generally found at shallower depths than petroleum.

Resources cannot be classified as oil shale solely on the basis of composition because oil shale is an economic term. Although frequently misused as a lithologic term, oil shale means only that the rock is of interest for the production of oil. No minimum yield is specified, nor should one be. For instance, in China lean shale of 20 L/t has been processed for oil for 70 years because it had to be removed to reach the coal below it. At the rich end of the spectrum, there has been a 150-year controversy about what is coal and what is shale or pyrobitumen. To avoid this controversy, Fig. 1 includes only kerogenous rocks that are good sources of oil as oil shale. Humic coals have hydrogen-to-carbon atomic ratios of less than unity and were not considered good sources of oil using the simple pyrolysis practiced when the term oil shale came into use. The sapropelites, which can be lithologically shale or coal depending on the amount of mineral matter they contain, have hydrogen-to-carbon atomic ratios greater than unity and are excellent sources of oil using simple pyrolysis. The Australian and European oil industries were initiated on sapropelites and considered them the feedstock of choice. The early North American oil industry preferred the famous pyrobitumens from New Brunswick, albertite and sterralite, as feedstock but quickly turned to using sapropelites as pyrobitumen resources were exhausted (Ramsay, 1910).

1.2 Relevant Theories Regarding the Origin of Hydrocarbons

Theories about the origin of hydrocarbons are important for predicting their future availability and finding additional resources. Historically, petroleum and asphalt were believed to be primordial materials of the Earth that rose from its bowels through fissures in the crust for man to find and use. However poorly founded on knowledge, this was an abiogenic theory for the origin of hydrocarbons. As it became necessary to find and develop oil reservoirs systematically, petroleum geologists associated petroleum with organic materials deposited in sedimentary basins, and the biogenic theory of the origin of petroleum became dominant. In recent decades, as space exploration has provided new insights into the existence of hydrocarbons in the universe, the possibility of at least an abiogenic contribution to the availability of hydrocarbons in the Earth's crust is gaining credibility. A deep biogenic gas theory suggests that organic material falling to the ocean floor is pushed under the continental plates at subduction zones and is ultimately converted to methane or hydrogen-rich thermogenic gas.

The combination of these theories suggests that descending sedimentary materials *may be* enriched with hydrogen by ambient gas rising in the crust of the Earth. The nature of the sediment falling with the organic material and the geochemistry of the sedimentary basin will determine the type of rock formed with the kerogen. The role of hydrogen enrichment in the conversion of organic material to kerogen and the subsequent conversion of kerogen to petroleum is uncertain. Many petroleum geochemists now believe that water plays an important role in petroleum formation. When kerogen is converted to petroleum at greater depths, escaping gases may enrich younger layers of sediment; therefore hydrogen enrichment does not depend on deep gas or an abiogenic source of hydrogen or hydrocarbons.

1.3 Specific Characteristics and Properties

The specific characteristics and properties of OS&TS are important for planning extraction techniques and predicting economics. Table 1 is a summary of mineral content of the three geologic types of oil shale present in the world's largest known deposits. Some physical characteristics and properties of these shales are presented in Table 2. The properties of tar sands vary with those of the host rock and the impregnating hydrocarbon. Table 3 presents a summary of the known important properties of the tar sands in three of the world's largest deposits. The properties presented in these tables are only representative of the world's OS&TS; each deposit is unique, and the characteristics and properties of each must be determined to plan extraction. Characteristics and properties also vary by location and horizon within the deposit.

2. RESOURCES

The kerogen in sedimentary rocks is converted to petroleum as depositional basins mature, and petroleum degrades into tar sands as basins become overmature. OS&TS deposits are therefore best understood when the depositional basin in which they were formed is viewed as a whole.

2.1 Major Deposits

The geography and geology of six of the great depositional basins of the world are discussed below with a brief description of the OS&TS deposits found in them. These descriptions should be viewed as important data points in the Earth's crust and its history that illustrate the great variety and broad distribution of OS&TS. The quantity of kerogen in oil shales and asphalt in tar sands in just these six basins is sufficient to serve man for many centuries.

2.1.1 Western Canada Basin The Western Canada Basin (Meyer, 1987, p. 6) covers 770 000 km^2 in Alberta; tar sands deposits cover 31 000 km^2. Hydrocarbon deposits are found in this basin in the entire range of sedimentary rocks from Devonian to late Cretaceous. The depth and thermal maturity of

the basin are greatest along its southwest edge, next to the Rocky Mountain uplift. Numerous oil and gas reservoirs have been delineated throughout the basin. The world's greatest deposits of tar sands are found in the shallow northeast portion of the basin. One of the geologic mysteries of this basin is that the combined volume of oil (1.35×10^{11} barrels) in the four largest tar sands deposits (Athabasca, Cold Lake, Wabasca, and Peace River) and the numerous oil reservoirs in the basin cannot be explained by the volume of source rock present. The asphalt of these tar sands deposits is biodegraded and is most logically explained as the residue of once-mobile petroleum that saturated the extensive deposits of unconsolidated sand on the northeast boundary of the basin. Current reservoir temperatures in the tar sands deposits are 13–21 °C. At these temperatures the hydrocarbon residue is not mobile. Considerable tar sands in this area are exposed or have limited overburden; therefore, they are suitable for large scale surface mining.

2.1.2 Eastern Venezuela Basin The Eastern Venezuela Basin (Meyer, 1987, p. 6) covers 155 000 km^2 and contains the largest combined accumulation of oil, heavy oil, and tar sands in the world. The tar sands deposits cover 41 000 km^2. The basin extends north from the Orinoco River to off-shore beyond the north coast of South America and off-shore to the east to include Trinidad. As in the Western Canadian Basin, most of the tar sands have accumulated in the shallow part of the

[a] The Aldan Arch Region in Russia has only recently been recognized as surpassing in magnitude the tar sands resources of the Melekess Basin, thereby becoming the third largest source of tar sands in the world. The solid hydrocarbons of the Aldan Arch Region are distributed in nine zones and have highly variable properties.

basin, in this case the southern boundary area, formerly called the Orinoco Tar Belt. Some of the material, normally defined as tar sands with API gravities less than 10° at normal temperatures, can be exploited by primary methods because reservoir temperatures in the basin range from 38 to 85 °C. The name of the area has been officially changed to Orinoco Heavy Oil Belt to reflect the presence of some oil that can be produced by primary methods.

Two famous lake asphalt deposits, Trinidad's Pitch Lake and Bermudez Pitch Lake near Guanoco, Venezuela, punctuate the northeast corner of the Eastern Venezuela Basin. These unusual occurrences result from very sediment-laden, heavy, warm oil flowing up along faults in this area to the surface.

2.1.3 Aldan Arch (Russia) The Aldan Arch (Meyer, 1987, p. 77) is a large uplift in Russia's Siberian Platform. This single structure with 1 300 000 km^2 underlain by asphalt rocks and asphaltite deposits will probably prove to be at least the third largest tar sands deposit in the world. The origin of the collection of tar sands in this relatively undeveloped area is more easily explained than is the origin of the Alberta tar sands. The Siberian Platform accumulated 9000 m of sedimentary rock from Riphean time (925×10^6 years ago) to Ordovician time. Considerable oil had formed in this great mass of sediment when magma moved under the area, creating the Aldan uplift. Heat from that intrusion drove the volatiles from large oil deposits that had moved into porous formations or the voids and joints created as the area was disturbed, leaving behind extensive asphaltites and other tar sands.

2.1.4 Green River Formation (U.S.A.) The Green River Formation (Russell, 1990, p. 85) of the Rocky Mountain Region of the United States is the largest and richest resource known on Earth. The term resource is used to describe this complex geologic formation instead of OS&TS deposit because of the unique collection of minerals that are commingled with the kerogen. The formation contains enough kerogen to produce 2×10^{12} barrels of oil, but the formation is also a remarkable collection of massive quantities of unique saline minerals that exist only in minute quantities elsewhere in the world. The formation covers 41 000 km^2 and is up to 2200 m deep.

The genesis of this anomaly was a large, inland stratified body of water that remained remarkably stable for 10^7 years from 60 to 50 Ma ago during the Tertiary Period. With no outlet, the water became very salty at depth but supported verdant algae blooms. These blooms produced the large volume of organic matter that became kerogen as 10 Ma of sediment piled up. The water existed for most of the period in two lakes: Lake Uinta in what is now northwest Colorado and northeast Utah, and Lake Gosuite in what is now southwest Wyoming. These lakes gradually diminished in size and became localized into six basins; clockwise around the Uinta Mountains the basins are the Green River, Great Divide, Washakie, Sand Wash, Piceance Creek, and Uinta. Each basin received slightly different runoff and developed different geochemistry.

The Piceance Creek Basin supported the most consistent growth of algae and was warmer and deeper than the other basins; consequently, surface effects did little to disturb normal stratification of the water. The deep center of the lake became a giant chemical system producing massive quantities of the saline minerals nahcolite, dawsonite, and sodium chloride in what is known as the salt cap area. The production and deposition of algae produced an amazingly uniform 640 m of oil shale. Natural gas has been found in and under the oil shale horizons of the Piceance Basin.

The Uinta Basin was not as deep, and algae growth was not as great as in the Piceance Basin. As a result, oil shale in the Uinta Basin is not as rich, except for the Mahogany Zone of rich shale that pervades the entire Green River Formation. An earlier sediment basin near the Uinta Mountains was buried and heated sufficiently to produce the Cedar Rim and Blue Bell oil fields of the Altamont Trend. This earlier basin was also the likely source of the petroleum that migrated upward and formed the tar sands of Asphalt Ridge; the famous vein asphaltite, gilsonite; the pyrobitumen, wurtzilite; and the mineral wax, ozocerite, in and near the Uinta Basin.

Algae growth in the more northern basins was not as great nor as persistent; thus, these basins have only layers of rich oil shale. In the Green River Basin, varying periods of the unique geochemistry laid down layers of trona (a hydrous acid sodium carbonate) of sufficient thickness to be mined adjacent to the richest oil shale horizons. The entire Green River Formation was subsequently lifted in the mountain-building process, and the great quantities of oil shale remain as originally formed.

2.1.5 Great Appalachian Basin (U.S.A.) When the North American continent was still connected to a great land mass to the east during middle Devonian time, great rivers fed the giant inland Chattanooga Sea, which stretched from the present Appalachian Mountains to the center of the Great Plains. Organic growth in the inland sea was sufficient to produce some rich oil shale and enormous quantities of lean oil shale over a wide area. Variations in river flows produced clastic intrusions from the east, and subsequent glaciers and erosion buried or carved away great parts of the oil shale. Earlier depositions produced oil and gas under parts of the shale, but the Devonian/Mississippian/Pennsylvanian shales were never buried deep enough or otherwise matured to convert the kerogen in them to petroleum. Collectively, what remains of these shales has been estimated to contain sufficient kerogen to produce 2.6×10^{12} barrels of oil. Scattered sapropelic and tar sands deposits, including some asphaltite veins, dot the large basin. The shales range over 650 000 km^2 and vary in depth from a few meters to 250 m. Overburden varies from zero at outcroppings to hundreds of meters of glacial till. Much of the area has a limestone cap over the oil shale. Even the richest shales in this complex basin have a serious deficiency of hydrogen and leave considerable carbon when pyrolyzed to produce oil (Russell, 1990, p. 85).

2.1.6 Baltic Basin (Europe) The Baltic Basin (Russell, 1990, p. 487) contains the most-used oil shale deposit of this century. The basin contains two oil shale seams. The rich middle Ordovician carbonate or kukersite provides the feedstock for the Estonian oil shale industry. The lower Ordovician Dictyonema shale contains phosphorite but has not been exploited. The kukersite extends over just 5200 km^2 in the area between the Gulf of Finland and Lake Peipus in Estonia and extends east in Rûssia. Overburden varies from zero at the outcrop near the Baltic Sea to 250 m at the southern limits of the shale of commercial interest. Mining is beset by problems with groundwater and weakened areas that must be left as pillars during underground mining. Numerous conflicting estimates of the amount of kerogen in the basin suggest the potential to produce 0.6×10^{12} barrels of oil.

2.2 Historically Significant Resources

The above discussion of six of the world's giant OS&TS deposits confirms the enormous magnitude of these resources in the Earth's crust. Several smaller deposits have had unique roles in the history of use of OS&TS and are noted to illustrate the broad distribution and historical importance of even small resources. The known history of native asphalt begins with hydrocarbon-saturated soil that became known as the slime pits of Hetite in ancient Babylon, and nearly pure asphalt fished out of the Dead Sea (Abraham, 1960, p. 9). Native asphalt oozed into the Dead Sea, solidified, and broke off to rise to the surface of the water in chunks the size of horses. This source was economically valuable in its time; authorities are reported to have issued permits to fish for asphalt in the tepid water of the Dead Sea. These sources and numerous other seeps in the Middle East provided the material for the applications identified in ancient Egypt and Mesopotamia dating from before 5000 B.C. (Abraham, 1960, p. 23).

Oil shale has an even longer history of use. Bracelets of French Autun oil shale found on skeletons of Neolithic man of the late stone age may have been used to repel insects (Russell, 1990, p. 545). The first confirmed production of shale oil has been traced by its name, "Giant's Blood," to a legend that dates to 800 A.D. and the Seefeld oil shale of Austria (Russell, 1990, p. 532). Oil from this shale high in the Austrian Alps near Tyrol gained fame for the treatment of skin diseases and ultimately became the only authentic source of Ichthyol (Blade, 1938). A modern sulfonated version of this medication is still produced at outcroppings of the Seefeld oil shale in Austria and Italy.

The first recorded European use of hydrocarbons in the New World was the caulking of ships at Lake Trinidad during Columbus' third voyage (Abraham, 1960, p. 41). Although discovered first by Europeans, this sticky lake asphalt proved too difficult to haul back to Europe, and so a harder hydrocarbon deposit near Havana, Cuba, became the primary source of exports to Europe for the next century. Europe had numerous small tar sand deposits, and many, such as Seyssel, were worked to exhaustion as the demand for asphalt grew. The Seyssel tar sand deposit in France's Rhone Valley was discovered in 1735. Production there led to the discovery of modern road paving, as pieces of asphalt that fell off the wagons were compacted by subsequent traffic. Seyssel became the most important source of asphalt in Europe until it was exhausted. The asphalt rocks of Ragusa, Sicily, are reported to have been mined sporadically since Roman time. The Wietzer tar sand deposit in Germany was the scene of J. Taube's 1769 development of the hot-water process of extraction and distillation of asphalt that is the basis of modern commercial production of oil from tar sands (Abraham, 1960, p. 45).

The Scottish oil shale deposits near the Firth of Forth are the most famous as sources of oil. Although devoid of any advantage for mass production, these resources supported the Scottish industry for its entire 103 years of competition with the American petroleum industry. The deposits are actually nine thin seams of shale buried in 900 m of calciferous sandstone at the base of a carboniferous system of rocks (Sneddon, 1938, p. 54). The entire system is highly folded and steeply dipping. The shales are lenticular deposits cut by severe faults and subject to flooding by groundwater. The yield varied from 450 L/t initially to as low as 60 L/t—not likely candidates for a role in history.

The best-known oil shale of the 19th century was the rich torbanite of New South Wales, Australia. At the peak of the gas-lighting era, it was discovered that the addition of just 5% of this ultrarich (up to 900 L/t) shale to coal increased the luminosity of the resulting gas by a factor of 6 (Carne, 1903, p. 97). Demand for this unique shale pushed the industry for its production into the wilderness of New South Wales. Pieces of shale left in river valleys by floods were traced upstream to outcroppings in the Sydney Permian Basin. Individual deposits were thin seams of ox-bow shape exposed by the intense erosion of the area. Exposures usually occurred at the top of long talus slopes topped by sheer sandstone cliffs. The shale seams were under intense pressure from extensive overburden but could be mined easily by hand methods because the pressure caused the shale to splinter when struck with a pick. The industry moved to ever more remote areas, solving onerous materials handling problems, as the small deposits were exhausted and new ones discovered. Ultimately, the industry spawned its own railroad to the port at Sydney, where daily boat loads of raw shale were shipped to the gas light systems of the world. The seconds, or leaner shale (less than 300 L/t), were discarded at the mine mouth or processed in local plants for oil, wax, and other products.

The fame of the Australian torbanites led to testing of North American sapropelic rocks of similar appearance as a substitute for the imported product. The spread of agriculture led to discovery of numerous small deposits of cannel and boghead materials in the eastern United States and Canada that were initially identified as coal. Even albertite and stellarite were mistakenly identified by the courts as coal (Gesner, 1865, p. 49). North American sapropelic rocks, whether subsequently proven to be coal or shale, and pyrobitumens became the feedstock of choice for the American pyrolysis industry that blossomed in 1855 and that ended quickly with large-scale production of petroleum in 1859.

2.3 Summary of World Resources

Any tabulation of world OS&TS must recognize that these resources have been neglected for the last hundred or so years during which petroleum has dominated the supply of hydrocarbons worldwide. Except in the most recent two decades, when various oil crises generated interest in OS&TS, these solid hydrocarbons received little attention by the world's major hydrocarbon producers, who were in the position to define and explore them. Even recent interest has been limited to the giant deposits that could produce enough oil to replace petroleum. Most discoveries of deposits and extension of data about known deposits have been anecdotal to the search for petroleum. Generally, the more thoroughly a depositional basin is explored the more OS&TS are found. Thus in the 20 years between 1964, when Ball (1965) did a comprehensive survey of tar sand resources in the United States, and 1983, when Lewin and Associates, Inc. (1983) completed a similar survey, U.S. tar sand resources grew almost tenfold from 5.5×10^9 barrels to 54×10^9 barrels. This suggests that largely unexplored developing countries and undeveloped frontier areas such as arctic Alaska, Canada, and Russia, where some oil has been found, may have enormous undiscovered OS&TS resources. Table 4 presents estimates of the order of magnitude of oil in total resources of OS&TS.

3. PRODUCTION

As depicted in Fig. 1, oil shales, petroleum, and tar sands form a spectrum of hydrocarbon resources. Man has used various forms of these natural resources for centuries as fuels, lubricants, paving, building and manufacturing materials, cosmetics, and medicine. Archaeologists and historians have traced the use of petroleum, natural asphalt, and asphalt rocks to the earliest civilizations in the Middle East prior to 5000 B.C. Archaeologists have also found evidence of centuries of use of natural hydrocarbons by Chinese, Japanese, and aboriginal Americans of both continents. As the demand for hydrocarbons reached massive quantities during the industrial age, petroleum, which is the easiest form to extract and transport, became the dominant resource used and the use of OS&TS declined.

Table 4. Ultimate recoverable OS&TS resources.

Total	17,000	4,000

Sources: Preparation of this summary of OS&TS resources revealed numerous conflicts in data regarding these resources. The oil shale amounts are from Duncan (1965) for just the richest (over 104 L/t) shale, and the tar sands amounts are from Meyer (1987). The totals exceed the amounts derived by Durand (1980) of 3.7×10^{12} barrels for oil shale and 2.2×10^{12} barrels for tar sands. Duncan's total for oil shales yielding over 21 L/t is 2.092×10^{15} barrels.

3.1 Historical Production

Cycles of use of OS&TS predate their competition with petroleum. The ancient uses of asphalt in the Middle East faded as Roman building technology using cement became dominant. Subsequently, the growth of cities fostered the broad use of charcoal as fuel, and societies remote from petroleum sources learned about liquid hydrocarbons as a byproduct of charcoal production. A demand for liquid products, initially easily met with byproducts of charcoal, had been created, and when the forests were used up in populated areas, the availability of fuel of any type became a daily problem. Artificial tar sands, prepared by saturating earth with petroleum or other liquid hydrocarbons, were burned as a substitute for charcoal. Various patented or manufactured solid fuels using hydrocarbon binders became items of commerce. In 1838, builders, especially of railroads, rediscovered the advantages of pickling wood with liquid hydrocarbons. Coupled with the growing demand for liquid fuel for lighting, the resultant demand for liquid hydrocarbons became overwhelming. Prices for whale oil in the United States rose to \$16/L by 1846.

The oil shortage of 1838 triggered the first modern effort to perfect mass production of oil from solid hydrocarbons. Much was already known from the gas-lighting industry, which had started to produce gas from coal, other solid hydrocarbons including oil shales, and various organic materials by pyrolysis during the late 18th century. Petroleum was not unknown at the time, but its transportation problems had not been solved. As early man used more hydrocarbons, he found a more widespread and certain source in mining and cooking oil from rocks than in traveling great distances to skim oil from water wells, ponds, springs, and streams or primitive oil wells. Considering the primitive nature of transportation at the time, this was probably the correct economic choice. Even so, where liquid hydrocarbons could be found close to the Earth's surface, this relatively convenient resource was exploited. For instance, in 1838 there were at least 82 crude wells near Baku and 3500 pits for the production of oil on an island in the Caspian Sea. Marco Polo had described exporting oil from this area by animal train in 1298. Muspratt (1860, Vol. 1) also reported 520 oil wells operating in Burma exporting 400 000 hogsheads [$(0.6–1.4)\times10^6$ barrels) of oil per year prior to 1859.

It is a staggering paradox, therefore, that the petroleum industry waited until 1859 to explode onto the world from North America. This paradox did give rise to a short but flourishing and relatively modern oil shale industry. After a jump start from this short market pull and subsequent government protection from the predatory marketing practices of the U.S. petroleum industry, oil shale plants operated in Scotland, France, Spain, Estonia, Sweden, Germany, Brazil, and Australia. Some plants survived for many years in competition with the petroleum industry. In North America, there would be no such longevity. The initial oil shale plants of 1855 in Boston and New York, which operated on imported torbanites and pyrobitumens, and the Breckenridge, Kentucky, plant, which used cannel coal as feedstock, quickly grew to over 55 plants in the eastern United States by 1859. The largest was a 25 000-L/d plant near Pittsburgh. All were shut down or converted to oil refineries as large-scale petroleum production started in Pennsylvania in 1859.

Tar sands were well known in the 1830s, but this sticky material that caked so easily was hard to work with for the production of oil or fuel. Concerning this period, Muspratt (1860) reported what he considered many impractical attempts to use native asphalt in applications for which it was not suited. Natural asphalts, which appeared to have found their broadest use in early civilizations, made a dramatic comeback as road-paving material during the late 19th century. As the demand for paved roads spread across North America, dozens of local tar sands deposits were mined to supply paving material. The Kyrock Mine in Kentucky was a typical operation that shipped asphalt rock by river barge and rail to pave hundreds of miles of roads in midwest America. Two such mines still operate in Uvalde, Texas, supplying paving material to a distance of 175 km from the mines. Paving was the dominant use of tar sands for 50 years from 1870 to 1920. Production of paving material reached 0.25 Mt per year in both Europe and North America. The production of asphalt from petroleum was patented in 1894 and was gradually perfected. After 1920, the use of synthetic asphalt prepared from petroleum and local aggregates became more economical for most paving. In Russia, where distribution of petroleum products is still a problem, the local production and use of natural asphalts are reaching the levels reported during the early part of this century in Europe and the United States.

Among the tar sands, asphaltites in particular have been the basis of stable industries producing highly varied products for years. Grahamite, initially mined in West Virginia during the 1850s and burned as coal, has since been used to produce tar, lubricants, illuminating gas, and varnish. The gilsonite industry of Utah, in operation since 1888, has produced ink, insulation, paving material, roofing, varnish, asphalt additives, sealers, gasoline, and carbon control rods for nuclear reactors.

3.2 Current Production

OS&TS were worked in at least eight countries in 1992.

3.2.1 Brazil Brazil has nine significant oil shale formations. The Brazilian oil shale industry started in 1881 with 20 Scottish retorts operating on Tertiary shale at Taubate in San Paulo State. This plant operated until 1920, sat idle until 1941, and was then renovated and expanded for wartime production of oil, wax, and gas. A second company operating on Cretaceous shale in Bahia erected a plant of 52 Scottish retorts in 1884 and produced illuminating gas, oils, paraffin, candles, soap, and sulfuric acid. Production was equivalent to about a thousand barrels of oil per day. Several other plants produced shale oil products at intermittent times throughout World War II. Oil shale was also used as railroad locomotive fuel (Russell, 1990, p. 172). The high water content of the Cretaceous oil shale was a problem. In an attempt to improve the economics of Brazil's oil shale operations, the government investigated the dryer Irati shale. The Taubate plant was close to the Irati Formation; it was purchased by the national government in 1951 and became the start of the Petrobras research and development program that is currently demonstrating large-scale production of oil from the Irati Formation using the Petrosix technology (see Sec. 4.4.1).

3.2.2 Canada In 1967, after a half century of diverse trials, Great Canadian Oil Sands Ltd. (now Suncor) put the first modern commercial plant for the production of oil from tar sands into operation in Alberta. The Suncor plant is producing at design capacity of 65 000 barrels per day. A more recent effort, the joint venture Syncrude Canada Ltd., attained sustained production of 109 000 barrels per day during 1983 and produced at design capacity of 129 000 barrels per day during 1985. These operations use open-pit mining and hot-water separation of the tar and sand in surface plants. The development of horizontal drilling technology may result in larger-scale oil production from these massive resources by *in situ* methods.

3.2.3 China Oil shale is widely distributed in China; deposits are known to exist in more than a dozen provinces. Two deposits are currently worked. Fushun, in Manchuria, is the most famous and is the world's oldest continuous oil shale operation currently in production. The shale is lean, 20 L/t, but generally has to be removed to get to coal beds. Started as a local activity shortly after discovery of the shale in 1909, the operation has been expanded and renewed several times. In 1924, the Japanese added facilities at Fushun based on Estonian technology. The Japanese plant produced 5500 barrels per day during World War II. The Chinese took over the plant after the war, rebuilt it during 1954, and expanded it during the 1970s. Peak production had reached 7.5×10^6 barrels per year but has dropped to less than 0.5×10^6 barrels per year. A second oil shale operation was started in Maoming, southern China, in the 1950s using richer shale of 75 L/t.

3.2.4 Estonia Kukersite of the Baltic Basin has long been recognized for its fuel value and has been used extensively because of the unusual richness of so large a deposit. Farmers also burned it on their fields to use the ash for fertilizer and as a soil conditioner. Estonia became an independent country after World War I; three private companies and the Estonian government built plants for oil production. By 1938, the Estonian portion of the basin produced a million barrels of oil per year and employed 6000 people, meeting the fuel needs of two-thirds of Estonia's heavy industry. The industry was devastated during World War II, but produced at the rate of 1.75×10^6 barrels of oil per year for a period during German occupation. In 1945, Estonia became part of the Soviet Union. As part of implementing a succession of Five Year Plans, the Soviet central government built major gas and electric generation plants fueled by kukersite in the Baltic Basin. These plants produced gas and over 3000 MW of electricity for Leningrad and the northwest Soviet Union. The industry is now in decline because natural gas pipelines have been extended to the area, and the power plants have major environmental problems.

3.2.5 Russia Since the 17th century, many projects in Russia have produced natural bitumen and oil shale products (Russell, 1990, p. 470). None can be classified as large-scale oil producers, but the diversity of resources, lack of transportation, and great local demand for a wide range of products have prompted the greatest diversity in use of oil shale and tar sand products in the world. There are numerous local tar sands operations in the former republics of the Soviet Union. For example, a surface mining operation started in the 1950s in Kazakhstan is now producing more than 4 Mt per year. A large portion of the material is used directly for road paving. A 1991 report (Vakhitov, 1991) cited uses for fuels (in liquid, gas, and solid forms), petrochemical feedstock, varnishes, paints, insulating material, metalliferous products, biostimulants, building materials, and paving material.

3.2.6 Trinidad Asphalt from Trinidad's Pitch Lake continues to be produced by the government-owned Trinidad Lake Asphalt Company, Ltd. at the rate of 820 barrels per day, down from peak production of 3100 barrels per day during 1964.

3.2.7 United States Local paving still supports continuous operation of the two tar sand mines near Uvalde, Texas. Limited local operations of this type, once widespread, also continue intermittently, as needed for local paving, at Asphalt Ridge near Vernal, Utah. In the eastern Uinta Basin, commercial production of gilsonite began during 1888 and continues. Also, in the Green River Formation, the important saline minerals associated with oil shale are being exploited; trona has been mined in Wyoming since 1947, and solution mining of nahcolite in Colorado was initiated during 1990.

3.3 Prospects for Future Production

In addition to continuation of the operations listed in Sec. 3.2 at about their present levels, the following projects probably will go into production during the next decade.

3.3.1 Australia A large multinational oil company and an Australian oil shale resource company have persisted for several years in preparations to produce oil from shale in Queensland. Assuming reasonable cooperation from the Australian government, this group is expected to operate an open-pit mine and to retort shale using a modern surface pyrolysis technology within the next decade.

3.3.2 United States With enormous, rich oil shale deposits and widespread shallow tar sands and sapropelic deposits, the United States is a logical location for increased use of these resources. Small projects producing premium hydrocarbon products, mineral coproducts, and chemical by-products are more likely to be feasible earlier than large-scale projects competing with the petroleum industry.

3.3.3 Venezuela The great Orinoco tar sands have not yet been put into production. The high viscosity (100 000 mPa s at ambient temperature) of the bitumen is a problem, but Venezuela has learned a great deal about handling heavy oils from its experience throughout the Eastern Venezuelan Basin since the 1950s. Neither heating nor dilution with lighter crudes is considered to be a cost-effective method for extracting the viscous tar. The decision has been made to try to produce, transport, and burn the bitumen directly as an emulsion using a brine present in the deposit. Venezuela is testing world markets for the new power plant fuel called Orimulsion.

4. PROCESSING AND APPLICATIONS

The method of extracting useful products from OS&TS depends on the product desired, the formation geometry, and the physical properties and characteristics of the pay zone. Attempts to classify extraction methods tend to obscure the range of choices and combinations available to operators. The general categories of mining and direct combustion, mining and surface processing, *in situ* processing, and combinations of these methods have all been used or demonstrated at large scale.

4.1 Mining

Mining methods for OS&TS are very sensitive to the properties of the particular deposit under consideration and the overburden covering the pay zone. The two general categories of mining are surface and underground.

4.1.1 Surface Mining Open-pit mining is the method of choice for mining both OS&TS when depths of overburden permit. Most OS&TS in consolidated formations require blasting and mucking to remove the ore. For unconsolidated tar sand formations and weak shales, direct loading with large shovels or ripping and bulldozing is possible. Suncor's bucket-wheel loader and conveyor system in its Alberta mine is the leading example of large-shovel mining of tar sands. The rich shale of the Baltic Basin can be ripped directly from the mine face and loaded to rail cars or trucks with large shovels. The tar-impregnated Anacacho Limestone of Uvalde, Texas, is blasted and mucked with large shovels and load-haul-dumps, but the weak sandstone of Asphalt Ridge near Vernal, Utah, is ripped with bulldozers and pushed directly to the mixing table for further processing. The unique properties of gilsonite permit very efficient mining of this asphaltite even from very narrow vertical veins using high-pressure water jets. In each case, the physical properties of the ore body, volume of operation, and economics determine the exact choice of method and equipment.

4.1.2 Underground Mining Where depth of overburden requires underground mining, the operator is faced with a far broader set of problems. Access, whether by vertical, horizontal, or sloping adit, must be planned and mined out. A strong competent horizon of rock must be selected for the mine roof. Ventilation, dewatering (if needed), and emergency egress for every stage of mine development must be carefully planned. Room-and-pillar or chamber-and-wall mining have been the methods of choice for most large underground oil shale mines. The heights of rooms or chambers in the Green River Formation have dictated special drilling and blast hole loading equipment to reach the entire face of the mine. Similarly, specialized roof bolting equipment and techniques have evolved for large oil shale mines. The U.S. Bureau of Mines did considerable development work to perfect equipment and techniques for large production mines in the Green River Formation. Cleveland-Cliffs, Inc., Mobil Oil, and Unocal have all operated room-and-pillar mines safely in the Green River Formation. Numerous mechanical miners to replace blasting and mucking have been proposed for OS&TS operations, but although several have been carefully tested, none have been used in large-scale production. The Scottish and Australian oil shale mines worked only narrow seams of a meter or two compared to the 27-m cuts used in the hundreds of meters deep ore body of the Green River Formation. During 100 years of operation, the Scottish mines evolved from crude hand-pick operations to very sophisticated electrical operations (Sneddon, 1938, p. 53).

4.2 Crushing

An extensive choice of crushing equipment designed primarily for crushing limestone is available and very satisfactory for most OS&TS. Crushing tar sands from unconsolidated formations can be as simple as driving over the run-of-mine material with a bulldozer, as is done to produce road paving material at Asphalt Ridge. For harder ores, gyratory, jaw, cone, and roll crushers have been used successfully. Particle size is usually dictated by the choice of subsequent oil extraction process or firing method.

4.3 Direct Use

Historical evidence suggests that oil shales have been used directly as fuel for hundreds of years. The use of kukersite as power plant fuel in Estonia is the leading contemporary example of this practice.

The outstanding direct use of tar sands has been for road paving. Processing for this application may range from simple compaction of run-of-mine material to some crushing and softening with hydrocarbon solvent, as is done at Uvalde, Texas, or blending with water, as is done at Asphalt Ridge in Utah.

4.4 Methods of Oil and Gas Production

Converting of kerogen in oil shale to oil and separating bitumen from the host tar sand material have many similarities, but the properties of bitumen offer more choices for extracting useful products. The bitumen in tar sands melts, can be decomposed or cracked at high temperatures, can be washed off the host material with hot water in some cases, and is soluble. Kerogen in oil shale does not melt and is insoluble; therefore, it is generally separated from the host rock by application of heat to decompose the solid kerogen into gases and residual carbon. This process is called pyrolysis and is completed in a reaction chamber called a retort for both surface and *in situ* operations. The atmosphere in which pyrolysis occurs is critical because the newly formed products of pyrolysis are very reactive with any other elements present in the pyrolysis zone, particularly oxygen. Retorts are therefore designed to have inert gases sweep the product gases out of the pyrolysis zone to a condenser or condensing zone in the retort where the oil and uncondensable gas fractions are separated. The residual carbon and uncondensable gases may be burned to provide heat for the process. Maximum oil production requires pyrolysis at the lowest possible temperature (about 480 °C) to avoid unnecessary cracking of the hydrocarbon molecules, which reduces oil yield. Higher temperatures can be used to produce lighter oil and a greater volume of gas at the expense of oil yield. Supercritical extraction techniques have been tested on oil shale to improve oil yield. This involves washing intermediate products of kerogen conversion out of the host rock at lower temperatures than used for pyrolysis.

Where permeability of the host rock is sufficient or can be created, several methods of *in situ* heating are technically feasible for both oil shales and tar sands. The basic objective of both surface and *in situ* operations is to complete the minimum decomposition of the hydrocarbon component necessary to get it free of the mineral matrix and do as little heating of the mineral matter as possible. Minimum heating of the mineral matter is particularly important for carbonate shales because the carbonate decomposition reaction if triggered is highly endothermic and generates unwanted carbon dioxide but no useful products.

4.4.1 Surface Pyrolysis The most recently developed surface pyrolysis technology is the Alberta Oil Sands Technology and Research Authority (AOSTRA) Taciuk Processor (ATP). Developed for tar sands, the ATP has also been tested on oil shale and has been used to remove hydrocarbons from contaminated soil. This rotary retort, developed for thermal treatment of Alberta tar sands, is the method that has been chosen for the Australian oil shale project previously mentioned (Kuss, 1994). The ATP is illustrated in Fig. 2.

Another surface pyrolysis technology suitable for both oil shales and tar sands is the Lurgi–Ruhrgas technology developed in Germany to process coal fines. This technique, which features a lift pipe to recycle hot solids, has been successfully tested for processing the diatomaceous earth tar sands of the McKittrick Formation in California and for Green River oil shale. It has been found useful on a wide range of feedstocks. Figure 3 shows a configuration of the Lurgi–Ruhrgas technology suitable for processing tar sands.

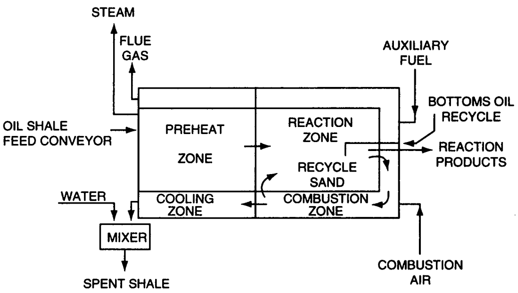

FIG. 2. AOSTRA Taciuk Processor (ATP). The ATP consists of a single, horizontal, rotating vessel in which separate compartments or zones are maintained by the geometry of the equipment and flow of gases. The reaction zone is heated by a combination of conduction from the combustion zone, where residual carbon is burned off the spent feedstock, and a portion of the hot spent feedstock, which is recycled to the reaction zone.

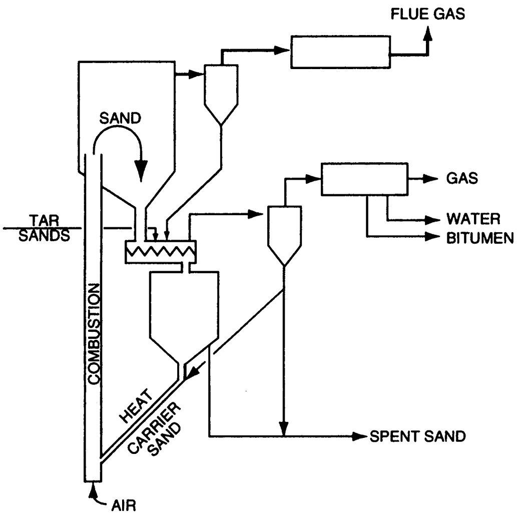

FIG. 3. Lurgi–Ruhrgas process. The unique feature of this system is the lift pipe in which residual carbon is burned off spent feedstock to provide heat. Burned feedstock is carried to the retort for solid-to-solid heat transfer to raw feedstock.

The largest surface oil shale pyrolysis reactor currently operating is the Petrosix 11-m vertical-shaft retort used in Brazil's development program. The modern vertical-shaft retort is the product of years of evolution that can be traced to the original change from horizontal- to vertical-shaft retorts in the Scottish oil shale industry. James Young and the Scottish oil shale companies shifted from the fixed horizontal retorts that had been adopted from the coal gasification industry to higher-throughput, vertical-shaft retorts to produce oil. A succession of outstanding engineers following Young improved the Scottish retorts and set the standard of efficiency for the world. The Scottish designs were exported to France, Australia, Spain, Brazil, and the United States. These retorts were indirectly heated by coal. When U.S. Bureau of Mines engineers set out to develop a high-efficiency, high-throughput oil shale retort specifically for the Green River Formation shale, they studied the Scottish design and elected to develop a vertical-shaft retort, called the Gas Combustion Retort (GCR), that would burn the uncondensable gases of the retorting process as fuel. Engineers who worked on that program went on to develop and build the Petrosix GCR for Brazil and the Paraho version of the GCR, which has been used extensively at pilot scale for various research and testing programs in the United States. The Paraho version is illustrated in Fig. 4 as an example of a modern, high-throughput, vertical-shaft retort.

Upon completion of the Bureau of Mines GCR demonstration program, a consortium of major oil companies leased the pilot and demonstration plants at Anvil Points, Colorado, and conducted proprietary testing. Subsequently, three of the major oil companies developed alternative concepts. Union Oil Company (later Unocal) perfected its rock pump retort to the demonstration stage. During 1949, Standard Oil Company (later Exxon) tested and patented a fluid-bed retort. Chevron demonstrated an ebullient or boiling-bed retort during the 1970s. The latter two designs are extensions of oil company experience in operating sand crackers and fast catalytic crackers in modern refineries.

During the most recent period of high interest in oil shale, the Kiviter retort replaced older equipment for the production of liquids from kukersite in Estonia. China continued to use the Pintsch retorts. The Institute for Gas Technology, with support from the U.S. government, developed hydroretorting in a vertical-shaft retort for the hydrogen-deficient Devonian shales.

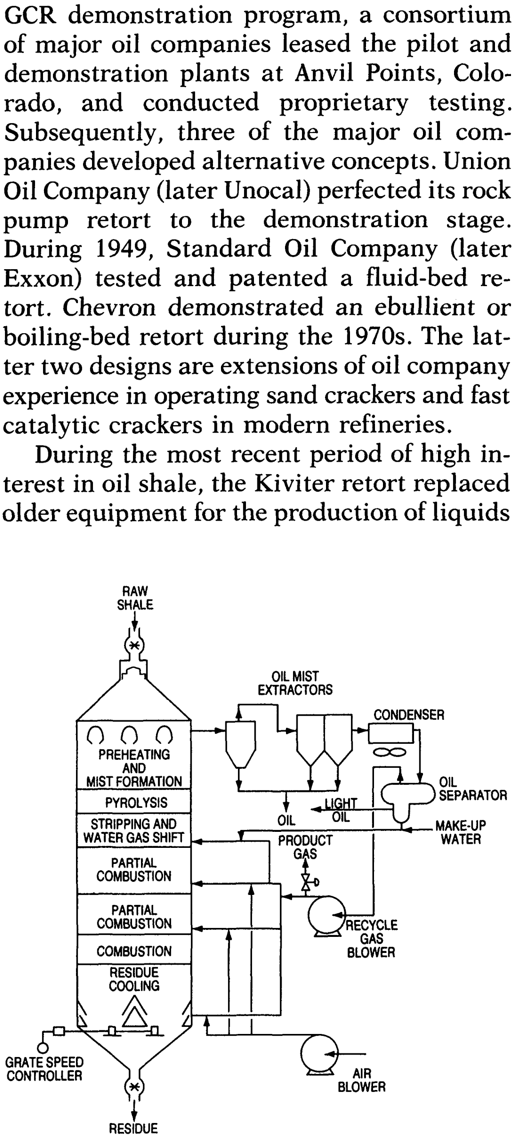

FIG. 4. Paraho retorting process. The Paraho process is typical of vertical-shaft retorts in which crushed shale with the fines removed descends through the retort under the influence of gravity. Zones for each step in processing the shale are maintained by managing gas flow in the retort. The direct combustion mode is shown here. When operated in the indirect mode, process gas is burned in a separate furnace and hot gases carry heat to the retort.

4.4.2 *In situ* Extraction *In situ* pyrolysis or heating of both oil shales and tar sands in place to produce oil has been tested extensively. One particularly successful operation involved using cheap hydroelectric power to heat shallow beds of shale in Sweden. The U.S. government provided extensive support of *in situ* OS&TS research and development during the 1970s. The cooperative program with industry resulted in the Geokinetics horizontal *in situ* process for shallow beds of oil shale and the Occidental vertical modified *in situ* process for deep, thick oil shale beds being tested to demonstration scale. These concepts are illustrated in Figs. 5 and 6.

4.5 Upgrading and Refining

Extensive testing and practice in the former oil shale industries of the world and Canada's tar sand industry have adequately proven that shale oil and bitumen from tar sands can be refined into the full range of petroleum products. Some shale oils contain high concentrations of nitrogen or arsenic and must be hydrotreated to be suitable as feedstock for conventional refineries. Trace metals, sulfur, and chlorides can also be a problem, just as they are with some crude oils. Historically, most oil shale plants were so isolated that small refineries of custom design were collocated with them to process their output. This was also the case for the Utah gilsonite industry. When it was decided to make gasoline from this unique resource, a small refinery of special design was constructed at Fruita, Colorado. The larger oil shale plants contemplated during the 1970s would have included upgrading facilities, as did Unocal's demonstration plant. Minimal treatment in custom-designed upgrading facilities is required to make feedstock suitable for modern refineries.

5. ECONOMIC ASPECTS

The monumental works of Abraham (1960) and Russell (1990) chronicled the rise and fall of OS&TS industries around the world. The

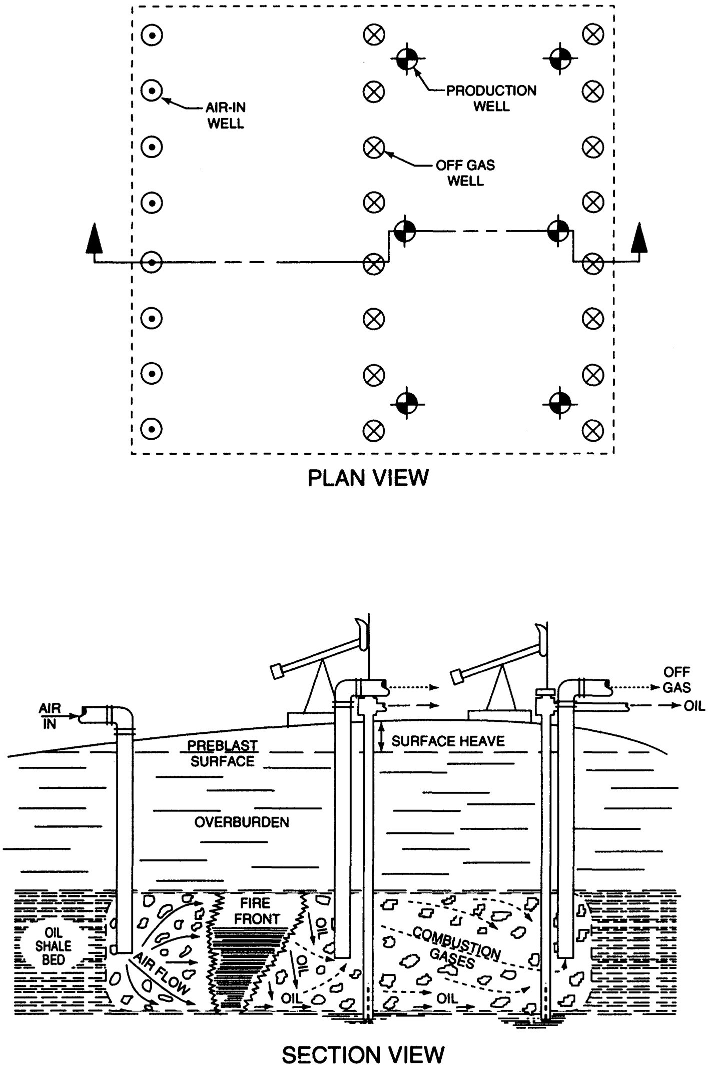

FIG. 5. Plan view and cross section of typical Geokinetics horizontal *in situ* process. This scheme for retorting shallow beds of shale in place depends on uniform blasting of the shale and surface heave to create void space for gas to flow through the shale. The shale is set afire at the air inlet wells, and air flow is managed to move hot inert combustion products through the balance of the shale ruble.

existence of an industry cannot be assumed to prove independent economic viability because special tax structure and tariff policy are well known to have sustained industries that otherwise would not have been profitable. The simplicity of just heating rock to get oil accounts for the long history of use of OS&TS. The economic competition between petroleum and even this simple method of extraction accounts for the enormous variety of methods tried, as inventors attempted to improve the economics of operating with solid feedstock. No "cotton gin" of pyrolysis technology, however, was developed to fix the cost of producing shale or tar sands oil at or near that of petroleum extraction. At the time of the birth of the modern petroleum industry (1859), Muspratt (1860, Vol. 2, p. 99) reported a dozen methods for heating both hydrocarbons that melted (resins and asphalt) and others that vaporized or decomposed (kerogen and organic waste). By the time the U.S. Bureau of Mines surveyed oil shale patents a century later (Klosky, 1949, 1958), more than 1500 patents had been registered, and there are now about 2000. No commercial-scale production of oil from shale or tar sands since the emergency fuel production required during World War II, other than projects that received government subsidies, has survived more than a few years in the era of cheap Middle East oil. Neither have the opportu-

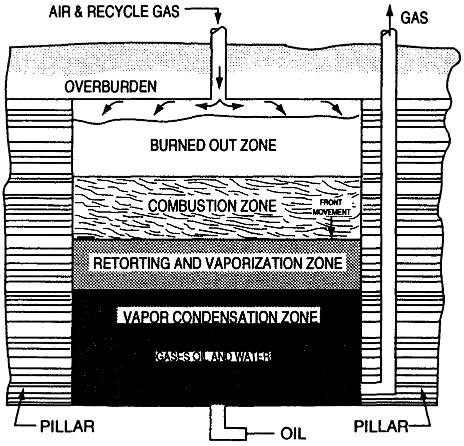

FIG. 6. Occidental vertical modified *in situ* process. This concept was developed specifically for the deep, thick shale beds of the Green River Formation. About 20% of the shale in the retort area is mined; the balance of the shale is then carefully blasted using the mined-out volume to permit expansion and uniform distribution of void space throughout the retort. A combustion zone is started at the top of the retort and moved down through the shale rubble by management of combustion air and recycled gases. Full-scale retorts would contain 350 000 m^3 of shale rubble.

nities offered by the fact that the bitumen in tar sands is soluble resulted in success. Most solvent projects failed because of the loss of expensive solvent adhering to the host rock or sand. The economics of all OS&TS projects were seriously impaired by the extra cost of mining and handling solid feedstock and disposal of spent feedstock. The materials handling problem has forced the development of ever more efficient surface plants and provided the impetus to experiment with *in situ* methods.

5.1 Historical Profitability

The Australian oil shale industry of New South Wales is a concise example of an industry's response to competition, outside influences, government policy, and technological change. As shown in Fig. 7, the small industry started experimentally in 1855, reached continuous production status in 1865, and flourished in relative isolation until the financial panic of 1873. After that, the struggling industry needed tariff protection from the predatory marketing practices of Standard Oil Company. The Provincial Government of New South Wales provided that protection, and the fledgling industry recovered and grew with the local economy. During 1902, central government came to Australia and canceled the protective tariffs in response to perceived greater national interests, and the oil shale industry went into decline. The gas mantle, invented in 1911, eliminated the export market for Australia's raw shale, and the tenacious little industry died shortly thereafter. It sprang to life again in response to the emergency needs in World War II and disappeared when the emergency was over (Sell, 1951).

Other OS&TS industries cannot be so neatly capsulized, but all that had reasonably sustained operations began and grew under special circumstances and declined when those conditions ended.

5.2 Current Profitability

The current large-scale operations in Brazil and Canada are not economical in competition with the petroleum industry. These projects barely meet operating costs and are currently paying little return on capital investment. Newell (1993) most recently reported operating costs of \$15/bbl (Canadian) in a facility that would now cost (\$8–\$10)$\times 10^9$ to build. World oil prices at the time of this announcement were in the range of \$17/bbl. The industries in Russia, Estonia, and China are not yet operating in true free-market economies. The proposed project for Queensland, Australia, has requested special tax treatment to compete with the petroleum industry. No current large-scale OS&TS operation can compete with the petroleum industry as a source of refinery feedstock as long as petroleum prices remain low. However, small tar sands operations, producing local paving material, have a long history of profitability. The gilsonite industry of Utah has a checkered history but overall has been profitable.

5.3 Prospects for Future Financial Feasibility

Both upstream and downstream costs are increasing for the petroleum industry and can be expected to increase at even greater rates as convenient reserves are used up and more production must come from sensitive and remote areas. Nevertheless, world petroleum

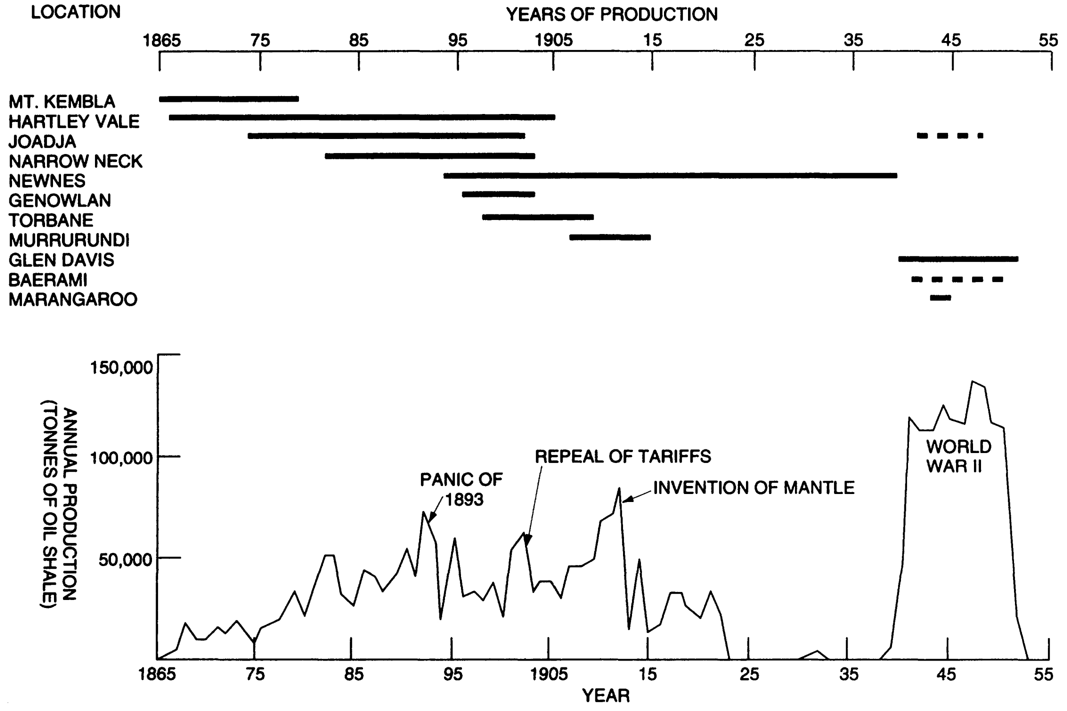

FIG. 7. Australian oil shale industry production.

producers can be expected to continue to operate as an imperfect Von Stackelburg monopoly (Greene and Leiby, 1993) and manage petroleum prices to a degree that makes large-scale production of refinery feedstock from OS&TS a financially unacceptable venture. Petroleum producers will keep prices between the long-term and short-term cost of producing petroleum, and both of these boundaries will increase with time. Unfortunately, justification of large OS&TS operations to produce oil in competition with petroleum requires a sharp increase in world petroleum prices at a predictable time. Sharp increases in petroleum prices, such as occurred in the 1970s, are certain to occur again, but their timing is uncertain. The most likely scenario will be more projects that expand the envelope of primary, secondary, and tertiary recovery of crude oil into the most convenient and most easily worked tar sands, including depleted shallow petroleum reservoirs. This movement forward along the geologic spectrum from conventional petroleum to heavy oil, extra heavy oil, and then tar sands is more likely to happen than any giant step to oil shale operations in competition with petroleum. Canadian *in situ* tar sands operations using horizontal drilling are the most likely candidates for success in this scenario. The production cost for this extraction technology is expected to be $6.00/bbl (Canadian). In any country where modern transportation is available, oil shale can compete with petroleum as a source of liquid fuel only if given special tax treatment, import protection, royalty forgiveness, or even direct government support. In some countries, these incentives may be provided to develop domestic resources, improve balance of trade, and create domestic employment.

5.4 Role of Byproducts and Specialty Products

The wide range of products and characteristics of shale oils and bitumen from tar sands makes them excellent sources of petrochemical feedstocks. The current liquid production in Estonia is used almost entirely for petrochemical production. The historically successful oil shale industries usually produced a range of products in addition to oil and gas. Oil shale development is most likely to occur as small projects justified by the high dollar value of specialty products, special petrochemical feedstocks, coproducts, and byproducts. The oil shale resources of the United States are most amenable to this type of development. The Green River Formation, as mentioned in Sec. 2.1.4, is a veritable warehouse of saline minerals and hydrocarbons. The New Paraho Corporation has found the high nitrogen content of Green River Formation shale oil, which is usually a problem for refining, to be an advantage in producing modern asphalt paving modifiers that greatly improve the performance of conventional asphalt produced from petroleum derivatives. Several test strips of highway paving using their Shale Oil Modified Asphalt Technology (SOMAT) under a variety of climatic condition show that the shale oil–derived modifier produces asphalt pavement of such superior characteristics compared to conventional asphalt that its production at commercial scale is economically justified (Lukens, 1993).

In addition to the current production of trona and nahcolite from the Green River Formation, dawsonite in the Piceance Basin is an enormous resource for potential domestic production of alumina. The potential for multimineral operations improves the prospects for overcoming the barriers to successful oil shale operations. The University of Kentucky is pursuing a similar approach in investigating integrated production of several products from Devonian shale.

5.5 Relationship to Petroleum Recovery Technology

Eventual large-scale production of shale oil in competition with petroleum will hinge on a better understanding of how nature converts kerogen to petroleum, including the role of water and ambient gases that may be present in the natural process. This requires fundamental research in aqueous organic chemistry and how the atmosphere in which pyrolysis occurs influences reaction rates and pyrolysis products. Similarly, large-scale production of refinery feedstock from tar sands in competition with petroleum will depend on better understanding of the thermal and biological degradation processes that generate tar sands. Some large oil companies and governments are sponsoring research in these areas.

The terms "oil shale" and "tar sands" may be misnomers, but they identify the largest and most widely distributed hydrocarbon resources in the world, with a close technological and geological relationship to petroleum. These resources represent an assured future source of petrochemical feedstock, even if hydrocarbons are no longer used as fuels for environmental or economic reasons. The technology for extraction of useful products from these ubiquitous resources, whether by mining and surface processing or by *in situ* methods, is particularly crucial when related to present tertiary petroleum extraction technology. Reservoir engineers concur that current primary petroleum extraction methods leave behind as much as two-thirds of the oil in the ground. Although the world has extracted between $(435 \text{ and } 440)\times 10^9$ barrels of oil from petroleum reservoirs and will probably extract that amount again, twice as much oil will remain in petroleum reservoirs and have to be extracted by methods akin to the extraction technologies for OS&TS. This fact alone establishes an enormous economic reward for developing the most efficient OS&TS extraction technologies. The real value of such technologies will only become apparent in the future, as they are used to clean out petroleum reservoirs. Economics will most likely dictate that exposed deposits and shallow reservoirs will be first worked by these methods, followed by ever deeper operations.

Ultimately, mankind may have to resort to use of the less economic portions of the spectrum of hydrocarbon materials available to us, such as fuels manufactured from renewable biomass, unconventional gas resources, and dirtier coals. Large-scale OS&TS operations have favorable economics in such scenarios.

6. OCCUPATIONAL, ENVIRONMENTAL, AND LEGAL ISSUES

The coincidence of renewed interest in OS&TS during the 1970s, and implementation of the environmental ethic of the 1960s, created a clash of interests that delayed many OS&TS projects. The long history of OS&TS operations, frequently at isolated locations, provides many opportunities for case studies of the effects of long-term exposure to raw OS&TS and their products on flora, fauna, and human populations. The common source and close relationship between raw OS&TS and their products and petroleum and petroleum products provide little reason to expect surprise environmental impacts from future OS&TS operations.

6.1 Historical Health Concerns

Health problems in the early oil shale industries depended on the nature of the feedstock and had much to do with the primitive state of technology and industrial hygiene. Antisell (1859) reported on a Rhenish feedstock that "on removing the cap of the retort, a strong smell of arsenic is perceived, and the workmen suffer from colic, ulcers at the root of the nose, of the joints, and an irritable condition of the skin." As early as 1920, Scottish shale oils, particularly the high-temperature fractions, were shown to have higher levels of carcinogenicity than other mineral oils tested (Key, 1974). As a consequence, the health histories of Scottish oil shale workers have been the subject of extensive studies. These studies confirmed that there was a higher incidence of skin cancer, especially scrotal cancer, among workers with prolonged exposure to Scottish shale oil and shale oil products. Classic high rates of scrotal cancer reported among British textile workers who oiled spinning jennies with shale-derived lubricants decreased as alternative lubricants were used. In general, the incidence of disease decreased as special precautions were instituted and improved hygiene became standard practice. Studies of the health of oil shale workers and residents in the area of the modern oil shale industry in Estonia reveal that an excess of skin cancer occurred only in women who worked in the industry for 10 or 20 years (Coffin, 1981). Investigations of health problems at isolated oil shale operations and villages in South Africa and Australia show that the workers and their families were generally very healthy but suffered from lack of immunity to communicable diseases brought in by visitors (Knapman, 1988). No unusual incidence of disease has been reported from current oil shale operations in Brazil or tar sand operations in Canada.

6.2 Environmental Issues

OS&TS share a common environmental problem with coal and petroleum: their use as fuel releases carbon dioxide and sulfur compounds to the environment. The carrying capacity of the environment, therefore, may limit future use of these fuels. In addition, OS&TS have the unique problem that the mining and extraction of their hydrocarbon content at commercial scale leaves enormous quantities of solid residue. Some shale oils, like some crude oils, contain enough heavy metals to be of concern. Many OS&TS contain connate water or water of hydration that results in an overall excess of water from their processing, which must be treated as wastewater. Air emissions are a potential problem for processing or burning OS&TS just as they are for any other hydrocarbon. Pyrolysis products such as shale oil are generally viewed as containing more carcinogens and toxic substances than other hydrocarbons. Special precautions must be taken regarding pyrolysis products from any source until their exact nature is known. The emissions from direct combustion of kukersite in Estonia are reported to be a severe environmental problem. The Estonian power plants do not have modern emission controls. Regardless of location, large-scale OS&TS operations will produce major socioeconomic impacts, population displacements, and transportation problems.

All of the above problems have been studied extensively (Bates, 1981). For the most part, there are technical solutions to the environmental issues of OS&TS development. Ultimately, each nation and the world collectively will have to make decisions regarding the tradeoffs involved in development of natural resources as population growth and world development demand greater quantities and varieties of products. The risks, dangers, and environmental damage of producing petroleum in sensitive frontier areas and transporting petroleum and petroleum products over great distances must be weighed against the environmental costs of meeting society's demands from more distributed alternatives.

6.3 Legal Issues

The marginal economics of OS&TS can make ordinary legal issues into insurmountable barriers to development. Among the legal issues are ownership of resources, mining and environmental laws, use of public lands and resources, and tax structure. The same laws and tax structure that are a nuisance to petroleum development can be an absolute barrier to OS&TS development because of the longer lead time and higher capital cost of the latter. Governments that seek to promote development of these alternatives to petroleum must be sensitive to the expectations of entrepreneurs evaluating higher-risk projects. Government ownership of the oil shale plant in Brazil, near-partnership operation of the tar sands plants in Canada, and support of clean fuels production in the United States are examples of government actions needed to promote large-scale production of alternatives to petroleum.

GLOSSARY

API Gravity: An arbitrary scale expressing the gravity or density of petroleum and petroleum products. The measuring scale is calibrated in terms of degrees API and is calculated by the following formula:

$$\text{Degrees API} = 141.5 \times [\text{specific gravity at } 15.56\ ^\circ\text{C}]^{-1} - 131.5.$$

Catagenesis: Regressive stage in organic metamorphism in which chemical bonds in large molecules of kerogen are broken by thermodynamic factors to form smaller petroleum (oil and gas) molecules.

Coal: Sedimentary rock containing sufficient carbonaceous material, usually of vegetable origin, to be of interest as fuel.

Dawsonite: A mineral consisting of basic sodium carbonate occurring in white, bladed crystals.

Diagenesis: Reconstructive process by which changes are produced in sedimentary rock during or immediately after their deposition and which is caused by such forces as weight of overburden or hot water. Stage in organic metamorphism in which disseminated organic material is converted to large molecules of kerogen.

Kerogen: The insoluble hydrocarbon material in sedimentary rock that upon destructive distillation forms oil and gas.

Lithologic: Relating to the character of rock in terms of its structure, mineral composition, color, and texture.

Metagenesis: Stage of organic metamorphism in which petroleum is altered by thermal or biological degradation under conditions that change the carbon structure and produce solid or nearly solid hydrocarbons.

Nahcolite: A mineral consisting of natural sodium bicarbonate.

Natural Asphalt or Bitumen: Soluble natural hydrocarbon material having less than 10° API gravity at ordinary temperatures.

Oil shale: Rock containing sufficient kerogen to be of economic interest as a source of oil.

Pyrobitumens: Natural bitumens that as a result of metamorphosis are insoluble in carbon disulfide and have characteristics similar to kerogen but are degradation products of petroleum.

Retort: A closed vessel or chamber with an outlet, used for distillation, sublimation, or decomposition by heat.

Sapropelites: Coal or oil shale formed from organic-rich sediment of marine, estuarine, or lacustrine deposition consisting of largely organic debris from aquatic plants and animals.

Tar Sands: Hydrocarbon-bearing materials formed by petroleum impregnation of mineral matter or voids along its migratory path in which the petroleum is subsequently degraded or metamorphosed leaving hydrocarbon material having an *in situ* viscosity greater than 10 000 cP at reservoir conditions. (*In situ* viscosity data are frequently not available, and so a gravity cutoff value of less than 10° API gravity or zero mobility at ordinary temperatures is used as a default value. This definition has evolved to rely on *in situ* viscosity as the key physical property and omits reference to mineral matter present with the hydrocarbon. Thus, the definition includes all of the solid products of petroleum degradation as well as natural bitumen left behind as petroleum is expelled or removed from reservoirs or migratory paths.)

Trona: Hydrous acid sodium carbonate in crystals or fibrous or columnar masses as a deposit from various soda-brine springs and lakes.

INTRODUCTION

Operations research is unusual among the sciences in that its beginnings—and even its name—can be traced unambiguously to an event in history: military operational trials being conducted on England's east coast in the summer of 1938.

In 1935, as part of Great Britain's effort to respond to the growing threat of German air power, scientists began an urgent series of developments and experiments aimed at detecting flying aircraft at a distance; by 1937, devices that came to be known as radar were in place and experiments were being conducted. Their technical success led in 1938 to large-scale operational trials involving both the radar sets and the fighter-plane defenses; they were aimed at testing the combined effectiveness in actual operations against an attacking force. In connection with this work, A. P. Rowe referred to its analysis as "operational research"—a term he is thought to have originated.

When the term crossed the Atlantic, it became "operations research," and the two synonymous usages remain today: operational research in the United Kingdom and parts of Europe, and operations research elsewhere; both are commonly abbreviated as OR. In the early 1950s, the term *management science* (MS) was introduced in the U.S. with a virtually synonymous meaning; thus, by the middle 1980s, the common subject was often referred to as OR/MS.

The 1938 partnership between the Royal

Air Force operational people and the scientists, who not only worked with the radar but also analyzed the results of the operational trials, was successful both in characterizing the results of the trials and in showing how the operations could be improved. The next section sketches the growth of this seminal experience into the activities of an important science and an influential profession.

As operations research developed, its field of inquiry came to be recognized as the operations of systems consisting of nature, men, and machines, this last term including not only man's technical artifacts but also his laws, common practices, human behavior, and social structures and customs.

Attempts to generalize this description based on the concept of a system have not proved to be fruitful. Rather, the concept of an *action program* (Boothroyd, 1978; summarized in Miser and Quade, 1988, pp. 489–507) is more useful: a function, operation, activity, or response that is related to and given coherence by a human objective, need, or problem, together with the system of people, equipment, portion of nature, organizational elements, and management or social structure involved. OR can then be defined as the science of action programs, its work including both developing new knowledge and applying it to the problems of real action programs.

Two U.S. pioneer operations analysts (as OR workers engaged in practice are sometimes called), the physicist Philip L. Morse and the chemist George E. Kimball, observed early that "large bodies of men and equipment carrying out complex operations behave in an astonishingly regular manner, so that one can predict the outcome of such operations to a degree not foreseen by most natural scientists." Much of the success of the wartime work arose from the ability of the analysts to identify aspects of complex operations that exhibited such regularities.

1. DEVELOPMENT OF THE PROFESSION

The success of the small British team that was conducting operations research in 1938 set a pattern that was soon widely imitated; well before the end of World War II, most of the military services and their major commands in Britain, Canada, and the U.S. had established multidisciplinary teams to do such work (McCloskey, 1987). G. Majone has observed that the success of these teams did not arise from deep new theories of operational phenomena but rather the craft skills of the scientists applied to analyzing complex operations and assembling theories from readily available scientific tools.

However, one new theoretical development did emerge: search theory (Stone, 1989). It deals with an activity common in warfare: searching from a moving platform (such as a ship or an aircraft) for a fixed or moving target (such as a hostile submarine, ship, or aircraft). The goal is to detect, locate, and identify the target so that appropriate action can be taken. In a peacetime setting, this theory has been applied successfully to finding a sunken treasure ship off the U.S. Atlantic coast (Stone, 1992).

The wartime analysts emerged with the strong feeling that, if the man/machine/nature systems of warfare could be subjected to successful analysis, there should be many operations in peacetime society that could also benefit from such work. This feeling was soon converted to reality, as the community of analysts grew and the context of their inquiries spread widely, not only into varied operating situations, but also around the globe. Soon valuable new theories and applications were emerging from the work.

1.1 Professional Societies

Within the dozen years after the war, professional OR societies had been established in the United Kingdom (1948), the U.S. (1952), France (1956), India (1957), and Japan (1957). An International Federation of Operational Research Societies (IFORS) came into being in 1959; by 1973, 26 national OR societies were members, and by 1993 there were 41, with five other professional groups also adhering to the federation (including The Institute of Management Sciences, founded in the U.S. in 1954). The world-wide OR/MS community in 1993 was estimated to consist of over 35 000 persons.

The principal IFORS activities are these:

1. Conducting triennial international meetings for the exchange of information and discussion of international OR concerns.

The first meeting, at which IFORS was designed and agreed upon, occurred in 1957; the 13th meeting took place in 1993. For the first 12 of these meetings there has been a published volume of proceedings.

2. Publishing, since 1961, *International Abstracts in Operations Research (IAOR)*, a journal devoted to abstracts of the world OR literature. Three independently published volumes (Batchelor, 1959, 1962, 1963) contain abstracts of the literature for the years before 1961.
3. Publishing, beginning in 1994, *International Transactions in Operational Research*, a journal that will publish refereed papers from the 13th and later triennial meetings, as well as other essays of international interest.

1.2 Journals

The first two journals in the field were the *Operational Research Quarterly* (now the *Journal of the Operational Research Society*), founded in the United Kingdom in 1950, and *Operations Research*, founded in the U.S. in 1952. By 1973, there were 15 primary OR journals and 22 others of significant interest to OR workers. In 1993, *IAOR* covered the literature in 35 primary journals, 76 supplemental journals, and 67 specialist journals.

This literature and the professional activities that have prompted its growth since 1938 represent a tremendous development of interest in OR, both the validity of its theories and the effectiveness of their applications to real-world problems.

1.3 Books

Three books were written at the end of the war about the wartime work. Only one, however, was published promptly (Morse and Kimball, 1951); the other two (Johnson and Katcher, 1973; Waddington, 1973) were held up for many years by military classification concerns. Thus, the Morse and Kimball book was the first to offer a coherent account of a major body of OR work.

By the early 1950s, several anthologies of articles had appeared, but the first textbook emerging from an educational program did not appear until 1957 (Churchman *et al.*, 1957). However, the decade of the 1950s saw some 20 more specialized treatises appear. In the ensuing decades, this stream became a flood, with both textbooks and specialized treatises emerging in numbers almost too great to count.

Of the textbooks, Harvey M. Wagner's volume (Wagner, 1969) was widely regarded as setting a new standard and was awarded the Operations Research Society of America's Lanchester Prize. Recently, Hillier's (1990) has been widely used.

1.4 Education

In the early postwar years, a person interested in working in OR could learn about it only from the scattered literature and/or by joining a group engaged in such work, where the knowledge and craft skills of experienced analysts could be passed along. By the early 1950s, however, short courses of varying durations appeared in several countries, and by the end of the decade a few more formal university curricula had been established. By 1973, there were 53 such curricula in the U.S., and by 1993 the number in the U.S. and Canada had grown to over 100. Some included undergraduate as well as graduate training. Growth in other countries had also occurred on roughly the same scale.

Further, well before the 1990s, graduate training in these OR curricula had become recognized as an important qualification for entry into professional OR work, whether teaching, research, or practice.

2. OPERATIONS RESEARCH AS A SCIENCE

Following Ravetz (1971; for a summary focused on OR, see Miser and Quade, 1988, pp. 469–489), science may be described in general as "craft work operating on intellectually constructed objects," each object defining a class of phenomena. Scientific work is thus aimed at establishing new properties of the objects and verifying that they reflect the reality of the classes of phenomena that they represent.

This description has four implications:

1. The intellectual objects—which most scientists call theories but which OR workers usually call models—are created by the imagination, informed by earlier knowl-

edge of the phenomena and objects that have described aspects of them successfully, as well as innovative ideas or new evidence from reality. For example, there is a queuing theory that describes a wide variety of situations in which there are arrivals that demand service, which may be obtained immediately, or after a wait until earlier arrivals are served.

2. There is a continuing reference to the phenomena of reality, in OR's case those of action programs, or nature/man/machine systems. For queuing theory to be representative of some reality, such as the operations of a bank's customer services, the behavior of both the arrivals and the servers would have to be observed and characterized so that the theory could be based on these characterizations.
3. Scientific inquiry then becomes the search for new properties of the classes of phenomena both by manipulating the objects (that is, the theories or models), and by seeking new evidence from reality as a basis for revising them. In the banking example, after the queuing theory has been adapted to the observed behavior of the arrivals and servers, it can be manipulated to explore what might occur if the arrangements in the bank were changed, such as adding more servers, or improving their skills in various ways.
4. The new properties deduced from the objects—theories or models—must then be compared with the appropriate aspects of the phenomena of reality. In the banking example, the theory's predictions for changed conditions would be compared with an actual realization of these conditions in order to confirm the theory as a representation of reality, or to suggest how it might have to be revised.

Since all of science shares this generic description, it is important to note how the different sciences—such as physics, chemistry, biology, or operations research—are distinguished: not by their theories, models, or methods, many of which are widely shared, but by the portions of reality that they are undertaking to understand, explain, and solve problems in (Kemeny, 1959).

Within the framework established by this conception, it is possible to distinguish three classes of problems, depending on their goals: to paraphrase Ravetz, scientific problems, where the goal of the work is to establish new properties of the objects of inquiry, and the ultimate function is to achieve new knowledge; technical problems, where the function to be performed specifies the problem; and practical problems, where the goal of the task is to serve or achieve some human purpose and the problem is brought into being by recognizing a problem situation in which some aspect of human welfare could be improved.

In the queuing situation being used as an example, the scientific problem is to develop a model describing a queuing process, the technical problem is to achieve practical calculations from the model (usually in this case a rather complicated and difficult process), and the practical problem is to use the results to solve practical problems, such as those of improving a bank's service, or—to mention the purpose for which the theory was originally developed—to design an efficient and effective telephone exchange.

In some sciences, the professional groups that solve scientific problems are distinguished from those that work on technical and practical problems (although there is, of necessity, considerable overlap in these activities); for example, chemists solve scientific problems, while chemical engineers work primarily on technical and practical problems.

It is important to note that, in the case of operations research, there has not yet been such a split: operations research comprehends the work in all three classes of problems, with an attendant richness of interaction among its workers.

Thus, we can now describe operations research as the science of action programs, encompassing work on scientific, technical, and practical problems. It should be noted that, when the basic phenomena underlying a problem situation are not adequately understood, to solve a practical problem may involve solving scientific problems to obtain the needed models and technical problems to fashion the technical means needed to support the work toward ameliorating the practical problem.

3. THE CONTEXT

Within the broad contextual framework suggested by the term action program, it is possible to distinguish two major categories in which OR work takes place: processes common to a variety of action programs, and action programs distinguished by their practical context. Table 1 lists common processes to which OR work has contributed, and Table 2 shows areas of application in which significant OR work has been done. Since these tables list the standard terms of classification used by *International Abstracts in Operations Research*, work in any of these areas can be traced through this journal.

4. THEORIES AND TECHNIQUES

In contrast with the wartime years of operations research, when only one essentially new theory was devised, the postwar years have been a time of extraordinary fecundity for the development of models and solution techniques (often called algorithms in OR). While many have been borrowed from other fields and adapted for use in OR contexts, others have grown up largely in OR. Also, the uses of many have spread to other scientific fields.

Table 3 offers a list of the model and technique areas being actively pursued in OR in 1993. The terms shown are the standard classifications used in *International Abstracts in Operations Research*, so that, again, work in any of these areas can be traced through this journal.

As this table suggests, the most extensive borrowing from other fields is from probability theory (*q.v.*) [including especially stochastic processes (*q.v.*)] and statistics; indeed, surveys of OR practitioners show that, of the various techniques they employ, most are from probability and statistics. This is a natural consequence of the activities of exploring the behavior of action programs that not only yield numerical data—often in great volume—but also significant variations in the observations.

The reader will also note, however, bor-

rowings from classical mathematics, such as the calculus of variations, combinatorial analysis (which has been spurred significantly by OR applications), differential equations, Lagrange multipliers, matrices (an essential ingredient in programming models), numerical analysis, optimization (a field whose development has been greatly spurred by OR work), probability (much used in view of the variabilities often encountered in the phenomena of action programs), and set theory.

In what follows, there is not space for even a cursory survey of all of the models and techniques commonly used in operations research. Thus, the ensuing subsections take up only a few of the most important that are regarded as especially associated with OR.

4.1 Linear Programming

The structure of the linear programming model, together with a procedure for obtaining solutions from it, was devised by George B. Dantzig in 1947 (Dantzig, 1963). While the original setting and motivation for it were largely economic, it soon became clear that it had many applications elsewhere, including business and industry, as well as in other sciences.

The simplest form of the linear programming model is this:

$$\text{Maximize} \quad c_1x_1 + \cdots + c_nx_n,$$

where the variables $x_1, \cdots, x_n$ satisfy the conditions

$$x_j \geq 0, \quad j = 1, \cdots, n,$$

$$a_{11}x_1 + \cdots + a_{1n}x_n \leq b_1,$$

$$\cdot \quad \cdot \quad \cdot$$

$$a_{m1}x_1 + \cdots + a_{mn}x_n \leq b_m,$$

and the c_j, b_i, and a_{ij} are constants.

One interpretation of this model that encompasses a wide variety of applications is this: There are n activities X_j, each producing x_j units of product, where each unit yields a value c_j. Each unit of the jth product consumes an amount a_{ij} of the ith resource, of which there is a maximum amount b_i that may not be exceeded by the sum of all of the activities. The problem then is to program a mix of activities that maximizes the total value (spoken of as the objective function) while remaining within the constraints on the resources.

The linearity implied by the statement of the model implies two basic assumptions underlying it: proportionality (that is, the resources used by an activity and their contribution to the objective function are proportional to the level of the activity) and additivity (that is, the combined use of resources by all of the activities is the sum of the individual uses). The third assumption is non-negativity (that is, negative quantities of activities are not possible).

The linear inequalities the variables x_j must satisfy correspond to the geometrical fact that a point $x = (x_1, \ldots, x_n)$ satisfying the model's conditions lies within or on the surface of a convex polyhedron (that is, one in which a line connecting any two points in or on the polyhedron also lies in or on it). If the objective function does not become arbitrarily large for points x on the surface of the polyhedron, then the maximum occurs at a vertex. Thus, the solution to a linear programming problem is one of finding the vertex, and therefore the point x, at which the objective function attains its maximum.

In addition to formulating the problem in this way, Dantzig devised a systematic and relatively economical procedure, called the *simplex method,* for discovering the point at which the objective function attains its maximum (Dantzig, 1963).

The model stated above has a dual:

$$\text{Minimize} \quad b_1y_1 + \cdots + b_my_m,$$

where the variables $y_1, \ldots, y_m$ satisfy the conditions

$$y_i \geq 0, \quad i = 1, \ldots, m,$$

$$a_{1j}y_1 + \cdots + a_{mj}y_m \geq c_j, \quad j = 1, \ldots, n.$$

If there is a maximum for the first problem there is a minimum for its dual and these two numbers are equal. This duality theorem is essentially equivalent to the minimax theorem of game theory (*q.v.*).

With the programming problem now expressed as minimizing an objective function, other applications come to mind. For example, there is a classical diet problem for mixing livestock and poultry feed that can be formulated in this way: If a_{ij} denotes the number of units of the jth nutrient in one unit of the ith food, c_j is the minimum amount of the jth nutrient needed for satisfactory health, b_i is the unit price of the ith food, and y_i is the number of units of this food to be purchased, then find the point $(y_1, \ldots, y_m)$ that minimizes the objective function and produces a satisfactorily mixed diet at minimum cost.

Since manual calculations by the simplex method become very laborious even for problems of modest size, computer programs for this method were introduced as soon as computers became powerful enough to handle them. By now, both the methods of solution and the computer programs for them have evolved to the point where problems of fairly large size can be handled on personal computers and problems with thousands of variables and constraints can be dealt with successfully at modest cost on large machines.

The resulting tools have greatly expanded the possible applications in many fields, including agriculture, business, government, manufacturing and service industries, transportation, and economics, and OR workers have achieved thousands of such applications. The theoretical basis for such work has also expanded similarly. By 1993, hundreds of papers were appearing yearly on both theory extensions and their important applications.

4.2 Descendant Programming Models

The value of a theory or model and its associated solution technique can be judged by the vigor with which they are extended either by theoretical developments or a widened coverage of the phenomena of reality. Thus, the ensuing value can be judged in part, first, by the scope of the phenomena that the model helps to understand and, second, by the importance of the problems the technique can deal with; but this judgment must also include, third, their fecundity in prompting the development of descendant models and techniques, that is, ones suggested by the basic model and its central technique but demanding important new approaches. The previous subsection suggests that linear programming has high value on the basis of the first two of these criteria; this subsection describes some descendant theories that support its value based on the third. In each case, there are also descendant solution techniques.

4.2.1 Convex Programming Let x be a set $(x_1, \ldots, x_n)$ of points in n-dimensional space. Then, a function $f(x)$ is a convex function if it is defined over a set of points x in a convex set and if the set of points $z \geq f(x)$ is convex in the $(n + 1)$-dimensional space (x,z).

Early investigators were able to amend the simplex method to apply to programs where the constraints and the objective function are convex.

4.2.2 Quadratic Programming A quadratic form in n variables is the sum of terms $a_{ij}x_ix_j$, where both i and j take on values from 1 to n. Such a form is positive semidefinite if its value is greater than or equal to zero for all values of the x's. By suitable transformations of the variables, it is possible to set such a form equal to the sum of squares of the new transform variables.

The transformed quadratic form can now be recognized as a convex function, which allows programs with positive semidefinite objective functions to be solved for the minimum value of this function by adjusting the methods for convex functions. A similar statement can be made for programs seeking the maximum of the negative semidefinite quadratic objective function. These special cases allow some improvements in the efficiency of the solution procedure.

4.2.3 Flow through Networks Consider a network connecting two nodes, a source and an destination, by means of a series of intermediate arcs that meet at intermediate nodes. Flows can take place in the arcs and through the intermediate nodes. Each arc has two flow capacities associated with it, one for each direction. The problem is to find the maximal flow that the network permits from the source to the destination. Efficient procedures for solving this problem are available.

It has also been generalized—for example, for a network with many sources and destinations and stipulated amounts at both, to minimize the costs of the flows that will be required for the flows from the sources to achieve the stipulated amounts at the destinations at minimum transportation cost—and suitable algorithms have been developed. This model and its associated solution algorithm have been applied, for example, to the problem of assigning children to schools.

4.2.4 Integer Programming It was recognized early that there were many attractive problems for which the variables in a program are constrained to be integers. Unfortunately, simply approaching these problems with continuous variables and their solution techniques does not work satisfactorily, so that special procedures must be devised for them.

The pioneer work in this regard was done by R. E. Gomory in 1958 (Gomory, 1991). Since then, tremendous advances have been made in developing solution algorithms, and they have been applied to numerous important problems, some quite large.

The well-known traveling salesman problem can also be formulated as an integer program. This problem arises when a salesman desires to keep his total travel distance or time to a minimum while making one visit to each of a number of cities and returning to his starting point at the end of his trip. Similar problems can occur in a wide variety of situations.

Further, this line of research has generated its own descendant models and their applications, including those for so-called mixed-integer problems (where some of the variables are continuous but others are restricted to integral values).

In cases where it is possible *a priori* to state upper and lower bounds for the maximum value, there is a branch-and-bound procedure that has had many applications. It has also been much developed since it was first set forth.

4.2.5 Other Developments As Table 3 indicates, there are a number of other descendant programming models and solution techniques. While there is not space here to describe them all, a few may be mentioned.

It can happen that a programming problem is stated such that there is no vector x that satisfies all of the constraints. If one can establish penalty costs for violating one or more of the constraints, then goal programming finds a solution that violates the constraints in such a way as to minimize the total penalty cost.

The programming structure has also been used to formulate models in which the functions are nonlinear (as, for example, in convex and quadratic programming, as mentioned earlier), and various special cases of this situation have yielded reasonably economical solution techniques.

So far, the programming formulations have treated the coefficients in the constraints as completely known. In many practical situations, however, these coefficients may not be known with precision, or may in fact be subject to random variations. Chance-constrained programming considers such cases under a few simplifying assumptions. Stochastic programming deals with more general cases.

For a modern overview of linear programming and its descendant theories, see Nemhauser *et al.* (1989).

4.3 Dynamic Programming

The word programming in the name of this subject might suggest that it is another theory that descended from linear programming, but this is not the case. Rather, dynamic programming is concerned with a sequence of decisions that must be made over time.

Unlike linear programming, which has specific models that can be solved by various techniques, dynamic programming deals with a structure and an analytic approach that can be applied to a variety of models.

The dynamic programming approach deals with problems that can be put into this structure:

1. The decision variables and their associated constraints are grouped according to stages to be considered sequentially.
2. For a given stage, the only information about previous stages relevant to selecting optimal values for the current decision variables is summarized by a quantity called the state variable.
3. For a given stage in its current state, the current decision has a forecastable influence on the state at the next stage.
4. The optimality of the current decision is judged in terms of its forecasted impact on both the present stage and all later stages.

There is a canonical form for the central recursion relation that can be developed in this way: Consider an N-stage process that is n stages from completion. Let s stand for a state of the system, S_n for the set of all possible states at the nth stage, d_n for the decision made at the nth stage, and $D_n(s)$ for the set of all the feasible values of d_n for the system in the nth state. Also for the nth state, let $R_n(s,d_n)$ be the immediate value of decision d_n and $T_n(s,d_n)$ the transformed state of the system at stage $n - 1$. If $f_n(s)$ is the value of the optimal decision at the nth stage, then we can say that it depends not only on the state the process is in at the nth stage, but also on the number of stages left to be completed. Then the dynamic programming recursion states that $f_n(s)$ is the optimum (that is, either the maximum or minimum) over all $d_n(s)$ in $D_n(s)$ of $R_n(s,d_n) + f_{n-1}(T_n(s,d_n))$ for every s in S_n.

Perhaps the most striking aspect of this procedure is that it begins with the last stage and works toward the beginning. Its advantage over the complete enumeration of all possibilities at all of the stages is that it optimizes at each stage over a limited number of decision variables.

Here are some problems that can be formulated with a dynamic programming structure: inventory rules indicating when to replenish an item and by what amount; capital budgeting for allocating scarce resources to new ventures; scheduling for routine and major overhauls of complex machinery; and formulating a long-range strategy for replacing depreciating assets. For further examples, see the classic book by Bellman and Dreyfus (1962).

4.4 Queuing Theory

Queuing is one of the commonest processes in developed societies: telephone calls arrive at an exchange, customers arrive at lunch counter, vehicles arrive at a car wash, aircraft arrive at an airport, and so on, each demanding service; when others are ahead of them, they wait in a queue until served. The theory of this process began early in this century in connection with telephony, but did not move significantly out of this context until it was adopted in the early postwar years by operations research, after which it experienced an explosive growth.

The simple examples just mentioned suggest the three aspects of a queue that are important for developing a theory of it: the arrival process, the service mechanism, and the queue discipline.

Consider the simplest case, in which the arrivals are random over time, and the service times are exponentially distributed. If λ and μ are the average arrival and service rates, respectively, then the average traffic density ρ is λ/μ. For the number N of customers in the system, the queue length Q, the waiting time W, and the total time D the customer is in the system, if we denote the probability that $Q = j$ ($j = 0, 1, \ldots$) by $Pr[Q = j]$, the average or expected number of customers in the system by $E[N]$, the expected length of the queue by $E[Q]$, the expected time a customer waits until service begins by $E[W]$, the expected total delay for a customer (waiting time plus service time) by $E[D]$, and the variance of the queue length by $Var[Q]$, then the following relations can be derived from the theory:

$$Pr[Q = j] = (1 - \rho)\,\rho^j, \quad E[N] = \rho/(1 - \rho),$$

$$E[Q] = \rho^2/(1 - \rho), \quad E[W] = \rho/(1 - \rho)\mu,$$

$$E[D] = 1/(1 - \rho)\,\mu, \quad Var[Q] = \rho/(1 - \rho)^2.$$

There are a tremendous number of other queuing processes with other assumptions about the arrival processes, the service-time distributions, and the queue disciplines, but, unfortunately, only a few yield simple formulas like those just set forth. Rather, more complicated expressions must be dealt with, approximations employed, or the queuing process simulated on a computer (Gross and Harris, 1985).

4.5 Simulation

Any theory or model is, of course, a representation—that is, a simulation of a sort—of some aspect of the phenomenon that it purports to describe. However, the term simulation here means something different: instead of representing a process by a model, it is a somewhat simplified ideal process that imitates selected aspects of the one from reality.

Consider an operational process where it is possible to subdivide it into a series of stages or steps, such as the queuing process just discussed: An arriving customer either takes a place at the end of the queue if there is one, or, if there is no queue, proceeds to obtain the desired service; whenever a service is completed, the queue, if there is one, is reduced by one waiting customer. This example can easily be simulated by hand, provided the analyst has been able first to establish a series of random arrivals and exponential service times to draw from as the simulation proceeds. However, it can also be programmed on a computer.

Similarly, many processes, such as for highway toll-collection operations, air-traffic arrivals at airports, banking service operations, or telephone ordering operations, can be simulated, either to solve problems or to see how revised procedures might work.

It is usual to represent the chosen aspects of the operations by a computer program that imitates them; OR workers usually call such a representation a simulation, but in other fields it is also called a Monte Carlo process. This procedure has been used quite often by OR workers when no simplifying theories have existed to make the analysis more compact and efficient. They do this in spite of the procedure's shortcomings: that specific assumptions about the situation have to be made instead of more general ones that a theory could incorporate, that a large number of trials (or "runs") may be needed to achieve a stable set of results, and that complicated situations may call for very large computer programs whose results may be difficult to interpret and apply.

Indeed, there is a standing—if informal—rule of action among OR workers that simulation is to be shunned if any analytic models can be made to represent the situation adequately, and that therefore simulation should be a last resort. Nevertheless, OR workers have found many situations in which simulation has been helpful to decision makers, and there has been substantial development in this field. Whereas in the early days of OR it was necessary to construct computer simulations from the basic elements and principles, by 1993 it was far more common for an analyst to adapt a commercially available simulation package. The journal *OR/MS Today* (December 1993, pp. 62–78) describes the essential properties of 55 such packages (see also Law and Kelton, 1991).

Simulation has an advantage in that it can portray to a user or client the steps in the process, thus conveying an important sense of reality. And it is a technique that can be used when analytic models cannot cover the problem situation adequately. Historically, successful simulations in OR have run all the way from relatively simple ones conducted by hand on a large sheet of paper to very complicated ones managed on large computers.

4.6. Other Theories and Techniques

As Table 3 indicates, there are many other theories and techniques that occupy a place in modern OR work; STOCHASTIC PROCESSES (for a modern overview, see also Heyman and Sobel, 1990), GAME THEORY, ARTIFICIAL INTEL-

LIGENCE, COMPUTER DATA BASES, and COMPUTER GRAPHICS are discussed elsewhere in this Encyclopedia. Space in this introductory overview does not permit others to be described, but they can be traced easily in the literature through the references and *International Abstracts in Operations Research*. For a survey of computing from an OR perspective, see Coffman *et al.* (1992).

4.7 A Perspective on Standard OR Models and Techniques

Over the last four decades, the community of OR workers primarily interested in scientific problems has not only developed many new models, but also algorithms (that is, solution techniques) for them where they were appropriate. This growing community of OR scientists has exhibited great skill and inventiveness in this process. Thus, such tools exist in many of the categories listed in Table 3 (as hinted at in the brief introductory descriptions above).

Many of these models and algorithms can be thought of as standard in the sense that they are reference points for OR workers looking at the phenomena of action programs with a view to constructing models to represent them and algorithms to obtain specific results. Thus, they can be considered to be an OR analyst's tool kit. And, of course, they form the substance of advanced treatises and courses in OR theory.

On the other hand, OR workers facing technical or practical problems can relatively seldom simply apply one of these standard tools; rather, the problem structure and its elements usually demand that the tools be adapted to the new situation. Indeed, how to be effective in adapting the tools in the kit of standard models and algorithms can be considered one of the essential craft skills of the OR practitioner.

It has been pointed out that OR comprehends work on all three classes of problems: scientific, technical, and practical. The close association of work on all three classes of problems has an important benefit for operations research: Not only do the model and algorithmic tools help practitioners quite directly, but also the process of looking at new situations and their phenomena has a feedback benefit to OR's theorists, as it often brings new modeling and algorithmic possibilities to them that might otherwise be overlooked.

5. PRACTICE

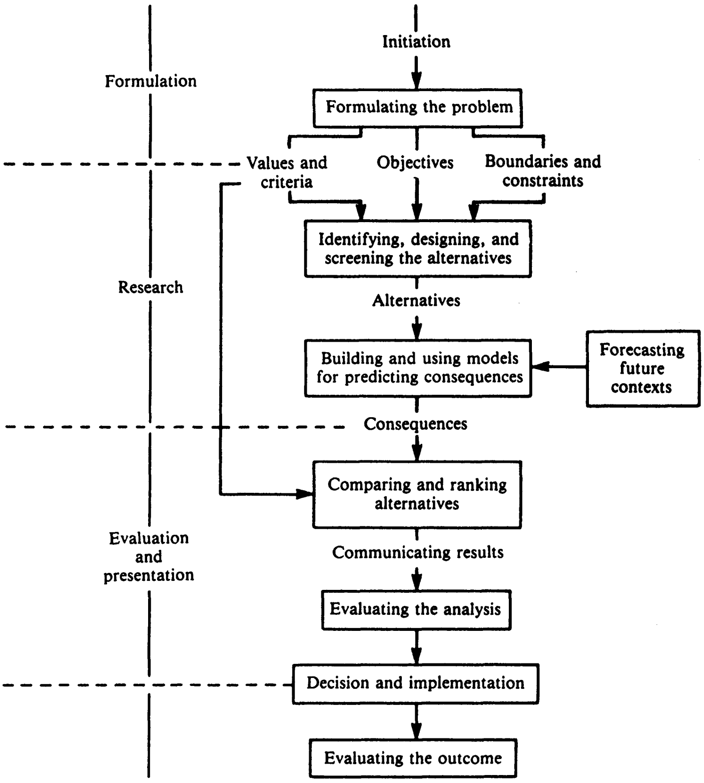
An OR analyst working to solve a practical problem is said to be involved in practice. Such work may entail, as has frequently been the case, work on technical problems when instrumentalities need to be designed to achieve desired goals, or on scientific problems when the underlying phenomena are not yet understood well enough. In any case, regardless of what subproblems the work may require solving, the overall goal of practicality qualifies the whole as being practice.

An OR analyst is often consulted when someone with a suitable responsibility or interest in an action program discerns a problem situation that needs improvement. While this person—and perhaps others—may have diagnosed the problem and may even have a belief about the course to take toward its possible solution, it is commonly the case that the forces actually at the core of the problem situation lie buried deeply enough to make such an early diagnosis questionable, and the preconceived fix inappropriate. Thus, typically it is best for the analyst—or the team of analysts if the problem situation is large and complex—to approach it with an open mind and explore it thoroughly before deducing its essential properties and using them to devise a scheme for ameliorating its undesirable aspects.

5.1 The Practice Processes

While each situation in practice may properly be regarded as unique, it is nevertheless possible to describe a central analysis process that contains elements central to most—if not all—of practice, as follows.

Figure 1 offers a synoptic view of these elements. It proceeds from the general recognition that a problem situation exists to the implementation of some policy or course of action and the evaluation of its effects. Since each situation has its own unique properties, few OR practice engagements follow such a procedure exactly—and sometimes not even approximately. However, it is common for at least some of these elements to occur during the work. Thus, Fig. 1 is not intended to be



Formulation

Evaluating the outcome

FIG. 1. Important elements in an operations research practice engagement that runs from problem formulation through research and implementation to evaluating the outcome. [From Miser and Quade (1988), p. 23; reproduced by permission.]

prescriptive; rather, it offers a suggestive structure as the basis for discussion.

5.1.1 Formulation The work begins with a thorough exploration of the problem situation. It is vital for the client and people in the action program to cooperate in this work. The purpose is to formulate the problem to address. Once this is done and the client has agreed with the analysis team on the diagnosis, it is possible to plan the work to be done.

This early work also identifies the values and criteria that should inform the choice of what eventually will be done to ameliorate the client's concerns, sets up the objectives to be sought by the solution, and agrees with the client on the boundaries and constraints that must be observed in devising it.

5.1.2 Research This stage extends the information- and data-gathering that began in the formulation stage. The findings that emerge from processing these results allow the analysis team to identify, design, and screen possible alternative courses of action that may help with the problem. Against this background, the analysis team can build models capable of deducing the consequences of adopting each of the alternatives chosen for further investigation within the framework of possible future conditions.

5.1.3 Evaluation and Presentation With estimates of the consequences in hand, the analysts may compare—and possibly rank—the alternatives against the criteria chosen earlier in the analysis, plus any new ones that may have emerged during the work. These findings must then be presented to the client and other parties at interest in a way that enables them not only to appreciate the results but also have at least a broad overview of the logic and its factual basis that produced them. These understandings, combined with the client's wider and more general knowledge of the situation, may then enable him or her to adopt a suitable policy or course of action—and, when necessary, persuade the various parties at interest to accept it.

5.1.4 Implementation and Evaluation The client, and not the analysts, must decide on what to do and how to carry it out effectively, and the client must see to the implementation and take full responsibility for it. Nevertheless, experience shows that it is very important for the analysis team, or at least some analysts who understand and appreciate what was done, to work cooperatively throughout the implementation stage.

Later, if an evaluation of the efficacy of the results is undertaken, it is also desirable for someone familiar with the input analysis to be involved.

5.1.5 Variations While it is possible to specify a core diagram of the principal elements of OR practice, it must be admitted immediately that few, if any, such engagements follow this outline exactly. Rather, since each problem situation is different, the analysis must be adapted to it. Thus, in studying a series of cases, one finds variations such as these:

1. Instead of proceeding linearly from the top to the bottom of the diagram, the work cycles from intermediate stages back to earlier ones as the research program brings new insights and fresh intermediate results that may prompt reconsidering the beginning foundations of the work.
2. Some work may be aimed more at fleshing out the client's understanding of the situation than prompting a significant change, so it may stop at one of the intermediate stages.
3. The relative effort expended in the various stages may vary tremendously from case to case: one case may have to expend its major effort in just the information- and data-gathering stage, after which what needs to be done may be fairly apparent without much further analysis. Another case may proceed fairly expeditiously through the outline of Fig. 1 and then have a very long and complicated period of work to achieve what may appear to an outsider to be the implementation of a fairly simple set of proposals.
4. In some cases, an intermediate stage may dominate the work, as a result of such factors as technical difficulty in devising proper models, major uncertainties in forecasting future conditions, complexities of the underlying situation, and so on.

In any case, the procedure outlined here as the basis for discussion must be regarded as one that has stitched together the key elements that may enter OR practice to varying extents depending on the peculiarities of the situation being analyzed.

5.2 Systems Analysis

There is a branch of operations research devoted to problems of such large scale that they almost always involve major efforts by teams of analysts drawn from a variety of disciplines in addition to operations research. In the mid-1950s, it came to be called systems analysis (in this meaning not to be confused with the same term used in the computer community). While there is a separate literature about such work (Miser and Quade, 1985, 1988; Miser, 1995), its essential properties are sufficiently close to those of OR as it is usually understood that inferences back and forth between the two kinds of work are quite appropriate.

5.3 The Relation between Analyst and Client

Based on close study in a variety of fields of the ideal relation that should exist between professional practitioner and client, Schön (1983; for a relevant summary, see Miser and Quade, 1988, pp. 508–520) advocates a "reflective contract" that works in this way: "... in a reflective contract between a practitioner and client, the client does not agree to accept the practitioner's authority but to suspend disbelief in it. He agrees to join the practitioner in inquiring into the situation for which the client seeks help; to try to understand what he is experiencing and to make that understanding accessible to the practitioner; to confront the practitioner when he does not understand or agree; to test the practitioner's competence by observing his effectiveness and to make public his questions over what should be counted as effectiveness; to pay for services rendered and to appreciate competence demonstrated. The practitioner agrees to deliver competent performance to the limits of his capacity; to help the client understand the meaning of the professional's advice and the rationale for his actions, while at the same time he tries to learn the meanings his actions have for the client; and to reflect on his own tacit understanding when he needs to do so in order to play his part in fulfilling the contract."

Not all OR practice engagements realize this ideal, of course, but successful practitioners achieve a suitable form of it in their work. In any case, the practical arrangements aimed at achieving the ideal of the reflective contract must, of necessity, be evolved in the light of the circumstances and people peculiar to each engagement. It is common, as one way of supporting this concept in practice, for a member of the client's staff to work with the analysis team throughout the OR engagement. And, of course, it is wise for the client and the analysis team to have frequent interactions as the work proceeds.

5.4 Examples of Good Practice

Fortunately for someone interested in seeking out cases of good practice, there is a convenient central source: Since 1973 the journal *Interfaces* has specialized in publishing papers on such work. Assad *et al.* (1992) offer a selection of 19 cases from this source, accompanied by discriminating discussions. Miser (1995) centers his attention on cases, and Miser and Quade (1985, 1988) accompany their general discussions of analysis principles with illustrative cases.

Two areas often associated with operations research are discussed elsewhere in this Encyclopedia: MANUFACTURING ENGINEERING, and COMPUTER-AIDED MANUFACTURING. Three areas of application had by 1994 been given overviews in handbook volumes: logistics of inventory and production (Graves *et al.*, 1993), marketing (Eliashberg and Lilien, 1993), and problems in the public sector (Pollock *et al.*, 1994).

Each year there is a muscular and carefully administered competition in the U.S. for the best papers on practice. Since 1975, *Interfaces* has published the finalist papers in this competition; since there are five or more finalists in each competition, this competition alone offers a large number of papers and a wide variety of work. For example, in recent years there have been papers on computer-aided train dispatching, planning the management of the freshwater resources of the Netherlands, how OR is used in a large petroleum company, the size and deployment of a sales force, scheduling police patrols in a major city, assigning operators in a large urban transportation system, analyzing the basis for U.S. Medicare payments to hospitals, improving passenger traffic management at a major international airline, and considering the effectiveness of a needle-exchange system as a device for reducing the incidence of AIDS among drug addicts in American cities. Two contrasting cases, the first of which won this prize, are described briefly below.

5.4.1 Improving the Distribution of Blood to Hospitals Human blood, a living tissue of unique medical value, is a perishable product. In the U.S. when this study was being done, it had a fixed lifetime during which it could legally be used for transfusion to a patient of the proper type and after which it had to be discarded; this lifetime, since extended, was 21 days.

The blood is collected in units of one pint (approximately a half liter) from volunteer donors at various collection sites such as a regional blood center (RBC). After a series of typing and screening tests, it is shipped to a hospital blood bank (HBB) in the region of the RBC. The units are then stored at the HBB, where they are available to satisfy the random daily demands for transfusions to patients. Since in general not all units demanded and assigned to a patient are used, a unit can be assigned several times during its lifetime before it is transfused or outdated and discarded.

To manage the blood resources of a region is a difficult task. The blood distribution problem is complex, because of the blood's perishability, the uncertainties of its availability to the RBC, and the random nature of the demands and usages at the HBB's. Superimposed on these complexities are the large variations in the sizes of the hospitals—and therefore their HBB's—to be supplied, in the relative occurrences of the eight different blood groups, and in the mixes of whole blood and red blood cells called for when this study was done (since then the development of other blood products has complicated matters further). Finally, on the one hand, there is the imperative of having blood available when and where needed (although elective surgery can be postponed because of a blood shortage, this act incurs additional costs for all concerned), while on the other hand there is the desire to operate efficiently and economically, and thus to avoid wasting the precious individual gifts of blood.

The two most common performance measures for an HBB are the shortage rate (that is, the proportion of days when supplementary unscheduled deliveries from the RBC have to be made to satisfy the hospital's demand), and the outdate rate (that is, the proportion of the hospital's blood supply that is discarded because of its becoming outdated). Suitable calculations convert these measures for individual hospitals to similar ones for a region.

In 1973, two analysts in the U.S., one a blood expert and the other an OR analyst, reported a study that went most of the way toward solving this problem of managing blood supplies efficiently for the Greater New York Blood Program, which supplies over two hundred hospitals. After studying the patterns of demand and supply, they were able to characterize the situation with relatively simple models that were variants of standard ones adapted to suit this new purpose. On the basis of these models they were able to devise a decision support system for an RBC that addressed these questions: What are the minimum achievable outdate and shortage rates that can be set for the region? What distribution policy will achieve these targets? What levels of supply are needed to achieve alternative targets?

The blood management system they devised was characterized by centralized management at the RBC, prescheduled deliveries to the HBB's supplemented by emergency deliveries when needed, and a distribution policy according to which some blood was rotated among the hospitals. The operation of this system is based on a programming model whose objective was to optimize the allocation of the regional blood resources while observing policy constraints.

The final step was to implement this programmed blood distribution system (PBDS) in a trial region on Long Island near New York City. The success of this trial led to the system being spread throughout the region served by the Greater New York Blood Program.

Before PBDS came into effect on Long Island, the RBC made an average of 7.8 blood deliveries per week to each hospital in the region, all unscheduled, and the outdate rate was 0.20. After PBDS was implemented, the average number of deliveries dropped to 4.2, of which only 1.4 were unscheduled, and the average outdate rate fell to 0.04, which appears to be about the lowest possible for this situation (some wastage being an inevitable consequence of the random demand and limited supply). These management improvements represented substantial cost savings.

The analysis designed the PBDS so that it could easily be adapted to other regions, and some adaptations were made.

For the prize-winning account, see Brodheim and Prastacos (1979); for an extended summary accompanied by discussions of its lessons for practice, see Miser and Quade (1985, pp. 68–79 and *passim*).

While this analysis was conducted by a team of two analysts, one with an expertise in blood properties and detailed management and the other with a background in OR, the next example involved a large interdisciplinary team led by an OR expert and including representatives of many scientific specialities.

5.4.2 Protecting an Estuary from Flooding In 1953 a severe storm in the North Sea flooded much of the delta region of the Netherlands, killing several thousand people. Determined not to allow this to happen again, the government started a program to increase the protection from floods by constructing a new system of dams and dikes. By the mid 1970s this system was complete except for the protection of the largest estuary, the Oosterschelde. Three alternatives for this last segment were under consideration: building an impermeable dam to close off the estuary from the sea, building a flow-through dam with gates that could be closed during a storm, and building large new dikes around the estuary.

In 1975, the Netherlands Rijkswaterstaat (the government agency responsible for water control and public works) and The Rand Corporation of Santa Monica, California (a research institution with substantial experience in systems analysis), began a joint project with a view to helping decide what should be done. It set out to determine the major consequences that would follow from implementing each of the three alternatives for protecting the estuary.

These consequences were grouped into eight categories: financial costs; security from flooding; effects on jobs and profits in the fishing industry; changes in recreational opportunities; savings to carriers and customers of the inland shipping industry; changes in production, jobs, and imports for the 35 industrial sectors of the national economy; changes of the populations of the species that make up the ecology of the region; and, finally, the social impacts—displacement of households and activities and significant effects on the regional economies. A major uncertainty was the severity and frequency of the super-storms that make the provisions for protection necessary.

By intention, the study did not conclude by recommending a particular alternative. Rather, it clarified the issues by comparing, in a common framework, the many different impacts of the three alternatives. The choice among them was left to the political process, where the responsibility properly resides. (To go further by trying to rank the alternatives was inappropriate—as it usually is in a complex study of policy.)

There was no dominant alternative; rather, each was found to have a major disadvantage that might be considered serious enough to render it politically unacceptable. The storm-surge barrier alternative (that is, the flow-through dam) was by far the most costly; the impermeable dam was the worst for the ecology; and the open case, with new dikes around the estuary, lacked security.

The Rijkswaterstaat supplemented this work with several special studies of its own and submitted a report to the Cabinet recommending the more costly storm-surge barrier plan to the Parliament. It was adopted in 1976, and construction was completed about a decade later.

This study was not only a major effort, involving dozens of analysts and specialties, it also developed some novel ideas about how to present multifaceted results to policy makers with divergent backgrounds and concerns. Thus, in addition to helping the Dutch government reach a decision about an overwhelmingly important problem, it broke new ground on how to carry through and present the results of such a complicated analysis. A summary volume (Goeller *et al.*, 1977) is supported by a variety of volumes on specialized contributing analyses; for an overview and comments on the professional implications of the work, see Miser and Quade (1985, pp. 89–109 and *passim*).

6. PRESENT STATE AND FUTURE PROSPECTS

There is a tendency in mature knowledge-based professions for the academic theorists to have acquired dominance over the professional view of quality, relevance, indices of prestige, and rewards (Abbott, 1988). While this force is visible in operations research, it has yet to achieve the dominance shown elsewhere. Thus, OR workers devoted to successful practice continue to be honored along with their colleagues who center their attention on solving scientific problems. The resulting mix of interests and the communication among them still can be seen as one of the OR profession's great strengths, on which much of its current success has been built.

On the other hand, the creation of a profession with an identified body of knowledge and clearly understood foci of practice, while it has produced the strengths leading to the profession's success, has also tended to inhibit its willingness to look outward to entirely new contexts in which many of society's new and pressing problems are found. Major problems seldom occur in unidisciplinary form; rather, their successful analysis demands multidisciplinary inquiry. While OR has traditionally either led or played an important part in such teams, this form of effort has not grown commensurate with the needs that exist for this form of work.

In spite of the tremendous success of the profession, both in developing theoretical tools and applying them to important problems, it has yet to develop a widely shared underlying philosophy for its work, or a well-based epistemology of practice.

Thus, the vitality of the profession in the future depends to an important extent on maintaining the balance between theory and practice, reaching out to more important and diverse problems as part of the team efforts that will be needed to address them, and developing widely shared underlying concepts as the basis for the profession's work. Some efforts to meet these challenges are being made, but it is not yet clear what their outcomes will be.

GLOSSARY

Action Program: A function, operation, activity, or response that is related to and given coherence by a human objective, need, or problem, together with the system of people, equipment, portion of nature, organizational elements, and management or social structure involved.

Algorithm: A set of rules or a procedure for solving a problem; in operations research the term usually refers to a method for obtaining numerical solutions from a model or theory.

Convex Polyhedron or Set: A set (or polyhedron) is convex if any two points in it or on its boundary can be connected by a straight line that lies in it or on its boundary.

Descendant Model or Theory: A variant or extension of an earlier model (or theory) that extends it to a new class of phenomena.

IFORS: The acronym for the International Federation of Operational Research Societies.

Linear Programming: A model, together with its solution algorithm, that seeks the maximum (or minimum) of a linear function of n variables where these variables are positive and subject to linear constraints.

Model: The term used by operations research workers for a theory.

Operations Research: The science devoted to understanding the behavior of operating systems, including nature, men, and machines, this last term including not only the artifacts of modern technology but also laws, common practices, human behavior, and social structures and customs. More briefly, operations research is the science of action programs. Its activities include work on scientific, technical, and practical problems.

OR: The acronym for operations research.

Practical Problem: A problem brought into being by recognizing a problem situation in which some aspect of human welfare could be improved and where the goal is to serve or achieve some human purpose.

Scientific Problem: A problem whose solution has the goal of establishing the properties of the object of inquiry, the ultimate function being to achieve new knowledge.

Systems Analysis: The portion of operations research devoted to addressing large-scale problems, usually with interdisciplinary teams.

Technical Problem: A problem specified by the function to be performed.

Theory: An intellectual construct representing a class of phenomena.

INTRODUCTION: GENERAL ASPECTS OF ORDER AND DISORDER

In nature, order is a recurrent theme. As such, we are conditioned to expect and recognize order in most physical systems. This experience has left us with an intuitive concept of order that, although it has served us well, requires some elaboration to be applicable in the realm of science. In most instances, order can be defined precisely in terms of mathematical concepts and be uniquely characterized using experimental probes, such as diffraction of x rays or electrons. Thus, the definition of order can be made void of subjective and/or semantic overtones. It is perhaps more difficult to rely on our intuition to define the concept of *disorder*, i.e., the *lack of order*, which appears, at first sight, to be a relative concept. However, we can find equally precise mathematical definitions of disorder. We will come back to these in the following sections so that we can expand upon the intriguing phenomenon of the transition from a disordered to an ordered state.

Undoubtedly the most apparent transition from a state of order to one of disorder is that of melting. In this case, an "ordered" crystalline state, which is stable at low temperatures, gives way to a "disordered" liquid state at high temperatures. Among several important features of this transition is the fact that the discrete translational symmetry characteristic of the crystalline state (see CRYSTALLINE STATE) is replaced by the continuous translational symmetry of the liquid. In the latter, all points in space are equivalent. The consequences of melting, in terms of physical properties, are generally quite apparent.

Other order-disorder transitions are less evident, although they also have profound effects on physical properties. In alloys, for example, and without ever abandoning the ubiquitous crystalline state, atoms of different kinds may be distributed more or less randomly (disordered state) or following a well-defined pattern in a unit cell (ordered state). Examples of these two states are schematically shown in Fig. 1 on the unit cell of a body-centered-cubic (bcc) crystalline lattice. Figure 1(a) shows a possible ordered state in which atoms of one kind (open circles) occupy all the cube corners, whereas the other type (full circles) occupy the cube centers. The crystal itself is constructed by repeating this unit which, in crystallographic terminology, is referred to as a simple cubic unit cell with two atoms per cell. We note in passing that this is the structure adopted by many ionic crystals, a typical case being cesium chloride (CsCl), and by a number of metallic systems,

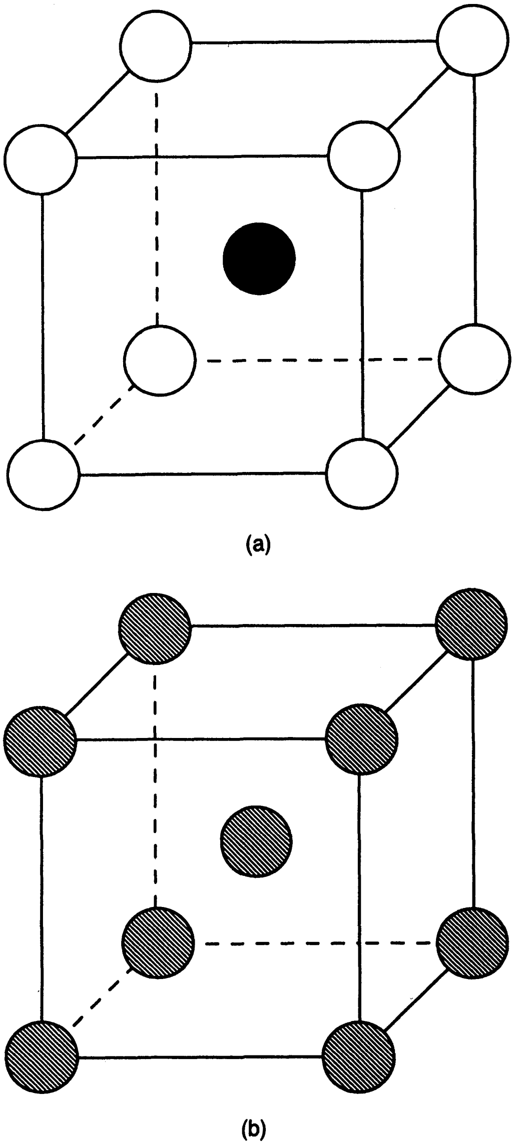

FIG. 1. Unit cells of (a) the primitive cubic CsCl and (b) the disordered bcc structures.

such as the low-temperature phase of copper-zinc (CuZn). Furthermore, since there are as many cube-corner as cube-center sites in the crystal, the numbers of Cs and Cl ions in CsCl, or of Cu and Zn atoms in CuZn, must be the same for perfectly stoichiometric compounds.

The representation of the disordered state is considerably more difficult since, strictly speaking, the unit cell is as large as the crystal itself and, thus, contains of the order of 10^{23} atoms. The disordered atomic arrangement is schematically shown in Fig. 1(b), in which an "average" atom (gray circle) is placed at each lattice site. As in the case of melting, the transition between the ordered and disordered states is also effected by temperature, and results in significant changes in the strength, brittleness, and electrical properties of the material.

Another easily recognizable order-disorder phenomenon is the spontaneous alignment of microscopic magnetic moments. Consider atoms having a well-defined magnetic moment and arranged on a crystalline lattice. At high temperatures, these atomic magnetic moments will be oriented in all possible directions such that the macroscopic, total magnetization of the crystal vanishes. Such a crystal is schematically shown in Fig. 2(a), which could be thought as a crude model of paramagnetic bcc iron. In many instances, including the ferrite phase of iron, the interactions between these atomic magnets are such that the energy of the crystal is lowered when the moments are aligned parallel to each other. Thus, the ground state, corresponding to the lowest energy state that can be achieved at low temperatures, is a ferromagnetic arrangement as shown in Fig. 2(b). In the ferromagnetic state, the macroscopic magnetization is nonzero and the material behaves as a permanent magnet (ferromagnet). Once again we find that macroscopic physical properties change significantly as the system undergoes an order-disorder transition.

There are certain common aspects to the three examples of order-disorder transitions discussed above. First and foremost is the fact that some physical property changes drastically in all cases. In melting the change is, primarily, in the ability of the material to withstand shear stresses; in the case of ordering in alloys, as in CuZn for example, it is in the strength or hardness of the material; and in the ferromagnetic transition is in the appearance of a permanent magnetic moment. These changes may reflect into either useful or detrimental properties. A material that is strong and ductile may become brittle upon ordering or, alternatively, some other desirable property, such as its electrical conductivity or high magnetic permeability, may be altered. These important practical aspects

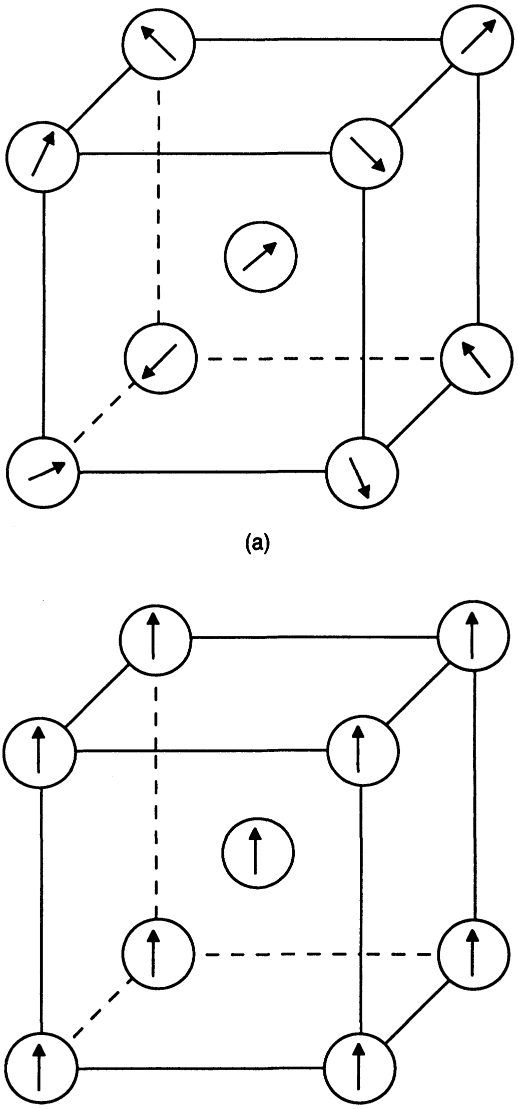

FIG. 2. Schematic representation of (a) paramagnetic and (b) ferromagnetic structures for the body-centered-cubic lattice.

have added to the interest in the study of order-disorder transitions in general terms as well as in specific systems.

A second aspect of commonality is that the transitions take place upon changes in some thermodynamic variable. In the cases discussed above, the thermodynamic variable is temperature although the transitions may also be effected by changes in pressure, in magnetic and/or electric fields, and, in the case of alloys, mixtures, or solutions, in the concentration of the different atomic or molecular components. Thus, the reasons for order-disorder transitions are to be found in the fundamental laws of thermodynamics and, more precisely, in the behavior of proper thermodynamic potentials or free energies.

A third aspect common to all order-disorder transitions is the existence of an *order parameter*. As a matter of convention, the order parameter is defined such that it vanishes in the disordered state whereas it takes finite values in the ordered state. The definition of the order parameter is not always intuitive, and it requires some characterization of the transition at hand before it can be identified. In the case of the paramegnetic-to-ferromagnetic transition, the order parameter may be defined as the macroscopic magnetization which, in turn, is the expectation value, or the average over the whole crystal, of the atomic magnetic moments. This average clearly vanishes in the paramagnetic state, where atomic magnetic moments point in all possible directions, and it is nonzero in the ferromagnetic state, where there is preferential orientation of these moments. In the case of ordering in alloys, as, for example, in the CuZn system, the order parameter is somewhat more difficult to visualize. However, a very precise definition can be given in terms of the probability of occupancy of cube-corner and cube-center sites by one type of atom, let us say Cu. Thus, the order parameter is given by the probability of a Cu atom occupying a cube-corner site *minus* the probability of a Cu atom occupying a cube-center site. Once again, the order parameter vanishes in the disordered state where Cu (and Zn) atoms occupy these two type of sites with equal probability and is nonzero in the order state. Unlike the case of the ferromagnet, where a nonzero order parameter can be put into evidence quite easily, the measurement of the order parameter in the case of the CuZn requires more sophisticated equipment such as an x-ray diffractometer.

A point of distinction between order-disorder transitions and general phase transitions is to be noted. Order-disorder transitions always involve a change in symmetry, which is not necessarily the case for phase transitions in general. For example, the translational symmetry is lost in melting, rotational symmetry is lost in the ferromagnetic state, and the *space group* of the crystal changes upon ordering in CuZn. In the last case, the crystal goes from a simple cubic structure in the ordered state to a bcc structure in the disordered state. This behavior is in contrast, for example, to the vapor-liquid phase transition at which the symmetry remains unchanged. The symmetry change characteristic of order-disorder transitions, generically known as *symmetry breaking*, usually provides powerful clues in the identification of the order parameter.

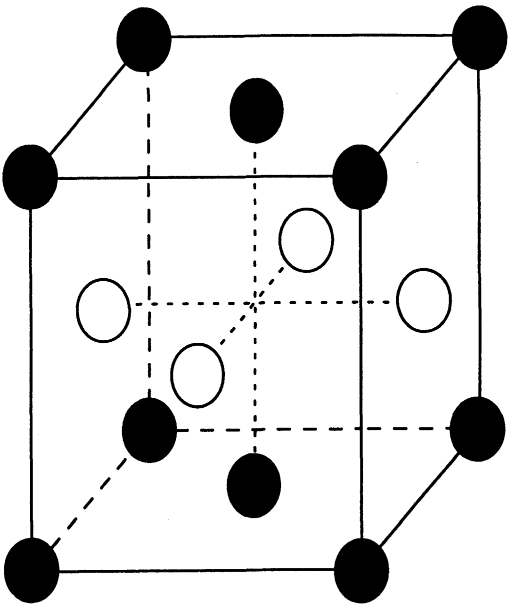
1. CHARACTERIZATION OF ORDERING

This section aims at providing a brief overview of the tools used in the description and characterization of ordering. The section begins with a few examples of ordered structures found in nature. These examples are chosen, primarily, because of their simplicity and as a way to introduce and highlight some of the relevant concepts. The elements needed for a more formal description of the ordered and disordered states are also given. The section concludes with a brief description of the thermodynamic principles involved in order-disorder transition, followed by examples of equilibrium phase diagrams.

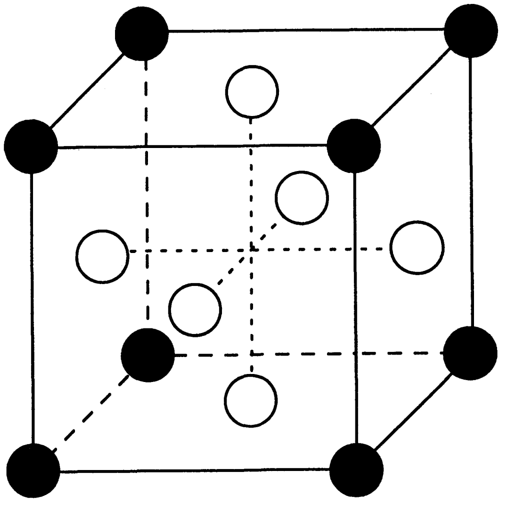
1.1 The Manifestations of Ordering: Examples

1.1.1 Ordering in Alloys: Intermetallic Compounds Like most solids at low temperatures, alloys, which are mixtures of different atomic elements, adopt a crystalline structure. The phenomenon of ordering in these systems refers to the way in which the atomic elements are distributed in the crystal sites. An example of this type of ordering was discussed above and shown schematically in Fig. 1(b) for the case of the Cu_xZn_{1-x} alloys, where x stands for the concentration of Zn in the alloy. Clearly, the structure described by the unit cell of Fig 1(b) can be achieved only if the concentration x equals 0.5, i.e., at 1:1 stoichiometry. The ordered structure in this case is an example of an *intermetallic compound*. Compounds of other stoichiometries are always possible. In the case of Cu_xZn_{1-x}, two other low-temperature intermetallic compounds are observed in addition to CuZn, occurring at stoichiometries Cu_5Zn_6 ($x = \frac{5}{11}$) and $CuZn_4$ ($x = 0.2$). Because of their crystalline nature, intermetallic compounds necessarily belong to one of the 230 possible crystallographic space groups listed in the Henry and Lonsdale (1965) (see CRYSTALLINE STATE). Although the space-group notation provides an unambiguous way of describing the symmetry of the compounds, it is not particularly helpful in describing the atomic arrangements, i.e., the ordering of atoms in the unit cell. Thus, this space-group notation is not universally used to describe ordered structures, and a variety of other conventions abound. Among them is the use of a prototype structure to refer to all structures of a certain type. In this mode, one would refer to ordered CuZn as the "CsCl structure" [see Fig. 1(a)]. It is also common practice to use a symbol in order to identify a given ordered structure. For example, in this notation, the "CsCl" structure is known as the B2 structure, and the disordered body-centered-cubic CuZn is identified by the symbol A2. The most extensive compilation of compounds to date is to be found in Villars and Calvert (1985). Pearson introduced his own notation which is also commonly used in the literature. For example, the cubic Primitive structure of CuZn becomes the cP2 structure in Pearson's notation, where the 2 shows that two atoms are present in the unit cell.

Two closely related intermetallic compounds, which are manifestations of ordering in the face-centered-cubic lattice, are those known as the $L1_0$ and $L1_2$ structures (see Fig. 3). The $L1_2$ structure is simple (primitive) cubic (space group $Pm\bar{3}m$), whereas $L1_0$-type ordering, usually accompanied by a slight tetragonal distortion, results in a simple tetragonal structure (space group $P4/mmm$). The $L1_0$ and $L1_2$ structures are representative of the simplest type of ordering that can be realized in fcc lattices. As such, they are observed to occur in a large number of alloys. For example, in the Cu-Au system, the two possible $L1_2$ structures, namely Cu_3Au and $CuAu_3$, as well as the $L1_0$ CuAu are present. Furthermore, all three intermetallic compounds go through an order-disorder transition in the solid state, adopting an fcc structure at high temperatures before, eventually, melting. In view of this, the intermetallic compounds CuAu and Cu_3Au are commonly



(a)



(b)

FIG. 3. Unit cells of (a) the body-centered tetragonal $L1_0$ and (b) the primitive cubic $L1_2$ structures.

used as the prototypes for the $L1_0$ and $L1_2$ structures, respectively.

1.1.2 Long-Period Structures

The simplicity of the low-temperature ordered compounds present in the Cu-Au systems is in sharp contrast to the appearance, around 1:1 stoichiometry and in a narrow temperature range of approximately 25 K, of an orthorhombic ordered structure known as CuAuII. Although CuAuII is closely related to the tetragonal $L1_0$ structure, the long orthorhombic lattice constant is approximately ten times that of $L1_0$. Structures such as that of CuAuII are known as *long-period* structures. At present, a seemingly endless list of long-period structures has been reported, with those related to the $L1_2$ structure of Cu_3Au being particularly common. Examples include Ag_3Mg, Cu_3Pd, Au_3Zn, Al_3Ti, etc. A characteristic feature of these long-period structures is that they can be constructed by introducing a periodic array of so-called *antiphase boundaries* (APB). Antiphase boundaries are planar defects that occur when two ordered domains meet. For example, an APB results if two otherwise identical ordered domains are displaced relative to each other by a distance that is less than a period of the lattice. Figure 4 shows schematically such an APB in the $L1_2$ structure.

A rather common structure, realized, for example, in the intermetallic compounds Al_3Ti and Ni_3Mo, can be obtained by arranging APBs every other $L1_2$ unit cell. The unit cell of the resulting tetragonal structure, known as DO_{22}, is shown in Fig. 5. The structure itself is made of a periodic distribution of APBs that separate domains two unit cells thick. Another example is the structure with periodicity 4, sometimes referred as the DO_{23}, shown in Fig. 6. DO_{22} and DO_{23} belong to a relatively simple sequence of structures for which the periodicity of the APBs is $2n$, where n is an integer number. It is interesting to note that the $L1_2$ structure corresponds to an infinite periodicity n and, thus, the terminology long-period structures is rather subjective.

More complex sequences of APBs are also

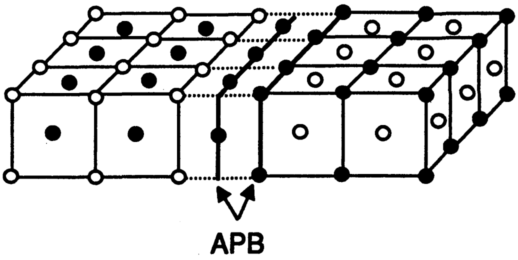


FIG. 4. Schematic representation of an antiphase boundary between two $L1_2$ ordered domains.

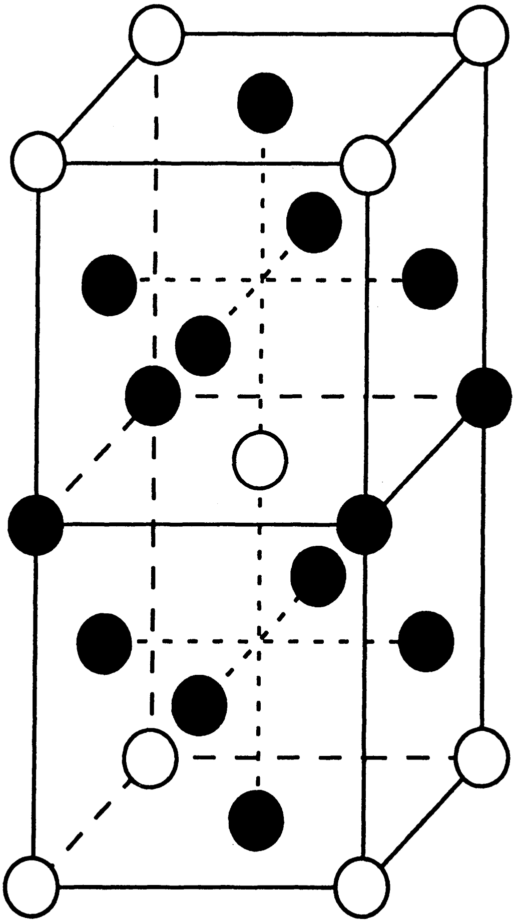

FIG. 5. Unit cell of the DO_{22} structure.

found in nature. To describe these structures a notation that indicates the sequence and the domain thickness in terms of the unit cell of the parent structure is commonly used. For example, the structure $\langle n_1 n_2 \ldots n_q \rangle$ corresponds to a sequence in which a domain of thickness n_1 is followed by an antiphase domain of thickness n_2, etc. As an example, the unit cell of the $\langle 211 \rangle$ ordered structure reported, for example, in the Pt_3V system is shown in Fig. 7.

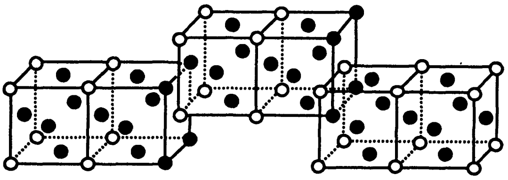

FIG. 6. Unit cell of a long-period structure generated by antiphase boundaries with periodicity 4.

1.1.3 Ordering in Low-Dimensional Systems When a physical phenomenon is strictly constrained to a surface, an interface, or an atomic plane in a crystal, the system may be construed as two dimensional. This reduced dimensionality has important consequences on general physical behavior and, in particular, on order-disorder transitions. The interest in the study of low-dimensionality systems is twofold. First, the physical understanding of phase transitions in two-dimensional systems is on very solid ground. For some simple models, such as the Ising model of two-dimensional ferromagnets, analytical results are known. Thus, these low-dimensional systems offer an excellent opportunity to test our most fundamental physical laws, models, and/or theories.

On the practical side, surfaces and interfaces are dominant in engineering systems and structures. For example, a modern microelectronics device is typically composed of several layers of different materials such as semiconducting silicon, noble metal gold, and transition metals—e.g., tungsten, titanium, and nickel—in close contact with each other. Surfaces also play a key role in friction, wear, and fracture of materials as well as in the performance of catalysts, adhesives, and composites and in biomaterials used for implants and prosthetics.

The order-disorder transition at a surface, for example, is generally found to differ considerably from that in the bulk. In many instances it is seen that, while the bulk undergoes a discontinuous or abrupt order-disorder transition, the surface orders continuously in the characteristic fashion of second-order transitions. This is the phenomenon of surface disorder or wetting, whereby a layer of the "disordered" or high-temperature phase develops at the surface as the transition temperature is reached from below. In the context of the solid-liquid transition, surface disorder is closely related to the phenomenon of premelting in which the surface region is seen to lose crystalline order at temperatures several degrees below the melting temperature of the bulk. The phenomenon of surface ordering has also been reported in ferromagnetic materials. In this case, the surface magnetization remains fi-

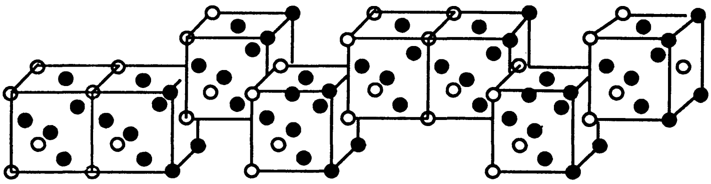

FIG. 7. Schematic representation of the ⟨211⟩ long-period structure.

nite at temperatures above the Curie temperature of the bulk.

The surface behavior in intermetallic compounds is governed by the interplay between at least one order parameter and the surface concentration. Furthermore, the symmetry breaking observed in the order-disorder transition is now constrained by the surface geometry and the crystallographic relation between the surface and the bulk. Consequently, surface-ordering phenomena and behavior in intermetallics are more complex than in the bulk. A case in point is the behavior of the (110) surface of Cu_3Au, for which two different surface-ordering transitions are reported to occur. This is in contrast to the single disorder-$L1_2$ transition taking place in the bulk at 663 K. Figure 8 depicts the atomic arrangements for each of the (110) surface phases, labeled 2x1 and 4x1, found in Cu_3Au. Note that perpendicular to the surface, the Cu_3Au crystal is made of alternating pure Cu and mixed (equiatomic) Cu-Au (100) planes. Thus, the 2x1 structure corresponds to a surface termination at a mixed (110) plane, whereas the formation of the 4x1 structure requires segregation of Cu to the surface.

Occasionally, a system is found where the order-disorder transitions can be described as a relatively simple two dimensional system. One such case is provided by the ordering of oxygen in the superconducting oxides, as exemplified by the celebrated $YBa_2Cu_3O_{6+x}$ system. The ordering of oxygen takes place, primarily, on one type of crystallographic plane. This ordering drives an important structural transition in the oxide from a high-temperature tetragonal structure to a low-temperature orthorhombic structure. The unit cells of both the tetragonal and orthorhombic structures are shown in Fig. 9 for the stoichiometric compound $YBa_2Cu_3O_7$. In the high-temperature tetragonal phase, shown in Fig. 9(a), the O1 and O5 oxygen sites are occupied with an equal probability of $\frac{1}{2}$, whereas the sites O2 and O3 are equivalent and occupied with probability 1. In the orthorhombic phase, Fig. 9(b), the O1 sites are now occupied with probability 1, leaving the O5 sites empty. In reference to the discussion of ordering in alloys, note that the $YBa_2Cu_3O_7$ system is

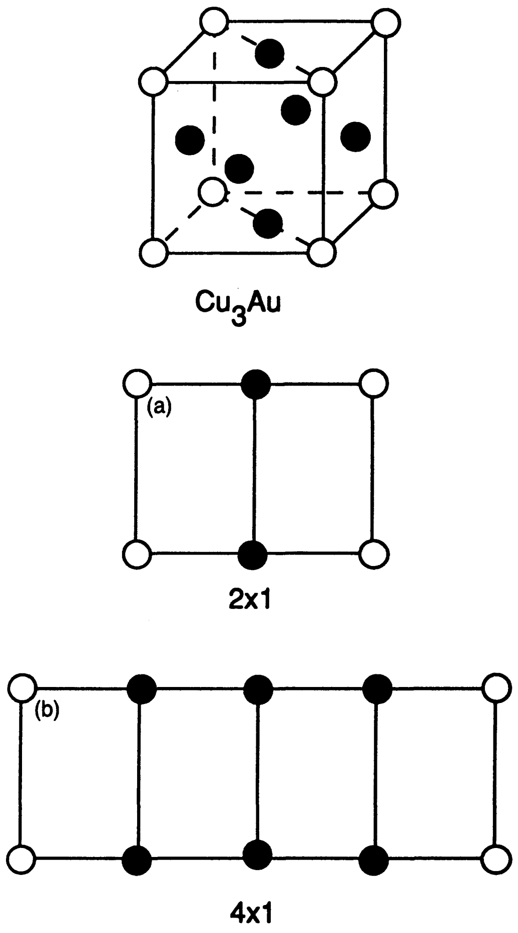

FIG. 8. Two-dimensional unit cells of ordered structures observed in the (110) surface of Cu_3Au. (a) The ordered structure with periodicity 2x1 appears at a temperature of 654 K, slightly lower than the bulk transition of 660 K due to surface segregation effects. (b) The transition to a 4x1 structure occurs at approximately 425 K.

equivalent to that of a binary alloy in which the ordering species are vacant sites and oxygen ions. A number of possible ordered structures have been reported in $YBa_2Cu_3O_{6+x}$, a fact that reflects the relative complexity of the oxygen-oxygen interactions. However, two of the most prominent structures can be easily understood in terms of a simple model based on the repulsion between neighboring oxygen ions, coupled with an effective attraction between oxygen ions mediated by a Cu atom. The two-dimensional unit cells for these structures are shown in Fig. 10, where the repulsive interactions between nearest- (V_1) and next-nearest-neighbor (V_2) oxygen atoms and the attractive Cu-mediated interaction (V_3) are also shown.

The use of simple models base on short-ranged atomic interactions has traditionally played an important role in the classification and prediction of ordered structures in both two- and three-dimensional systems. For these models, the enumeration of the ordered states with the lowest energy, generically known as ground states, can be cast in the form of the classical linear programming problem of enumerating vertices of a convex polyhedron (see below).

1.2 Formal Description of Order

1.2.1 Occupation Numbers and Correlations in Crystals A useful concept in the description of order in crystalline systems is

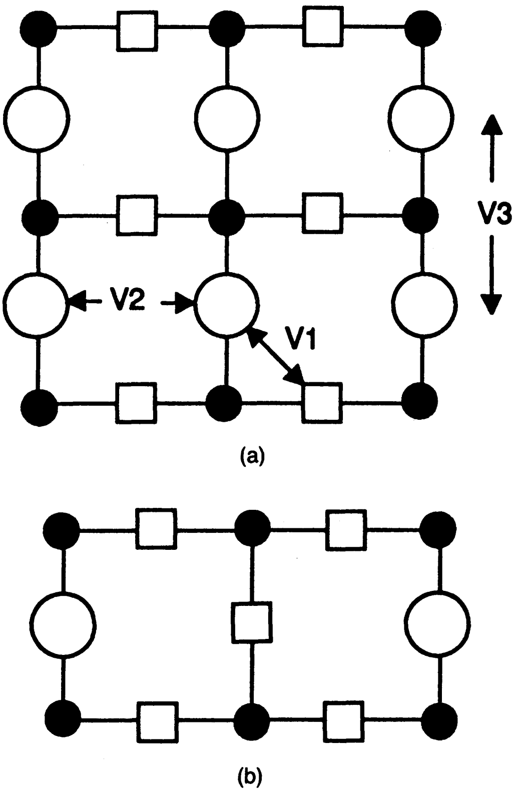

FIG. 10. Two-dimensional representation of oxygen ordering in the basal plane of the $YBa_2Cu_3O_{6+x}$ system corresponding to orthorhombic structures observed around (a) $x = 1$ and (b) $x = 0.5$.

that of an occupation number. In a binary alloy, for example, the occupation number σ_i takes two values, let us say $+1$ and -1. Each value of the occupation number indicates the atomic species located at the particular lattice site, which is labeled by the index i. The concept can be extended so that the occupation number refers, for example, to any number of atomic species, to the direction and magnitude of atomic magnetic moments, or, as in the case of the superconducting oxides discussed above, to vacant or occupied sites, A microscopic state of the system in which the identity of each atom at each crystal site is known can be fully specified by an N-dimensional vector $\boldsymbol{\sigma} = \{\sigma_1, \sigma_2, \ldots, \sigma_N\}$, where N stands for the total number of sites in the crystal. The total number of possible arrangements of A and B atoms, i.e., microstates, in a crystal with N lattice sites is 2^N.

A physical description of the system settles for a much less detailed knowledge in which only expectation values, or averages based on the equilibrium probability distribution, of certain key quantities are known. The calculation of such averages falls within the realm of statistical mechanics and thermodynamics and is essential for the study of the effect of temperature, pressure, and other thermodynamic variables on the order-disorder transition.

For a binary system, the average of the occupation number, denoted $\langle \sigma_i \rangle$, depends only on the concentration of each atomic species. If σ_i equals 1 for A atoms and -1 for B atoms, then $\langle \sigma_i \rangle = x_A - x_B$, where x_A and x_B are the concentrations of A and B atoms, respectively. The expectation value $\langle \sigma_i \rangle$ determines the composition of the binary alloy, but conveys no information on the state of order of the system. Some information regarding the atomic arrangement is provided by the pair correlation function $\langle \sigma_i \sigma_j \rangle$. These pair correlations depend strongly on the distance between sites i and j in the crystal. Note that for the perfectly ordered CuZn structure [Fig. 1(a)], the nearest-neighbor pair correlation equals -1, i.e., nearest-neighbor pairs are made of different atomic species, whereas it equals $+1$ for next-nearest neighbors in which case the two atoms are of the same type. On the other hand, for a random atomic distribution (totally disordered), the pair correlations vanish for 1:1 stoichiometry ($x_A = x_B = 0.5$). This stems from the fact that, for a random distribution, averages of products of the occupation numbers equal products of the averages; i.e., $\langle \sigma_i \sigma_j \rangle_{\text{rand}} = \langle \sigma_i \rangle \langle \sigma_j \rangle = (x_A - x_B)^2$.

The pair correlation functions contain enough information to distinguish between ordered and disordered states, although the characterization is not complete. For a complete description of the ordered state, all possible correlation functions are needed. The complete set of correlation functions includes averages of products of occupation numbers located on all possible sets of crystal sites. These sites can be visualized as forming well-defined geometrical figures, or clusters. In general, for a cluster α composed of crystal sites $\{i,j,\ldots,k\}$, i.e., $\alpha = \{i,j,\ldots,k\}$, the correlation function ξ_α is given by

$$\xi_\alpha = \langle \sigma_i \sigma_j \ldots \sigma_k \rangle.$$

As implied above, a full description of partially ordered and partially disordered states requires the characterization of an infinite number of correlation functions. Since, in practice, this cannot be achieved, approximations to the problem are called for. One approach consists of describing correlation functions up to a maximum cluster size. In this cluster approximation, the state of order is described by a finite set of correlation functions $\{\xi_\alpha\}$ corresponding to each of the subclusters of the maximum cluster. For example, a regular tetrahedron cluster made of nearest-neighbor sites is commonly used to describe ordering in the fcc lattice. At this level of approximation, four correlation functions are involved corresponding to the point, pair, triangle, and tetrahedron clusters. These clusters are shown schematically in Fig. 11. In general, the M-dimensional space spanned by the finite set of correlation functions ($M = 4$ for the tetrahedron approximation in the fcc lattice) is known as the configurational space of the system; i.e., any state of partial order corresponds to a point in this space. These M correlation functions are also subject to linear geometric constraints. For example, if the point correlation function $\xi_1 = \langle\sigma_1\rangle$ in a binary system is close to 1, implying that the system is made up almost entirely of A atoms, then the nearest-neighbor pair correlation function ξ_2 is also constrained to being close to 1. It can be shown that these constraints are linear, and that the space spanned by the correlation functions is a convex configurational polyhedron.

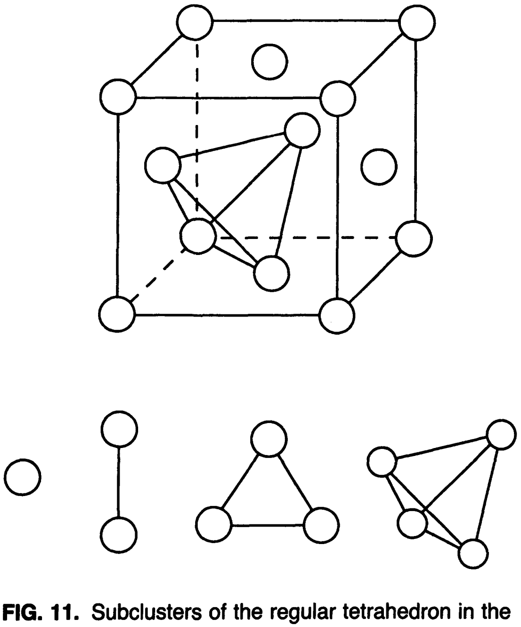

FIG. 11. Subclusters of the regular tetrahedron in the fcc lattice.

The cluster description of order is particularly useful for studying model systems with relatively short-range interactions. For these models, the expectation value of the energy is exactly given by a linear combination of correlation functions:

$$\langle E\rangle = \sum_{\beta\subseteq\alpha} V_\beta \xi_\beta,$$

where the sum is carried over all the subclusters β of the maximum cluster α, and where the coefficients V_β are known as *effective cluster interactions*. Since the energy is linear in the correlation functions and the configurational polyhedron is convex, it follows that the ground states are given by the vertices of the configurational polyhedron. Thus, a ground-state search is equivalent to finding all such vertices, itself a classical problem in linear programming. This procedure, although trivial in low dimensions (two or three), becomes rather cumbersome when the number of correlation functions is large, as would be the case for physical systems with long-range interactions.

The approximate description of order using finite clusters has been useful to describe and classify order structures in real systems. For example, a ground-state search for the fcc lattice with nearest- and next-nearest-neighbor effective interactions results in the structures shown in Fig. 12. In this simple model, the relevant parameter is the ratio R of first- to second-neighbor effective interactions. For example, for negative values of R, the model predicts the commonly observed A_3B ($Pm\bar{3}m$, Cu_3Au, $L1_2$) and AB ($P4/mmm$, CuAu, $L1_0$) structures. For $0 < R < 0.5$ the ground states are those labeled A_2B_2 ($I4_1/amd$), A_2B ($Immm$, Pt_2Mo), A_3B ($I4/mmm$, $TiAl_3$, DO_{22}) and A_5B. Finally, for R larger than 0.5, the ground states are indicated as AB ($R\bar{3}m$, CuPt, $L1_1$) and A_2B. The labeling scheme in Fig. 12 gives first the compound formula, which is followed, if available, by the space group, the prototype structure, and the corresponding structural symbol. This simple one-parameter model predicts a relatively large number of ordered structures, some of which are observed in nature. It should be noted that the number of possible ordered structures grows exponen-

tially with the range of interactions, underscoring the richness of ordering phenomena in crystalline systems.

1.2.2 Long- and Short-Range Order The state of perfect order and that of total disorder are idealizations seldom realized in nature. The correlation functions introduced above provide a hierarchical framework to measure states of partial order (or disorder) that are relevant in the physical world.

In the disordered state, the correlation functions measure deviation from randomness and, as such, they provide an infinite set of what are generically known as *short-range order* (SRO) parameters. In practice, slight modifications of the correlation functions, the so-called Warren–Cowley SRO parameters, are used. These parameters have been adopted almost universally since they can be measured rather precisely using x-ray or neutron diffraction techniques. For a binary system, the Warren–Cowley SRO parameters are defined by

$$\alpha(r_{ij}) = \frac{\langle\sigma_i\sigma_j\rangle - \langle\sigma_i\rangle\langle\sigma_j\rangle}{(1 - \langle\sigma_i\rangle\langle\sigma_j\rangle)},$$

where r_{ij} stands for the distance between crystal sites i and j. These SRO parameters vanish for the random state, and are normalized in such a manner that they equal 1 for $r_{ij} = 0$, i.e., when the crystal sites are equal and, thus, $\sigma_i^2 = 1$.

If in the disordered state atoms of the same type have the tendency to cluster together, then the pair correlations for short distances will be positive and larger than the value corresponding to a random atomic distribution. Thus, in this case, the SRO parameters are positive. If the system has an ordering tendency, however, the SRO parameters will oscillate with distance, being negative (positive) for distances at which atoms of different (same) types are preferentially found. In the disordered state, the amplitude of these oscillations decreases with distance, vanishing for sufficiently large separation between the two crystal sites. That is to say, the atomic occupations of distant sites are uncorrelated.

The SRO parameters are functions of the thermodynamic state of the system and, therefore, change with temperature, pressure, and composition. At sufficiently high temperatures the system becomes increasingly disordered, and the Warren–Cowley parameters tend to zero. On the other hand, as the temperature is lowered, and, let us say, an order-disorder transition is approached, the oscillations of the SRO parameters in the disordered state persist over longer distances, decaying much more slowly with distance. At and below the order-disorder transition, the characteristic decay distance becomes infinite. Thus, *long-range order* (LRO) sets in and the atomic occupancy of distant sites is now strongly correlated.

The onset of LRO at the transition is described, appropriately enough, by one or more LRO parameters. As is the case with short-range order, there is significant latitude in the choice of LRO parameters. However, all practical definitions are related to the symmetry breaking that takes place at the transition. In particular, the change of symmetry taking place at the transition establishes uniquely the number of order parameters needed to describe the transition. It is common practice to group the different order parameters into the components of a vector, and to refer to the number of components as the dimension of the LRO parameter.

Returning to the example of CuZn, consider the transition from a disordered bcc structure [Fig. 1(b)] to the ordered $B2$ structure [Fig. 1(a)]. In addition to being endowed with the translational symmetry of the simple cubic lattice, the disordered system is invariant to a translation by a vector equal to half the cube diagonal, i.e., $(a/2)[1,1,1]$, where a is the cubic lattice constant. This symmetry element is lost in the ordered $B2$ structure, for which the cube-corner and cube-center sites are not equivalent. Thus, the expectation values of the occupation number at the cube corners, $\langle\sigma_0\rangle$, and at cube centers, $\langle\sigma_1\rangle$, are different. In this case, the transition is described by a unique LRO parameter, which can be defined as $\eta_1 = (\langle\sigma_1\rangle - \langle\sigma_0\rangle)/2$. This one-dimensional order parameter is nonzero in the ordered state, vanishing identically in the disordered state where $\langle\sigma_0\rangle = \langle\sigma_1\rangle$.

The concept of sublattice is often used to emphasize the nonequivalence of different sites in the unit cell of the ordered structure. A sublattice, which is not necessarily a Bravais lattice, connects all equivalent sites in a crystal. In the $B2$ structure, two interpenetrating simple cubic sublattices, displaced from each other by half the cube diagonal, are easily identified [see Fig. 1(a)]. The independent averaging of the occupation numbers on each sublattice leads naturally to a nonzero order parameter in the ordered state. This procedure is referred to as sublattice averaging and is commonly used in the thermodynamic description of the ordered state.

Sublattices and the associated LRO parameters may be defined for any ordered structure. Knowledge of the space group of the low-temperature structure uniquely determines the number of nonequivalent sites within the unit cell. These nonequivalent sites are known as Wyckoff positions and are listed in Henry and Lonsdale (1965), together with all symmetry elements, for all the 230 space groups. If the number of Wyckoff positions for a given structure is $m + 1$, the dimensionality of the LRO parameter is m, and the different components are given by

$$\eta_k = (\langle\sigma_k\rangle - \langle\sigma_0\rangle)/2 \quad (k = 1,\ldots,m).$$

For example, the number of nonequivalent sites in the primitive cubic $L1_2$ structure is 2, so that its LRO parameter is of dimension 1. On the other hand, the unit cell of the body-centered-tetragonal DO_{22} structure, with space group $I4/mmm$ (Fig. 5), contains three different Wyckoff positions, and the dimension of the LRO parameter is 2.

1.2.3 Ordering at Finite Temperatures

The transition between the ordered and disordered states is governed by the behavior of a thermodynamic potential or free energy. The relevant free energy is dictated by external constraints. For example, at a fixed temperature, the relevant thermodynamic potential is either the Helmholtz or the Gibbs free energy, depending on whether the volume or the external pressure is kept constant.

The fundamental thermodynamic principle involved in the study of phase stability and order-disorder transitions is that, under the proper set of conditions, the free energy is minimum for the equilibrium phase. Although the actual determination of the free energy, either experimentally or theoretically, may in itself be a rather involved task, much can be learned from general principles. An elegant and relatively simple theory of order-disorder transitions was advanced by Landau and Lifshitz (1969) on the basis of the expansion of the free energy in powers of the LRO parameter. Subsequent developments have established that the free energy is singular at the transition and, thus, such expansions are not generally valid. Nevertheless, the theory of Landau and Lifshitz is frequently used since it captures the most important aspects of order-disorder transitions.

For the case of a one-dimensional order parameter η, a fourth-order Landau and Lifshitz expansion is of the form

$$F(\eta,T,P) = F_0(T,P) + A(T,P)\eta^2 + B(T,P)\eta^3 + C(T,P)\eta^4,$$

where $F_0(T,P)$ is the free energy of the disordered state, i.e., for $\eta = 0$, and the coefficients $A(T,P)$, $B(T,P)$, and $C(T,P)$ are, in general, functions of temperature (T) and pressure (P). A fourth-order expansion of the free energy is usually sufficient to describe the thermodynamic behavior of the system provided that the coefficient $C(T,P)$ is positive. In the event that the fourth-order coefficient is negative, the free-energy expansion must be carried out to, at least, the next even power with a positive coefficient. In general, the calculation of the expansion coefficients is a difficult task that requires the adoption of a specific model for the atomic interactions. However, some general thermodynamic properties can be established using symmetry and group-theoretical arguments. In particular, Landau and Lifshitz studied the conditions under which the coefficient B in the free-energy expansion vanishes. Their analysis led to a set of celebrated rules for the occurrence of continuous phase transitions.

A vanishing third-order coefficient B, which is solely determined by the symmetry of the ordered phase, implies that the free energy is an even function of the LRO parameter, i.e., $F(\eta,T,P) = F(-\eta,T,P)$. Thus, assuming $C > 0$, a plot of the free energy vs the LRO parameter looks as shown schematically in Fig. 13(a). The several curves in the figure correspond to free energies at temperatures above, at, and below the order-disorder transition temperature T_c. At high temperatures, the minimum in the free energy occurs at $\eta = 0$ and the equilibrium state is disordered. At the transition temperature, the second-order coefficient $A(T,P)$ vanishes, becoming negative below T_c. Thus, below T_c, two minima in the free energy develop at finite values of η, indicating that the ordered state is the equilibrium thermodynamic phase. These two states, with equal free energies and ordered parameters of opposite signs, correspond to the same thermodynamic phase. This can be seen, for example, for the $B2$ structure shown in Fig. 1(b). In this case, a change in the sign of the order parameter corresponds to a simple exchange of cube-corner with cube-center sites. This operation leaves the $B2$ structure invariant and, therefore, symmetry imposes the requirement that the free energy be an even function of the LRO parameter; i.e., $F(\eta,T,P) = F(-\eta,T,P)$. In turn, this implies the vanishing of the coefficient B in the free-energy expansion.

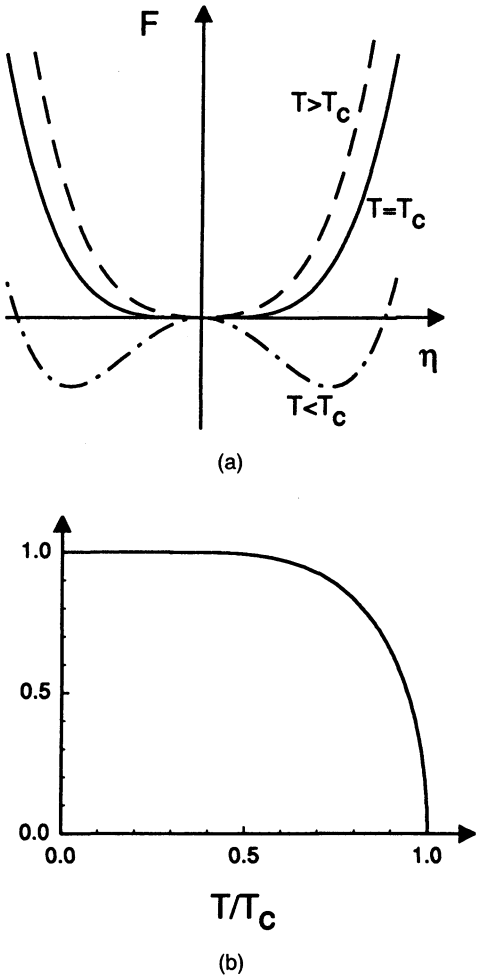

FIG. 13. Schematic (a) free-energy curves and (b) equilibrium long-range order parameter for systems displaying a second-order phase transition.

A plot of the value of η at which the minimum in the free energy takes place vs temperature is shown in Fig. 13(b). Note that the LRO parameter vanishes continuously as T_c is approached from below. This behavior of the LRO parameter is characteristic of *second-order* phase transitions.

The situation is significantly different when the third-order coefficient B in the free-energy expansion is nonzero, as shown in

Fig. 14. The free-energy curve may develop a local minimum at temperatures above the order-disorder transition. At the transition temperature, the LRO parameter jumps discontinuously from zero to a finite value corresponding to the ordered state. In this case, the order-disorder transition is said to be of *first order*.

For alloys, intermetallic compounds, and mixtures, the free energy is also a function of the concentrations of the different atomic or molecular components. For second-order transitions this concentration dependence of the free energy does not significantly alter the picture of order-disorder transitions given above. This is because at a second-order transition the compositions of the ordered and disordered phases are equal. For first-order transitions, however, an additional complication arises since the transition may now take place between phases of different average compositions. The situation is illustrated in Fig. 15, which shows schematic free-energy curves as a function of concentration for ordered and disordered phases in a binary alloy. The equilibrium condition of minimum free energy translates into a common-tangent rule that is also shown schematically in Fig. 15. The two points of tangency in Fig. 15 define three distinct regions: (I) a region where the disordered phase is stable; (II) a two-phase region where ordered and disordered phases coexist; and (III) a region where the ordered phase is stable. The information on the stability and coexistence between phases is commonly collected into graphs called *phase diagrams*. These phase diagrams are graphic representations of the temperature and composition ranges of stability and coexistence of all the thermodynamically stable phases in a given system. For example, the phase diagram of the Cu-Zn system is shown in Fig. 16, where the single-phase fields of the solid phases are indicated by Greek letters. The unlabeled regions in the figure correspond to two-phase fields, within which the adjacent phases coexist. The assignation of Greek letters to the stable phases is arbitrary and bears

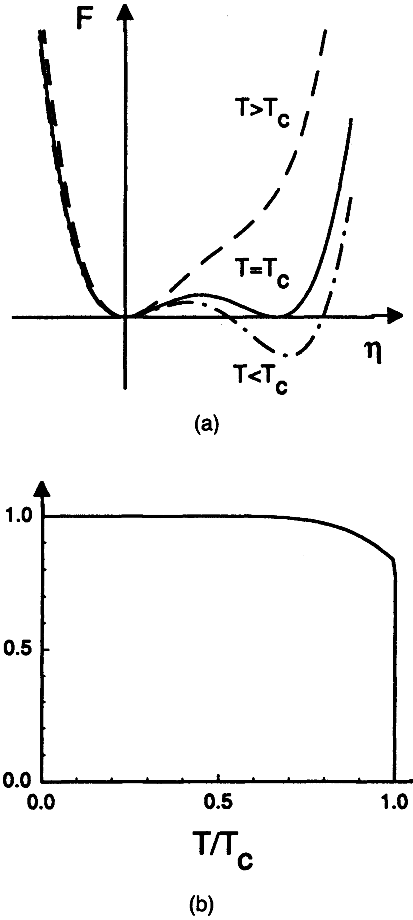

FIG. 14. Schematic (a) free-energy curves and (b) equilibrium long-range order parameter for systems displaying a first-order phase transition.

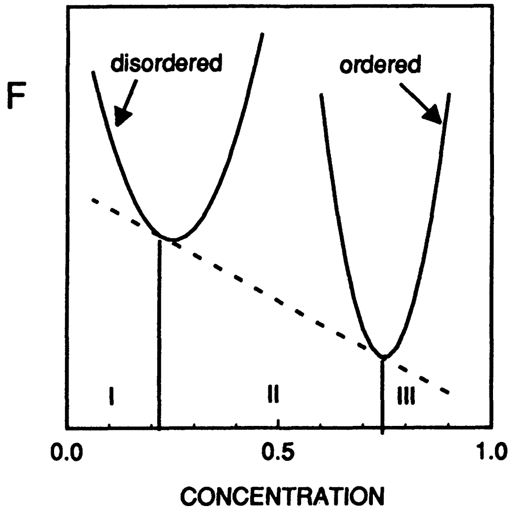

FIG. 15. Schematic free-energy curves vs composition for the ordered and disordered phases of a binary alloy that undergoes a first-order transition. The ordered and disordered phases are stable in regions I and III, respectively. For concentrations in region II both phases coexist.

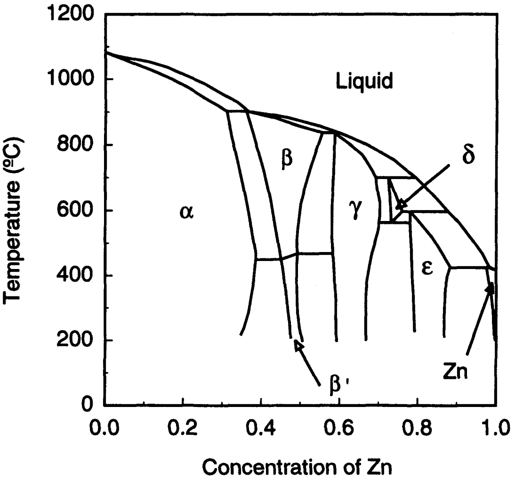

FIG. 16. Equilibrium phase diagram for the Cu-Zn system.

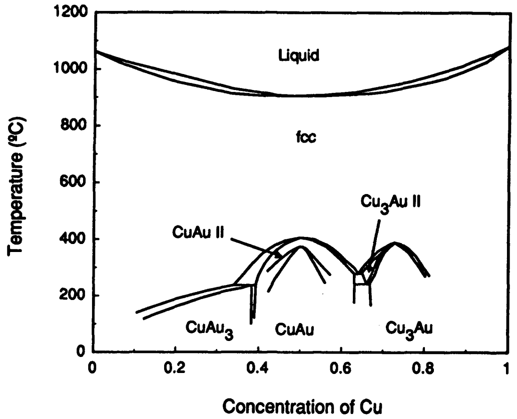

FIG. 17. Equilibrium phase diagram for the Cu-Au system.

no relation to the structure or to the symmetry of the phases. The phase indicated as α is a disordered fcc alloy. As the concentration of Zn increases beyond approximately 0.3, the α phase transforms, via first-order transitions, either to a bcc alloy (β) at high temperatures, or to an ordered *B*2 structure (β') at lower temperatures (Pearson's symbol *cP*2). The two intermetallic compounds labeled γ and ε have Pearson's symbols *tP*4 and *hP*2, respectively. The δ phase, occurring in a small concentration region at high temperatures, also has the *B*2 structure. At the Zn end of the phase diagram, the equilibrium phase is a hexagonal-closed-packed solid solution, with relatively low solubility of Cu.

Phase diagrams convey, in a concise and efficient manner, a great deal of information on the stability of different phases, on the occurrence of order-disorder transitions, and on the nature of these transitions. A well-known example is the CuAu phase diagram shown in Fig. 17. In this case, the system crystallizes from the liquid into a disordered fcc phase. As seen in the phase diagram, this disordered phase is stable over the entire composition range of the alloy. As the temperature is lowered, however, the phase diagram indicates that the disordered Cu-Au alloys undergo several ordering transitions. Around a Cu concentration of 0.25, the transition is from fcc solid solution to the $CuAu_3$ intermetallic compound that has the $L1_2$ structure. For larger concentrations of Cu the complexity and richness of the phase diagram increases: near a 1:1 stoichiometry the disordered solid solution first transforms into the CuAuII long-period structure, changing, at slightly lower temperatures, into the short-period CuAu ($L1_0$) phase. A similar sequence of transitions is found for higher Cu concentrations: the disordered phase also transforms to a long-period structure, labeled Cu_3AuII in Fig. 17, which, in turn, transforms to the Cu_3Au ($L1_0$) structure at lower temperatures. Finally, since all phases in Fig. 17 are separated by two-phase regions, it also follows from the phase diagram that all transitions are of first order.

2. SUMMARY

A few examples of well-known physical systems have been selected with the idea of exposing the fundamental and common aspects involved in the phenomenon of order-disorder transitions. Some well-known examples of ordering systems are followed through, starting with a description of their structure and symmetries and ending with a description of their equilibrium phase diagrams. The expectation is that readers will be able to transfer the knowledge gained here to other cases of interest since, quite clearly, a full treatment of the subject matter is beyond the scope of this article. There are excellent monographs, articles, and compilations that bring together the collective effort of over 50 years of intense research on order-disorder transitions. Some of these are listed below and recommended for further reading.

On a general note, it is perhaps worth while to reiterate two points that hopefully follow from the previous sections. First is the fact that the transition from order to disorder is accompanied by drastic changes in physical properties. Second, the diversity of ordered structures, either seen in nature or yet to be discovered, appear, if not endless, extremely rich. Consequently, understanding and controlling order-disorder transitions will continue to the be a key element in our efforts to tailor physical systems with desired properties.

INTRODUCTION

The first generation of electromagnetic radiation was by H. Hertz in 1886, but the electronic age was born with the invention of the triode vacuum tube by L. de Forest in 1906. Vacuum-tube oscillators, in their many forms (triodes, klystrons, magnetrons, gyrotrons, backward-wave tubes, etc.), were the only sources of coherent electromagnetic radiation until the transistor was invented in 1947. In the last 40 years, the transistor and other solid-state devices have replaced the vacuum tube in all applications requiring power levels of less than a few watts at frequencies up to the order of 100 GHz. The vacuum tube cannot compete with the small size, cost, and heat dissipation of the transistor. However, for high-power applications, the vacuum tube is difficult to challenge, with relativistic free-electron oscillators, for example, being able to generate very large amounts of power from microwave to optical frequencies.

The development of vacuum-tube oscillators was driven by the challenge of extending their frequency of operation to higher and higher frequencies. The development of transistor and solid-state oscillators has been driven by circuit integration, cost, size, and heat dissipation. Both the vacuum tube and transistor are conduction-current devices and, hence, share basic physics problems and limitations.

In this article, the point of view taken is that only two types of amplifier oscillators exist: conduction current and polarization current. This point of view permits one to concentrate on the basic oscillator physics of each class rather than to regard various oscillators as fundamentally different.

1. OSCILLATOR PRINCIPLES

Sinusoidal oscillators in general consist of an amplifier with positive feedback and a resonator. Two classes of amplifiers exist: those based upon conduction currents and those based upon polarization currents. From a circuit's point of view, conduction-current devices can be two-port (three-terminal) or one-port (two-terminal), while polarization-current amplifiers are two-terminal devices.

The basic elements of a two-port oscillator are illustrated in Fig. 1. Power conservation for the steady state requires that

$$G\mathcal{P}_i = \mathcal{P}_i + \mathcal{P}_R + \mathcal{P}_F + \mathcal{P}_o, \tag{1}$$

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

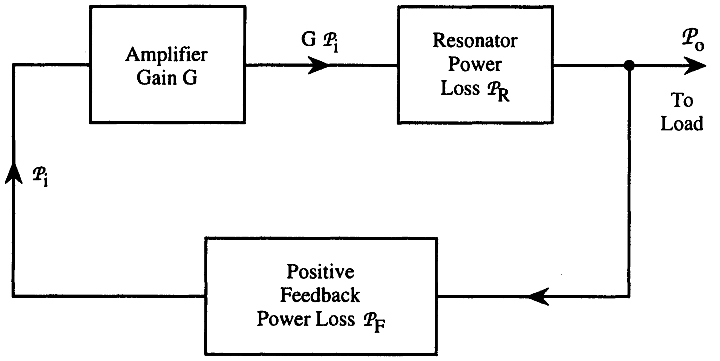

FIG. 1. Generic oscillator circuit.

where $\mathcal{P}_R$ and $\mathcal{P}_F$ are the power losses in the resonator and feedback system, $\mathcal{P}_o$ is the power output to the load, $\mathcal{P}_i$ the input power to the amplifier, and G the power gain. Gain nonlinearity must exist in the amplifier to limit $G\,\mathcal{P}_i$ to satisfy Eq. (1), although it could also be built into the feedback network. The oscillations build up from noise that always exists in a circuit at finite temperature, or from spontaneous radiation in the case of lasers. The two Barkhausen conditions for oscillation are as follows:

1. G must be greater than one; and
2. the phase shifts around the closed loop must be $2\pi n$ for the voltage and/or field to be single valued.

Maxwell's equations

$$\nabla \times \mathbf{E} + \mu_0 \frac{\partial \mathbf{H}}{\partial t} = -\mu_0 \frac{\partial \mathbf{M}}{\partial t}$$

and (2)

$$\nabla \times \mathbf{H} - \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} = \mathbf{J} + \frac{\partial \mathbf{P}}{\partial t}$$

along with Newton's and Schrödinger's equations are the starting points in determining the sources for electromagnetic (EM) fields and conditions for gain. It is readily seen that only two sources for EM fields exist: conduction currents **J** and polarization terms $\partial\mathbf{P}/\partial t$ and $-\mu_0\partial\mathbf{M}/\partial t$. From the invention of the triode vacuum tube by de Forest (1907) to the invention of the laser in the 1950s, the only amplifiers of EM fields were conduction-current devices. Now that polarization-current ($\partial\mathbf{P}/\partial t$) laser devices have been invented, one may wonder if any new breakthroughs on oscillators in a fundamental sense will be made in the future.

Powers ($\mathcal{P}$) absorbed or generated by a **J** or $\partial\mathbf{P}/\partial t$ device are given by the expressions

$$\mathcal{P} = \int \mathbf{E} \cdot \mathbf{J}\, dv$$

or (3)

$$\mathcal{P} = \int \mathbf{E} \cdot \frac{\partial \mathbf{P}}{\partial t}\, dv,$$

where v is the volume.

Since the coherent field **E** of interest will vary as $e^{j\omega t}$, **J** and/or $\partial\mathbf{P}/\partial t$ must have a Fourier component at ω for the average of $\mathcal{P}$ over a cycle to be different from zero. In particular, **J** and/or $\partial\mathbf{P}/\partial t$ must be out of phase with **E** for power to be generated. This means that in **J** devices the electron beam cannot be a dc beam but must be "bunched" or modulated in some manner. For a $\partial\mathbf{P}/\partial t$ or laser device, inverted populations or nonequilibrium distribution of the laser system must be obtained by means of the appropriate excitation or pumping scheme.

Given a two-level system with an electric dipole transition, it can be shown (Pantell and Puthoff, 1969) that **P** is given by the equation

$$\frac{\partial^2 \mathbf{P}}{\partial t^2} + \frac{2}{T_2}\frac{\partial \mathbf{P}}{\partial t} + \Omega^2 \mathbf{P} = \frac{2\Omega}{3\hbar}|\mu_{12}|^2 \times (N_1 - N_2)\mathbf{E}, \quad (4)$$

where $\hbar\Omega$ is the energy difference of the two levels, μ_{12} is the dipole matrix element (a measure of the coupling of the levels), N is the population, T_2 is a relaxation time, and

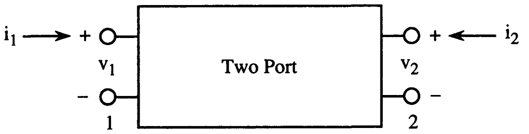

FIG. 2. Two-port circuit.

E is the field. Notice that for **E** sinusoidal, $\partial\mathbf{P}/\partial t$ will be sinusoidal, and that $\partial\mathbf{P}/\partial t$ will change signs when $N_2 > N_1$, the conditions for $\mathcal{P}_{AV}$ to be negative. From this point of view, there was no need to mention the words stimulated emission of radiation.

A principal practical motivation for the study of oscillators has been the quest for high oscillator frequencies, to provide more bandwidth and information capability. Conduction-current devices, with the exception of the free-electron laser, appear to have reached their practical frequency limit around 100 GHz. Lasers ($\partial\mathbf{P}/\partial t$ devices) can generate EM radiation almost across the spectrum from UHF to the ultraviolet.

In the next sections, various types of **J** and $\partial\mathbf{P}/\partial t$ devices will be examined from the point of view of the basic oscillator principles just described.

2. LOW-FREQUENCY TRIODE OR TRANSISTOR OSCILLATORS

2.1 Two-Port Devices

Low-frequency three-terminal, vacuum-tube and transistor oscillators employ lumped-circuit *LCR* circuit elements. These devices can be represented by the two-port network (Millman and Halhias, 1972) displayed in Fig. 2 with the hybrid equations

$$v_1 = h_{11}i_1 + h_{12}v_2, \tag{5}$$

$$i_2 = h_{21}i_1 + h_{22}v_2, \tag{6}$$

where the voltage and current variables represent small variations about the quiescent operating point. The *h*-parameter equivalent circuit, where terminals 1 and 2 are common, can be readily seen to be that given in Fig. 3. While the active elements on the circuits described here are semiconductor devices, earlier circuits used vacuum tubes in similar circuit configurations.

Given the *h* parameter of the amplifying two-port device, one needs to add an appropriate positive-feedback circuit to make an oscillator. The transfer gain A_f with feedback is given by the relationship

$$A_f = A/(1 + \beta A), \tag{7}$$

where β is a complex function of the frequency and *A* is zero-feedback gain. Oscillations can occur when $\beta A = -1$, the Nyquist criterion for instability.

The basic physics is concerned with processes within the "black box" two-port that yields the desirable *h* parameters of Eqs. (5) and (6) and how they might be changed. In both triode vacuum tubes and transistors, gain (or energy addition) is obtained by converting charge kinetic and/or potential energy into EM energy. In triodes and transistors, both dc ($\mathbf{E}_0$) and ac ($\mathbf{E}_1 \sin\omega t$) fields are present in the same region. Hence, the energy relations are from Newton's equation

$$m\mathbf{u}\cdot d\mathbf{u} = q\mathbf{E}_0\cdot d\mathbf{r} - q\mathbf{E}_1 \sin\omega t\cdot d\mathbf{r}. \tag{8}$$

The dc field is performing work on the charge *q*, which in turn is performing work on the ac field.

A key feature of a triode tube or bipolar junction transistor (BJT) transistor is the ability of the grid to control the flow of currents to the plate of the tube or the collector current to control the base current, respectively. By this means, charges are allowed into the interaction region of the device mainly

(c) Basic Transistor Oscillator Using L-C Circuit as the Resonator

FIG. 4. Basic Colpitts and Hartley oscillator configurations.

when they can deliver kinetic energy to the ac field.

A number of 180° feedback circuits have been developed to go with vacuum tubes and transistors to make oscillators, two of which have been given distinguishing names, Hartley and Colpitts. These low-frequency *L-C* oscillators (Hunter, 1956) are shown in Fig. 4, along with a simplified circuit to illustrate better the 180° feedback feature.

A phase shift of 180° in the positive-feedback circuit of an amplifier-oscillator can also be provided by a *RC* circuit as illustrated in Fig. 5. The loop gain condition yields the results

$$\omega_0 = [RC\sqrt{6 + 4R_C/R}]^{-1}$$

and (9)

$$\frac{R}{R_C} = \frac{h_{21} - 23}{58} > 0.$$

Piezoelectric quartz crystals with characteristic resonant frequencies can also be used in positive-feedback amplifier circuits to make an oscillator as shown in Fig. 6. Crystal oscillators can be made to be very frequency stable, having been used as frequency standards for many years.

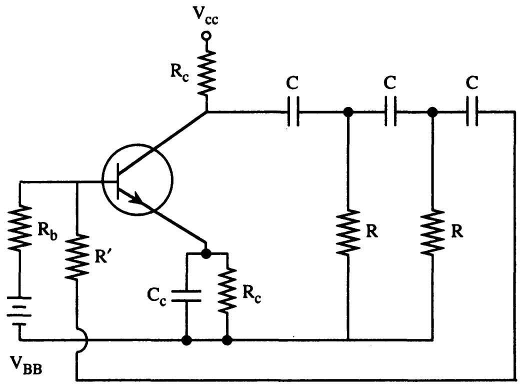

FIG. 5. Phase-shift oscillator circuit.

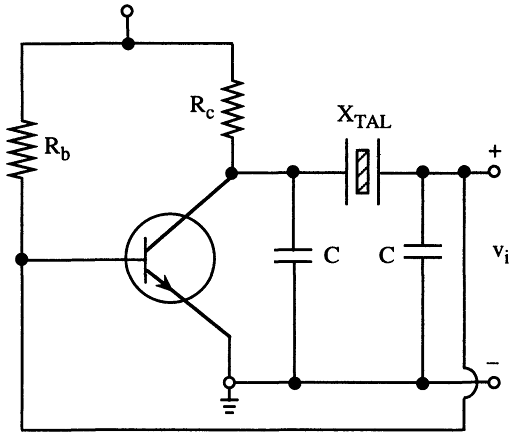

FIG. 6. Crystal oscillator circuit.

2.2 One-Port Devices

A number of two-terminal, one-port conduction-current devices have been discovered that display a negative ac resistance based upon a variety of physical processes. Their *I-V* characteristics are of the general form displayed in Fig. 7. Over the voltage range $V_1 < V < V_2$, assuming a linear relationship, it is seen that

$$I = a - V/r$$

and (10)

$$\frac{dV}{dI} = -r,$$

i.e., the device displays a negative differential resistance *r*.

To see, from a circuit point of view, how this diode amplifies, consider the simplified circuit of Fig. 8. The ac circuit equations are

$$e_s = i_D R + e_D = i_D(R - r)$$

with (11)

$$e = i_D R = e_s \frac{R}{R - r},$$

where e_s is the ac voltage signal and e the voltage output. Clearly, the output voltage e can exceed the input voltage e_s.

If the ac current and voltage amplitudes exceed the values $I_1 - I_0 = \Delta I$ and $V_2 - V_0 = \Delta V$, losses will occur to limit their values. The currents I_1 and I_2 and voltages V_1 and V_2 define the limits of the negative differential resistance region. Hence, the maximum ac power available from the diode is

$$\mathcal{P}_{AV} \le \tfrac{1}{2}(\Delta I)(\Delta V). \qquad (12)$$

The two-terminal devices of major interest are (Coleman, 1982; Liao, 1985) the Esaki tunnel diode, the Gunn diode, the IMPATT diode, and the resonant tunneling diode.

The Esaki diode consists of a heavily doped *p-n* junction where the Fermi levels are located within the bands themselves. As seen from Fig. 9, when a positive bias is applied electrons can tunnel from the filled electron states on the *n* side to the empty states on the *p* side at constant energy. With further

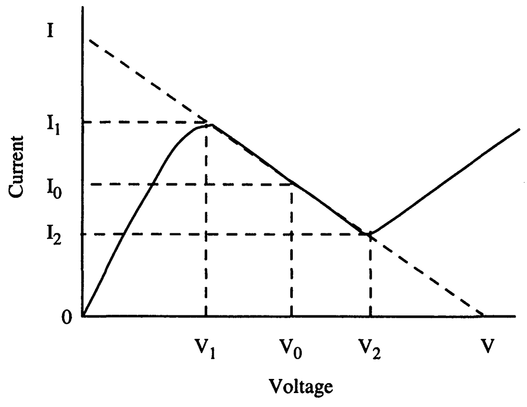

FIG. 7. Schematic *I–V* curves of a negative differential resistance device.

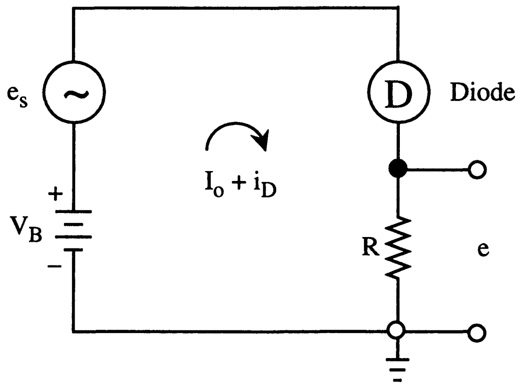

FIG. 8. Negative differential resistance diode amplifier circuit.

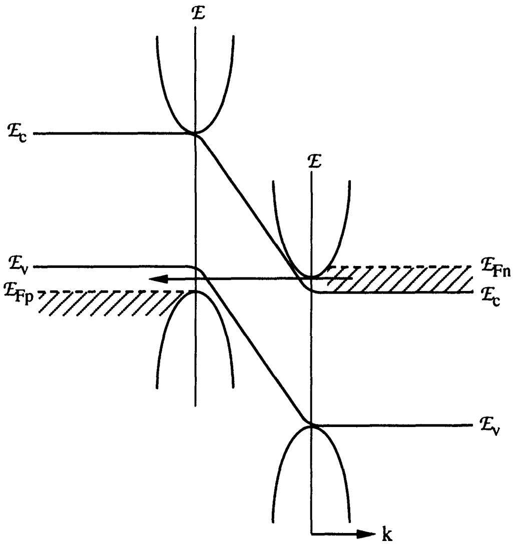
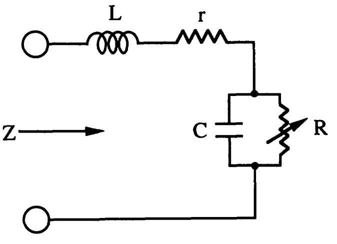


(a) Esaki Diode - Forward Bias



(b) Equivalent Circuit

FIG. 9. Esaki diode characteristics.

positive bias, the current decreases since there are fewer available states opposite the filled states. While the tunneling process is very fast, the negative resistance of the diode goes to zero at the frequency f_c given by the relationship

$$f_c = \frac{\sqrt{|R|/r - 1}}{2\pi C|R|}, \tag{13}$$

as can be determined from the equivalent circuit. With typical values for the circuit parameters, $f_c \sim$ 10–40 GHz.

The resonant tunnel diode (RTD) is a heterostructure with a double-barrier single-quantum well as illustrated in Fig. 10. Maximum current (resonant tunneling) occurs when the energy of the tunneling electrons is approximately in line with the quantized energy level for electrons in the quantum well. The equivalent circuit for the RTD is the same as that for the Esaki diode, but the cutoff frequency f_c can be made much greater, exceeding 100 GHz. Unfortunately, the product $(\Delta I) \times (\Delta V)$ of Eq. (12) is small so that only small amounts of power can be produced with this diode.

The Gunn diode is a bulk semiconductor electron-transfer device wherein electrons are transferred from the central valley of the material (i.e., GaAs) to an upper satellite valley where their velocity $(\hbar^{-1}d\mathscr{E}/dk)$ decreases when an electric field is applied to the semiconductor. This results in a negative differential (du/dE) velocity–field curve for the electric field greater than E_T as illustrated in Fig. 11. The usual semiconductor equations for the current J, electric field E, and electron density n (for one dimension),

$$J = qnu(E) - q\frac{\partial D(E)n}{\partial x} + \epsilon\frac{\partial E}{\partial t}, \tag{14}$$

$$\frac{\partial n}{\partial t} + \frac{1}{q}\frac{\partial J}{\partial x} = 0, \tag{15}$$

$$\frac{\partial E}{\partial x} = \frac{q(n - n_0)}{\epsilon}, \tag{16}$$

apply with the electron velocity u now a function of E. In general, these equations can only be solved by numerical methods. It is found that a number of modes of behavior exist (Copeland, 1967), viz., a transit-time dipole-layer mode, a limited space-charge accumulation mode, and a quenched dipole-layer mode.

Consider a dipole layer, illustrated in Fig. 12, moving from the negative to positive electrode of the semiconductor. The electric field inside the dipole is greater than the fields on either side. Thanks to the velocity property of the material, the electrons to the right of the dipole are moving more rapidly (running away from the dipole) leaving a depletion region while the electrons to the left of the dipole are catching up to form an accumulation region. The dc electron beam is being "bunched" to form the necessary ac current to drive the oscillator, with the frequency $f = u/L$. The dipole layer moves

through the crystal and disappears at the anode. The electric field then rises to form a new dipole layer to repeat the process. Gunn-diode oscillators can yield several watts of pulsed power at frequencies as great as 100 GHz.

An IMPATT diode is an n^+pip^+ semiconductor structure shown schematically in Fig. 13. It consists of a narrow p avalanche region

where carrier multiplication by impact ionization occurs and a drift region where the carriers drift at saturated velocity. A phase-shift delay is caused by the avalanche process and the finite transit time of the carriers drifting through the drift region.

The average power for the wave forms shown is given by the expression

$$\begin{aligned}\mathcal{P}_{AV} &= \frac{1}{2\pi}\int_{y\pi}^{x\pi} I_1V_1 \sin\omega t(d\omega t)\\ &= \frac{V_1I_0}{\pi}\left(\frac{\cos y\pi - \cos x\pi}{x-y}\right),\end{aligned} \qquad (17)$$

where $I_1 = 2I_0/(x - y)$ and I_0 is the dc current. Maximum power produced by the diode is seen to be

$$(\mathcal{P}_{AV})_{\max} = -\frac{V_1I_0}{\pi}\left(\frac{1 + \cos(\pi x)}{x - 1}\right). \qquad (18)$$

The avalanche process contributes a 90° inductive phase lag to the current generated in the avalanche region. This current is then injected into the drift region where an additional 90° phase in the external current occurs, thus resulting in the ac voltage and current being 180° out of phase. The diode will oscillate at a frequency and level where the diode plus external circuit admittance is zero.

3. MICROWAVE CONDUCTION-CURRENT OSCILLATORS

The oscillators discussed thus far were essentially lumped-circuit devices with *LCR* positive-feedback circuits, although Esaki and resonant tunneling diodes plus Gunn and IMPATT diodes could be embedded into transmission lines and microwave resonators. At microwave and millimeter-wave frequencies, propagation effects are present that require wave and field analysis to describe the amplification process. For tube or free-electron devices, methods need to be employed to cope with circuit reactance, circuit-tube loss, and electron transit-time limitations to obtain these higher frequencies.

3.1 Reflex Klystrons

The reflex klystron (see Fig. 14) consists of an electron-emitting cathode, a current-control grid, an anode-reentrant microwave resonator, and a repeller electrode. Electrons injected from the cathode are first velocity

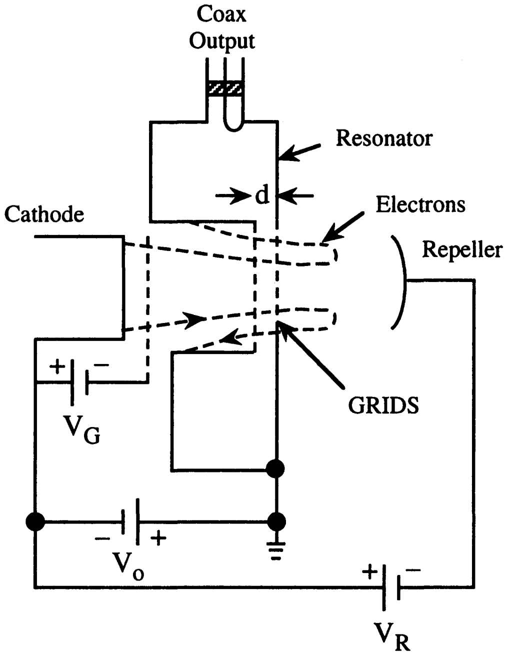

FIG. 14. Schematic diagram of a reflex klystron.

modulated by the cavity–gap field where the first electrons are decelerated and the later electrons accelerated to play a "handicap race" so as to yield a bunched ac electron beam. The electrons are then turned around by the repeller field and pass through the cavity–gap in the reverse direction 180° out of phase with the resonator field to give up a portion of their kinetic energy.

The determination of the ac currents in the bunched electron beam is obtained from Newton's equation as follows:

$$\int_{u_0}^{u} du = \frac{qE_1}{m} \int_{t_a - T/2}^{t_a + T/2} e^{j\omega t} dt, \tag{19}$$

where the transit time T across the resonator gap is given by $u_0 T \simeq d$ where d is the gap spacing, u_0 the dc beam velocity, and t_a the time the electrons reach the midpoint of the gap. Integration of Eq. (19) yields

$$\begin{aligned} u &= u_0 \left[1 + \frac{2V_1}{V_0} \left(\frac{\sin\theta/2}{\theta/2} \right) e^{i\omega t_a} \right] \\ &= u_0 [1 + 2\alpha A e^{i\omega t_a}], \end{aligned} \tag{20}$$

where $V_1 = E_1 d$, $m u_0^2 = 2qV_0$, $\theta = \omega T = \omega d/u_0$, $\alpha = V_1/V_0$, and $A = \sin\frac{1}{2}\theta/\frac{1}{2}\theta$. The electrons are returned to the resonator gap at time t_b given by

$$t_b = t_a + \frac{\ell}{u} \simeq t_a + \frac{\ell}{u_0} \left(1 - \frac{A\alpha}{2} \sin\omega t_a \right). \tag{21}$$

It is seen from Eqs. (20) and (21) that the transit time contained in the factor A is a key limitation in extending the frequency of a conduction-current device.

Finally, from conservation of electrons, the return current is

$$I_b = I_o \left| \frac{dt_a}{dt_o} \right| = I_0 \left| \frac{1}{1 - k \cos\omega t_a} \right|, \tag{22}$$

where $k = (A\alpha/2)(\omega d/u_0) = (A\alpha/2)(\omega T_0)$.

The current I_b is a periodic function, which can be analyzed into its Fourier components to yield for the fundamental

$$I_{b_1} = j2 I_0 J_1(k)\, e^{-j\omega t_o}, \tag{23}$$

where $J_1(k)$ is a first-order Bessel function, and the power generated,

$$\mathcal{P}_{AV} = V_1 I_0 J_1(k) \sin\omega t_o. \tag{24}$$

A reflex klystron can be frequency tuned mechanically by varying the gap spacing d, and electronically of the order of 1% by varying the repeller voltage. Reflex klystrons can be made to operate up to the order of 100 GHz. Power levels of the order of 10 MW can be obtained in the microwave range. For many years, they have been very useful oscillators for laboratory measurements, local oscillators in radars, linear accelerators, and missiles. Harmonic signals obtained from reflex klystrons driving Schottky diodes provided the first coherent millimeter–submillimeter radiation for the microwave spectroscopy of molecules. Microwave spectroscopy made key contributions to the invention of the NH_3 laser.

3.2 Magnetron

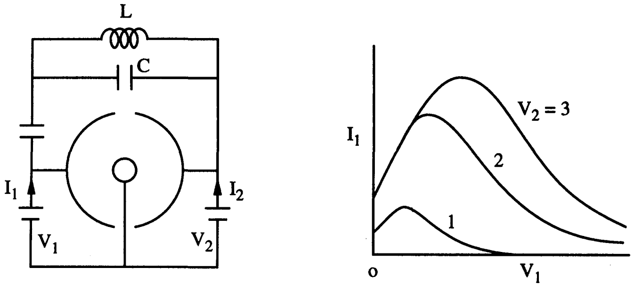
The magnetron (Coleman, 1982; Liao, 1985) is a crossed-field ($\mathbf{E} \cdot \mathbf{B} = 0$), termed M-type electron tube that was invented by A. W. Hull in 1921, although it was not developed into a high-power generator until World War II when the need for radar existed. Its high efficiency of 50%–80% makes it useful for many commercial uses such as in a microwave oven. It can produce pulsed powers as large as 10 MW in the microwave range, and it can be made to operate at frequencies approaching 100 GHz.

There are a number of different magnetron structures: a split-anode, a cylindrical traveling-wave slot, a cylindrical traveling-wave hole and slot, a rising sun, and a linear slotted magnetron, three of which are shown in Fig. 15. The electrons are tightly bunched when they are emitted from the large, high-current cathode, which leads to the high efficiency of the tube.

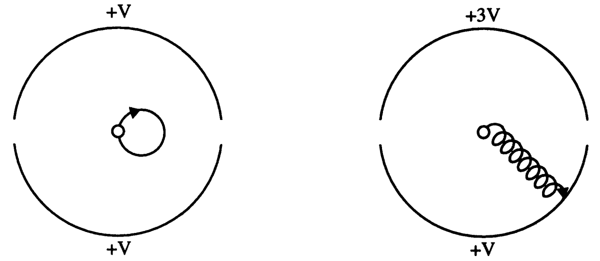
The fields in the interaction space are not simple and the charge motion, including space charge, is very complicated so that an analytical solution for a magnetron oscillator is not possible. Some of the features of a magnetron can be seen by considering a linear magnetron configuration.

Consider first the motion of electrons in crossed dc ($\mathbf{E} \cdot \mathbf{B} = 0$) fields where $\mathbf{E} = \hat{\mathbf{y}}\mathbf{E}$ and $\mathbf{B} = \hat{\mathbf{z}}\mathbf{B}$. Then Newton's equations are

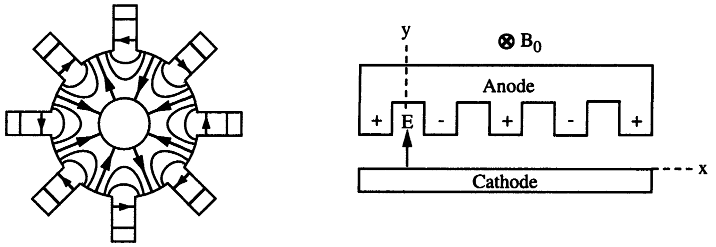
$$\ddot{x} = -\omega_c \dot{y}$$



(a) Circuit Configuration (b) Current-Voltage Characteristics



(c) Electron Paths in Split and DE Magnetron



(d) Lines of Force in a Cylindrical Magnetron (e) Linear Magnetron Configuration

FIG. 15. Various magnetron configurations.

and

$$\ddot{y} = -eE/m + \omega_c\dot{x}, \tag{25}$$

where $\omega_c = eB/m$, with the solution for $\dot{x}$ being

$$\dot{x} = -\omega_c R \sin(\omega_c t - \alpha) + E/B \tag{26}$$

and

$$y = y_0 + R \sin(\omega_c t - \alpha). \tag{27}$$

Equation (26) suggests that to realize an oscillator a travelling-wave field moving with the drift velocity E/B should be used. Since E/B will be much less than the velocity of light c, a heavily loaded slotted circuit, shown in Fig. 15(e), will be needed to reduce the phase velocity to E/B.

Adding rf fields to Eq. (20) results in a problem too difficult to solve analytically. Hence, a word description of the results will be given. Electrons with certain phases drift toward the cathode while other electrons in other phases drift toward the anode and do work in the rf field. Here the kinetic energy stays approximately constant ($E/B \sim$ constant), but the full potential energy is delivered to the rf field. Only a small amount of energy is lost to the cathode.

For a cylindrical magnetron, Newton's equations become in polar coordinates (r,θ)

$$\ddot{r} - r\dot{\theta}^2 = -\omega_c r\dot{\theta} + \frac{e}{m}\frac{dV}{dr}, \tag{28}$$

where $E_r = -dV/dr$, and

$$\frac{1}{r}\frac{d}{dt}(r^2\dot{\theta}) = \omega_c\dot{r}, \tag{29}$$

where $\omega_c = eB/m$. Given that the radial and angular velocity are zero at the cathode where $r = r_c$, Eq. (29) yields

$$\dot{\theta} = \tfrac{1}{2}\omega_c\,[1 - (r_c/r)^2]. \tag{30}$$

Now the energy equation is

$$\tfrac{1}{2}m\,(\dot{r}^2 + r^2\dot{\theta}^2) = eV. \tag{31}$$

Eliminating $\dot{\theta}$ between Eqs. (30) and (31) and using the condition $\dot{r} = 0$ for $r = r_p$ yields the cutoff voltage

$$V_c = \frac{er_p^2}{8m}B\left[1 - \left(\frac{r_c}{r_p}\right)^2\right]^2, \tag{32}$$

the voltage below which no electrons will reach the plate. Oscillations are usually observed in the vicinity of cutoff.

The slot magnetron structure of Fig. 15(d) is a resonator with certain allowed frequencies, which can be found by requiring the phase shift around the circumference to be $2\pi m$ to bring the field back to its initial value. Hence, given the phase factor β_0 of the rotating electromagnetic wave, it is seen that

$$\beta_0 NL = 2\pi m, \tag{33}$$

where N is the number of slots, L the periodic distance, and m an integer.

The mode for $m = N/2$ where N is even is termed the π mode of the resonator. Other modes are double in that they allow traveling waves to propagate in either of two possible directions around the magnetron. The large currents in a magnetron require that space charge be included in the analysis of charge bunching, again a problem that cannot be solved analytically. Numerical calculations yield the results that the electrons bunch into a configuration like the spokes of a wheel (see Fig. 16) that rotate in synchronism with the tangential electric field.

Magnetrons are used in a pulsed mode with pulse lengths typically 1–10 μs at pulse repetition frequencies of the order of 100–400 Hz. For microwave oven applications, they can be operated for many minutes at power levels from 400 to 800 W.

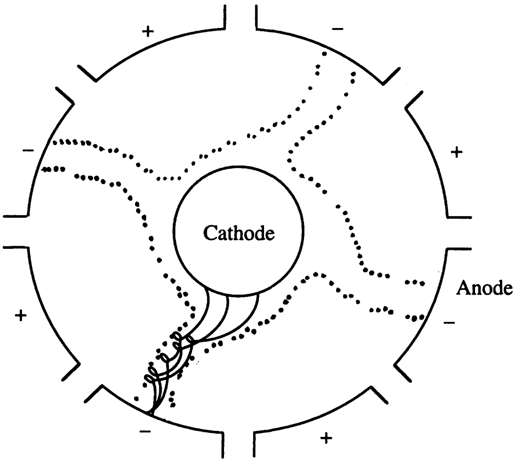


FIG. 16. Schematic of electron trajectories in a cylindrical magnetron.

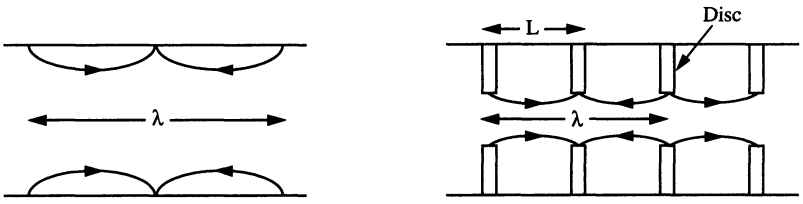
3.3 Backward-Wave Oscillators

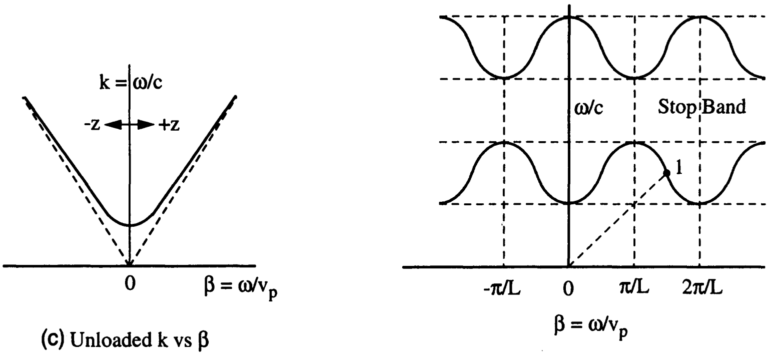
In order for a linear electron beam to interact with an electromagnetic traveling wave, be bunched, and deliver energy to the field, the electron velocity u_0 must be slightly greater than the phase velocity v_p of the wave. Since the normal transmission line or waveguide has a phase velocity $v_p \geq c$ where c is the velocity of light, some means must be found to reduce the phase velocity by a substantial amount if relativistic beam voltages are not used (Karp, 1955; Kompfner, 1947). Phase-velocity reduction of a waveguide can be made by making the structure periodic as illustrated in Fig. 17. What is also needed is a transverse-magnetic (TM) mode of propagation, where an axial field E_z exists on the axis and the transverse field is zero on the axis.

Periodic loading of the waveguide changes the ω vs β characteristics as shown in Figs. 17(c) and 17(d) so that the loaded guide now takes on filter stop-band properties. The calculation of β as a function of ω is a difficult task, but some general results can readily be obtained. Since the field is spatially periodic, one can expand the axial electric field in a



(a) Unloaded Guide

(b) Periodically Loaded Guide



(c) Unloaded k vs β

(d) Loaded k vs β

FIG. 17. Characteristics of unloaded and periodically loaded waveguides.

Fourier series:

$$E_z = \sum_n E_n \exp\{j[\omega t - (\beta_0 + 2\pi n/L)z]\}$$
$$= \sum_n E_n \exp[j(\omega t - \beta_n z)], \qquad (34)$$

where

$$\beta_n = \beta_0 + 2\pi p/L = \omega/v_{pn}, \qquad (35)$$

i.e., the phase velocity will get smaller as n increases.

It will also be observed from Fig. 17(d) that for $n = 1$ (the first spatial harmonic), the group velocity v_{gr} is negative:

$$\frac{1}{v_{gr}} = \frac{d\omega}{d\beta_n} = \frac{d\omega}{d\beta_0} < 0$$

for operation at point 1 on the ω vs β curve.

The gain analysis of a backward-wave oscillator (BWO) is the same as a traveling-wave-tube amplifier (TWT). However, since the group velocity of the spatial harmonic field being used is negative, the power output is taken at the cathode end of the tube as illustrated in Fig. 18. The feedback is internal in the structure. If the beam velocity ($u_0 \sim v_p$) is changed, the frequency of the BWO is changed as point 1 moves along the ω vs β curve.

Backwave oscillators (also termed O-Carcinotrons), as developed by French scientists (Convert *et al.*, 1959), have reached 1 THz in frequency. These nonrelativistic beam tubes are strong competitors as continuous sources of millimeter and submillimeter waves, having achieved 1 W cw at 300 GHz with a beam voltage of the order of 10 kV.

3.4 Gyrotron

3.4.1 Gyrotron Principles The requirement of a synchronization of the electron velocity u_o and phase velocity v_p in a TWT or

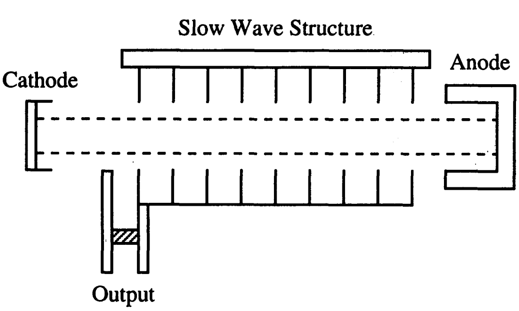


FIG. 18. Backward-wave oscillator schematic.

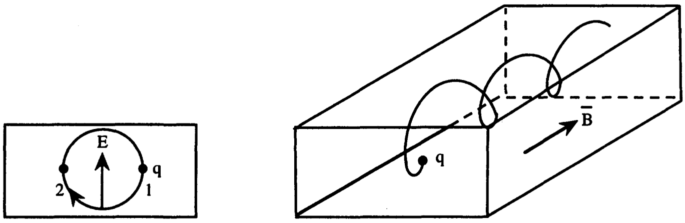

(a) End View of Charge Motion (b) Charge Motion in Waveguide

FIG. 19. Quasi-velocity matching.

BWO meant that the waveguiding structure of the tube had to be periodically loaded to achieve the condition $u_o \simeq v_p$. Loading the waveguide reduced its cross-sectional area. As the frequency of the tube was extended, the periodically loaded guide became uncomfortably small and the electron beam had to approach the loading elements more closely to maintain efficiency. What was necessary to solve this problem was to remove the periodicity from the waveguide and introduce the periodicity on the electron beam (Sprangle and Drobot, 1977). A quasisynchronism between the wave and beam is achieved by allowing the wave to skip past the beam, with the interaction taking place with different "parts" of the wave in consecutive cycles.

For example, consider a spiral electron beam in a field $\mathbf{B} = \hat{\mathbf{z}}B$ in a TE-mode waveguide as illustrated in Fig. 19(b). At point 1 of Fig. 19(a), the charge is doing work on the field. When the charge rotates with angular velocity $\omega_c = qB/m$ to position 2, the field $\mathbf{E}$ needs to reverse directions to continue the interchange. Hence, it can be seen that

$$t_{12} = \frac{\pi}{\omega_c} = \frac{d}{u_z} = \frac{d + \lambda q/2}{v_p} = \frac{d + \pi v_p/\omega}{v_p}; \tag{36}$$

solving for ω, one obtains a Doppler frequency relation

$$\omega = \frac{\omega_c}{1 - u_z/v_p} \tag{37}$$

for the quasisynchronous condition, where d is the distance traveled in the z direction with velocity u_z.

The electrons follow a helical trajectory around the lines of the axial dc magnetic field inside a TE-mode waveguide ($v_p > c$) as illustrated in the gyrotron schematic of Fig. 20. In the case of a linear, nonperiodic beam, the electron bunching is longitudinal. For the gyrotron with its periodic electron beam, the electron bunching is transverse or azimuthal phase bunching as indicated in Fig. 21. This bunching occurs because the cyclotron frequency qB/m depends on the relativistic mass $m = \gamma m_o$. It is not possible to solve the relativistic trajectory equations in closed form. However, the "handicap race" can readily be seen. The electron at position 1 is losing kinetic energy to the field; hence, it rotates faster with a smaller radius trying to catch up with electron at position 2. The electron at position 3 is gaining kinetic energy from the field and rotates more slowly with a larger radius, allowing electron 2 to catch up in position. At a later period of time, electrons 1, 2, and 3 will be lined up in azimuth.

The gyrotron shown in Fig. 20 uses a hollow electron beam and a TE_{01}-mode waveguide to obtain an E_ϑ field so that there are many orbits of the electrons as displayed in Fig. 21(b). Also, the electron beam must have most of its energy transverse to the axis of the tube (typically by a factor of 1.5–2).

In 1982, Temkin *et al.* (1982) built a gyrotron at 140 GHz with a pulsed power of 100

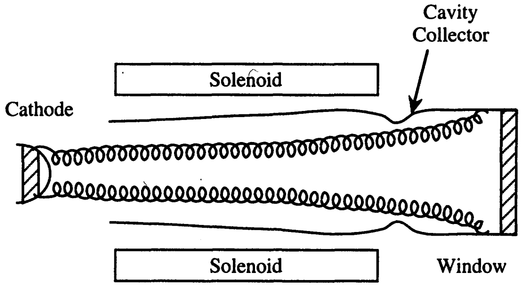

FIG. 20. Gyrotron circuit configuration.

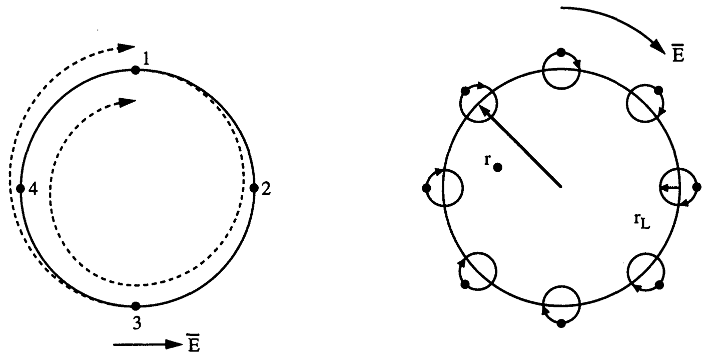

(a) Single Orbit

(b) Multiple Orbits

FIG. 21. Transverse electron bunching in a gyrotron.

kW and efficiency of 17% using a TE_{031}-mode resonator, 80-kV beam, and 5.4-T magnetic field. At lower frequencies (~30 GHz), scientists of the former Soviet Union achieved efficiencies of over 40%. For high-power pulsed operation, the gyrotron is in a class by itself.

3.4.2 Mathematical Models of the Gyrotron In the treatment of oscillators in this article, it was implied that conduction-current (**J**) devices could be analyzed by solving a Newton problem for the current and Maxwell's equations for the gain and fields. Of course, any classical problem can be quantized, even an *LC* circuit, but quantum effects would be indeed difficult to observe at 100 MHz. On the other hand, a polarization-current ($\partial\mathbf{P}/\partial t$) device requires a quantum treatment since the polarization **P** cannot be calculated classically. In this article, a $\partial\mathbf{P}/\partial t$ device has been called a laser and a **J** device a free-electron oscillator irrespective of how it is analyzed. The mathematical model cannot change the physics of the problem.

From this perspective, the gyrotron has had an interesting history. In the initial work to determine the operating principles of the gyrotron, a quantum-mechanical approach was used and the phase "electron cyclotron maser" was coined. It was implied that a gyrotron was a $\partial\mathbf{P}/\partial t$ device with observable quantum effects. While this is an interesting point of view, a quantum-mechanical model contributes little to the detailed analysis of the gyrotron interaction process.

4. NOVEL CONDUCTION-CURRENT OSCILLATORS

4.1 High-Energy Free-Electron Oscillator

In this review, oscillators have been classified as (1) conduction- or (2) polarization-current devices. The high-energy or relativistic free-electron oscillator has been termed a laser in the literature in spite of its being a conduction-current oscillator. Basically, the oscillator consists of an accelerator to produce a pulsed electron beam, a "wiggler" magnet to force the electrons to oscillate, and a Fabry–Pérot mirror system, as shown in Fig. 22. Because of relativistic effects, the radiation is strongly forward directed and Doppler shifted.

The wavelength λ_d of the radiation can be approximately calculated as seen in Fig. 22(b), by observing that while the radiation emitted by an electron at position 1 reaches position 3, the electron will have moved from position 1 to 2. Both the electron and wave will have undergone one cycle.

The "wiggler" magnet concept first appeared in the dissertation of P.D. Coleman (1951). Phillips (1960) developed the periodic magnetic field idea with his invention of the Ubitron, and in 1970 Madey (1971) extended the concepts to the optical range.

If the Fabry–Pérot mirror were not present, the electron emission would be strictly incoherent. With an optical field present to provide feedback, the electrons can be accelerated and decelerated slightly so that the faster electrons (more mass) can catch up with the slower electrons (less mass) to form

FIG. 22. Schematic drawing of a free electron oscillator.

bunches spaced at optical wavelengths (Parker *et al.*, 1982).

The relativistic equation of motion is

$$\frac{d}{dt}(m_o\gamma\mathbf{u}) = -e[\mathbf{E} + \mathbf{u} \times \mathbf{B}] + \mathbf{F}, \qquad (38)$$

where $\gamma = (1 - \beta^2)^{-1/2}$; $\beta = u/c$, $\mathbf{F}$ is the self-force, and $\mathbf{B} \simeq \mathbf{B}_0 \sin(2\pi x/\lambda_e)$. If the self-force is neglected, then

$$m_o c^2 \frac{d\gamma}{dt} = -e\mathbf{E} \cdot \mathbf{u} = \mathbf{u} \cdot \frac{d}{dt}(m_o\gamma\mathbf{u}), \qquad (39)$$

where $\mathbf{E}$ is the transverse electromagnetic (TEM) optical field in the resonator.

While the electron velocity is modulated, the greater change is in the modulation of the electron mass $m_o\gamma$. The electrons and wave are in resonance on the forward pass and out of resonance on the backward pass. It is a complex problem to calculate the velocity $\mathbf{u}$ and acceleration $\dot{\mathbf{u}} = d\mathbf{u}/dt$ of the charge e because of the relativistic equations.

The power radiated can be estimated from Larmor's formula (Stratton, 1941)

$$\begin{aligned}\mathcal{P} &= \frac{Q^2\dot{u}^2}{6\pi\epsilon c^3} \frac{1 - \beta^2 |(\mathbf{u}/u) \times (\dot{\mathbf{u}}/\dot{u})|^2}{(1 - \beta^2)^3} \\ &\to \frac{Q^2\dot{u}^2}{6\pi\epsilon c^3(1 - \beta^2)^2},\end{aligned} \qquad (40)$$

where if the electron bunch is small compared to the radiation wavelength $Q^2 = (ne)^2$, when n is the number of electrons in the bunch.

Pulse power levels (Szöke, 1981; Granatstein and Roberson, 1985; Brau and Newnam, 1987; Süsskind, 1988) in a free-electron oscillator can be enormous compared to other types of conduction-current devices. Robenson *et al.* (1987) have reported a peak laser power output of 6 × 10^8 W at a wavelength of 514 nm with a free-electron oscillator driven with a 1.3-GHz linear accelerator having the pulsed current output shown in Fig. 23. The efficiency of this oscillator is seen to be

$$\begin{aligned}\frac{\mathcal{P}_{\text{LASER}}}{\mathcal{P}_{\text{BEAM}}} &= \frac{6 \times 10^8}{100(120 \times 10^6)} \\ &= \frac{0.6\ \text{GW}}{12\ \text{GW}} = 0.05.\end{aligned} \qquad (41)$$

Power levels in the optical resonator can readily reach levels that damage the metal mirror of the Fabry–Pérot system.

It is tempting to use Larmor's formula [Eq. (40)] to estimate the peak power. The peak acceleration $\dot{u}$ can be approximated from the relation

$$\dot{u} \simeq c(qB/m). \qquad (42)$$

Then

$$\mathcal{P} = \frac{(nq)^2(qB/m_o)^2}{6\pi\epsilon c(1 - \beta^2)^2} \simeq 10^{-12}n^2\ \text{W}. \qquad (43)$$

The number of electrons in the 100-A, 20-ps pulse is 1.25 × 10^{10}; hence, $\mathcal{P} \simeq 0.16$ GW at the peak magnetic field.

4.2 Coherent Cherenkov Oscillators

4.2.1 The Boundary-Value Problem The generation of electromagnetic radiation (oscillators) can be based upon a number of physical phenomena. In the case of classical EM theory described by Maxwell's equations, it is the solutions to the equations, not the equations themselves, that provide a

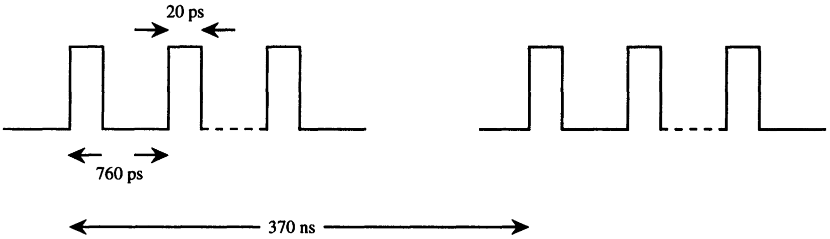

FIG. 23. Current pulses from accelerator driving the free electron oscillator.

mathematical description of the physical phenomena. From this point of view, the last fundamental phenomenon derived from Maxwell's equations was the Cherenkov effect, viz., a charge moving through a polarizable medium with a *constant* velocity faster than the medium's phase velocity will radiate. The Cherenkov effect can be studied by considering the excitation of the elementary dipoles by the passing charge or as a straightforward Maxwell boundary-value problem. It is not necessary for the charge to pass through the medium, just close to it.

While the Cherenkov effect was studied extensively by P. A. Cherenkov from 1924 to 1938 and a theory was constructed by Frank and Tamm (1937), coherent Cherenkov radiation in the microwave range was not demonstrated until 1960 by Coleman and Enderby (1960).

Consider the boundary-value problem of a bunched (ac) electron beam passing through a cylindrical hole in a dielectric as illustrated in Fig. 24. The equation for the vector potential $\mathbf{A} = \hat{\mathbf{z}}A$ is

$$\nabla^2\mathbf{A} - \mu\epsilon\frac{\partial^2\mathbf{A}}{\partial t^2} = -\mu\mathbf{J}_n e^{jn\omega_0(t-z/u)} \tag{44}$$

for the nth harmonic current density $\mathbf{J}_n$.

In region II outside of the beam, Eq. (44) becomes

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{dR}{dr}\right) + \left(\frac{n\omega_0}{v}\right)^2[\mu\epsilon u^2 - 1]R = 0, \tag{45}$$

where $A_z = R(r)e^{jn\omega_0(t-z/u)}$. If

$$\mu\epsilon u^2 = (u/v_p)^2 > 1 \tag{46}$$

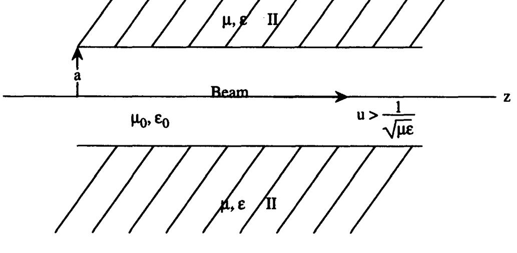

FIG. 24. Bunched cylindrical electron beam passing through hole in a dielectric.

(Cherenkov condition), then

$$R(r) = H_0^{(2)}(br)$$

(Hankel function—outgoing waves), where

$$b = (n\omega_0/v)[\mu\epsilon u^2 - 1]^{1/2}$$

For the driven oscillator system considered, coherent radiation will be produced at all harmonic frequencies $n\omega_0$ for which the Cherenkov condition is satisfied.

4.2.2 Self-Excited Cherenkov Oscillator A self-excited Cherenkov oscillator can be made by passing an electron beam through a dielectrically lined double-slab waveguide or a dielectrically lined cylindrical waveguide as illustrated in Fig. 25. Here the Cherenkov effect takes the form of a traveling-wave amplifier with internal feedback wherein the beam velocity u_0 is greater than the wave phase velocity.

It is of interest to briefly consider the physics of electronic motion in a traveling-wave field (Hutter, 1960). Here Newton's equation for one dimension takes the form

$$m_o\frac{du}{dt} = m_o\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial z}\right) = qE_1e^{j\omega t}e^{-\Gamma z}, \tag{47}$$

with

$$u = u_0 + u_1e^{j\omega t}e^{-\Gamma z},$$

where u_0 is a constant velocity and u_1 is a small amplitude. Solving Eq. (47) one obtains

$$u_1 = \frac{qE_1/m}{j\omega - \Gamma u_0}. \tag{48}$$

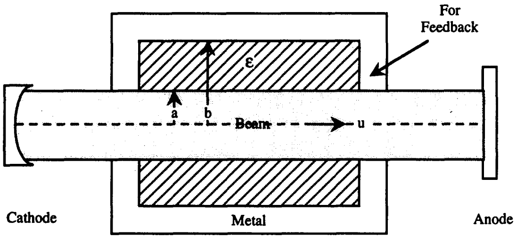

FIG. 25. Configuration of a Cherenkov oscillator.

Next let the charge density ρ and current J be

$$\rho = \rho_0 + \rho_1 e^{j\omega t} e^{-\Gamma z}, \tag{49}$$

$$J = \rho u = J_0 + J_1 e^{j\omega t} e^{-\Gamma z}, \tag{50}$$

with

$$\frac{\partial J}{\partial z} + \frac{\partial \rho}{\partial t} = 0. \tag{51}$$

Solving for J_1 yields the result

$$J_1 = \frac{j\omega}{u_0} \frac{J_0 E_1 e/m}{(j\omega - \Gamma u_0)^2}. \tag{52}$$

If the propagation constant Γ is purely imaginary, J_1 and E_1 are out of phase, no electron bunches are formed, and no work is done. However, if Γ is complex, work can be done, leading to attenuated or amplified waves. The value of Γ can be found by using J_1 in Maxwell's equations, applying boundary conditions for the problem, and obtaining a self-consistent solution.

Garate (1987) has analyzed a dielectrically lined double-slab waveguide driven by a relativistic electron-beam wave, using the procedure outlined, and obtained the data shown in Fig. 26. Von Laven *et al.* (1982) using a 1–40-A, 100–25-keV beam with a pulse duration of 4 μs, obtained 30–100 kW of pulsed power in the 30–50-GHz range using the structure shown in Fig. 25.

The use of microwave-type transmission lines and resonators in a Cherenkov oscillator will limit its frequency most likely below 300 GHz. The beauty of a Cherenkov oscillator is its simple beam-coupling structure. No high-technology, submicron fabrication techniques are needed to make the oscillator.

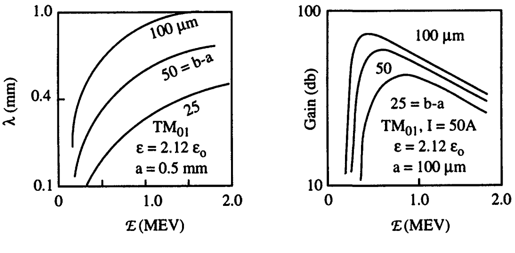

FIG. 26. Wavelength and gain vs electron energy of a Cherenkov oscillator.

5. RELAXATION OSCILLATORS

While the generation of sine waves is important, especially at high frequencies, there are many uses for other wave forms (pulses, rectangles, triangles, trapezoids, etc.)—generators, for example, in timing applications (Chance *et al.*, 1949). The relaxation oscillator that will be considered here is the astable plate-coupled multivibrator, which can provide nearly rectangular pulses of a specific duration. This multivibrator circuit has two triode tubes with *RC* coupling from the plate of each tube to the grid of the other tube as shown in Fig. 27.

The cycle of operation consists of alternate periods when one tube and then the other is cut off with rapid switching from one condition to the other. Suppose the plate current i_{b_2} increases, thereby lowering the voltage e_{b_2}. This in turn causes a sequence of actions with e_{c_1} decreasing, decreasing i_{b_1}, increasing e_{b_1}, increasing e_{c_2}, further increasing i_{b_2}. As the charge on capacitor C_1 decreases, e_{c_1} rises toward zero and, as soon as the cutoff voltage e_{c_0} is reached, turns tube 1 from off to on. Thus, the current is suddenly transferred from the plate circuit of one tube to that of the other. The various voltage wave forms are also displayed in Fig. 27.

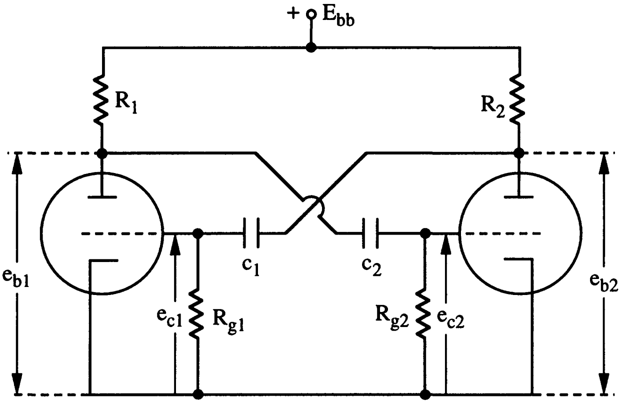
The periods τ_1 and τ_2 depend on the *RC* time constant and the ratio of the voltages involved. For example,

$$\tau_2 = R_{g_2} C_2 \ln(e_2/e_{c_0}). \tag{53}$$

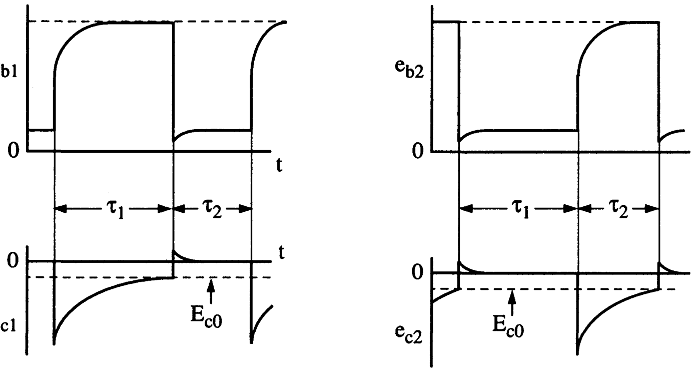
Switching times are much smaller than 1 μs, and the periods τ_1 and τ_2 can be changed by varying R_{g_1} and R_{g_2}.

6. POLARIZATION-CURRENT (LASER) OSCILLATORS

From a Maxwell-equation, mathematical point of view, conduction-current (**J**) and polarization-current ($\partial\mathbf{P}/\partial t$) oscillators represent different driving terms for the EM fields. Given **J** or $\partial\mathbf{P}/\partial t$, the mathematics of solving for the fields is the same. In this case, **J** or $\partial\mathbf{P}/\partial t$ must be out of phase more than 90° with



(a) Circuit Diagram



(b) Waveforms

FIG. 27. Astable multivibrator oscillator.

the field **E** to deliver energy. For a **J** device, this means generating an ac or bunched electron beam, and for a $\partial \mathbf{P}/\partial t$ device it means creating a non-thermodynamic-equilibrium distribution in a quantum system. In some cases, both can use the same feedback or resonator configuration, as, for example, the free-electron oscillator, which uses a Fabry–Pérot resonator. One key difference in the two devices is that the laser oscillator does not have a transit-time limitation on its frequency range.

However, a basic physics change had to be made in the analysis of **J** and $\partial \mathbf{P}/\partial t$ oscillators in that quantum mechanics has to replace Newtonian mechanics to calculate $\partial \mathbf{P}/\partial t$. This is not surprising since the laser is a quantum system. The equation for **P** for a two-level system, assuming an electric dipole transition, has been given in Eq. (4). It is to be observed that this second-order linear equation is of the same mathematical form as an *LRC* circuit driven by a voltage source. Since sinusoidal oscillations are being considered, this too is not unexpected.

The sign of $\partial \mathbf{P}/\partial t$ can be changed by making $N_2 > N_1$, i.e., a population inversion or change in the distribution function away from its thermodynamic equilibrium value. Equation (4) allows one to calculate the electric susceptibility χ_e since

$$\mathbf{P} = \epsilon_0 \chi_e \mathbf{E} = \epsilon_0(\chi_e' - j\chi_e'')\mathbf{E}, \tag{54}$$

and the loss α (or gain) of the EM wave traversing the medium,

$$\alpha = \omega\chi_e''/v_g, \tag{55}$$

where v_g is the group velocity.

Various types of lasers are described in other articles (see LASER PHYSICS; LASERS, FREE-ELECTRON; LASERS, GAS; LASERS, SEMICONDUCTOR; LASERS, SOLID STATE; ORGANIC DYE LASERS; TUNABLE DYE LASERS) and hence are discussed only to make comparisons with **J** devices. Conduction-current oscillators, as has been seen, have the challenges of transit time, circuit sizes, and losses, as they are extended to higher frequencies. Lasers have the challenges of devising specific excitation schemes to create highly non-thermodynamic-equilibrium distributions in the face of fast relaxation and damping processes.

In this author's opinion, while technological advances will be made on **J** devices in the future, finding new physics phenomena to exploit is becoming more difficult. No basic new **J** device has appeared for many years. A possible new frontier exists for $\partial \mathbf{P}/\partial t$ laser devices for nuclear energy-level systems.

INTRODUCTION

Oscillographs are a means of graphically studying oscillatory or cyclical phenomena—hence the term "oscillo" + "graph." With this fundamental definition, probably the earliest use of oscillography was the sundial. This simple device portrays the movement of the sun across the sky as a shadow cast across a scale to indicate the time of day.

A more sophisticated and widely familiar example is the seismograph used to record earth tremors and quakes. Here, a graphical record of seismic activity is penned onto a paper chart for detailed study. The process uses a slowly rotating drum onto which the blank graph paper is attached. The drum's rotation is controlled to correspond to a time scale. A seismic sensor detects earth tremors and converts them to a corresponding electrical signal which is used to drive a pen mechanically back and forth across the moving chart paper. The result is a graph of seismic amplitude vs time.

Historically, numerous general-purpose and highly specialized oscillographic devices have been developed to further the recording and study of physical phenomena. Prior to the advent of electronic devices, however, oscillography was generally confined to chart recorder and photographic methods.

It was not until the age of radio that an unavoidable need emerged for observing electronic wave forms. Engineers needed to

digital Encyclopedia of Applied Physics

see into the radio circuits they were developing in order to measure wave-form distortion and other amplifier effects. Using cathode-ray tubes (CRT), which had previously been developed in the study of x rays, engineers built their own rudimentary oscilloscopes based on designs passed along through symposia and journals. These first instruments were referred to as oscillographs, but gained the name oscilloscope by the 1940s to distinguish them from the broader category of oscillographs. The term uses the root word scope, from the Greek "skopos," meaning an instrument for viewing, as in telescope.

The basic function of an oscilloscope is to provide an *x-y* graphical view of physical phenomena. In the most common applications today, the display is voltage amplitude vertically on the *y* axis vs time horizontally on the *x* axis. This is because an oscilloscope is an electronic instrument designed for acquisition and display of electrical signals. However, it is of the utmost importance to realize that the displayed electrical signal, or wave form, can represent virtually any physical phenomenon.

What the oscilloscope display represents is determined by the application and by the type of probe or sensor used at the oscilloscope input. For example, optical events can be captured and displayed via an optical-to-electrical converter. Similarly, a microphone can provide an audio signal input, an accelerometer can provide a motion signal, and a thermocouple can provide a temperature signal input.

Thus, by judicious choice of sensors or probes, an oscilloscope is potentially able to provide monitoring, measurement, and analysis of almost any physical phenomenon or event. The phrase "potentially able to" is used here because actual display, measurement, or analysis depends on the type of oscilloscope selected and its various capabilities.

The most basic selection issue, of course, is adequate frequency bandwidth of the oscilloscope for the event signals being investigated. For example, a 20-MHz oscilloscope is inadequate for acquiring and displaying 100-MHz signals. Even with adequate bandwidth, however, there can be certain classes of signals that still cannot be displayed adequately on certain types of oscilloscopes. For example, a fast transient signal often will not create a visible trace on the display of a conventional analog oscilloscope, but will be clearly visible on the display of a real-time digital oscilloscope or transient digitizer. On the other hand, extremely fast transients may only be brought to light by the use of fast analog techniques and special CRT photography.

The point here is that careful and informed oscilloscope selection is paramount in successful display, measurement, and analysis of physical phenomena. This requires an understanding of basic oscilloscope concepts, the different oscilloscope technologies available, and the key advantages of each. This article provides the basic information necessary for informed oscilloscope selection.

1. BASIC OSCILLOSCOPE CONCEPTS

The most basic elements of any oscilloscope are acquisition, processing, and display. These elements may be implemented in a wide variety of manners with either analog or digital technologies, or a combination of both.

Acquisition begins, fundamentally, as an analog process. It includes, first of all, probing or sensing the phenomenon to be displayed or measured. It also includes triggering on a particular event or aspect of the phenomenon and generally includes some preconditioning (amplification or attenuation) of the input signal.

Processing, in general, is anything that is done to or in conjunction with the input signal to provide a useful display of the signal. This almost always includes use of a time base to set a calibrated display sweep or to control a sampling interval. It may also include other functions, such as subtracting a ground reference or even performing a fast Fourier transform on the signal.

Display is the method of formatting and presenting the acquired signal for observation. This may include scale factors, measurement cursors, and even measurement results. Most often, the primary display is the oscilloscope screen. However, displays may include separate numeric readouts as well as results sent to a printer.

There are two classes of oscilloscopes available for signal acquisition, processing, and display. These are generally referred to as the *analog oscilloscope* and the *digital storage oscilloscope.* Figure 1 shows a basic block diagram of each oscilloscope class for purposes of comparison in the following discussion.

1.1 Analog Oscilloscopes

Beginning with the input signal from a probe or sensor, the first operation of an analog oscilloscope is input signal conditioning. This consists of either attenuation or amplification to provide an amplitude-calibrated signal within the vertical display range of the oscilloscope. This input signal drives the display trace vertically, similar to the y-axis pen drive on a plotter or chart recorder.

The input signal amplitude or y-axis drive provides one dimension of the display. The second dimension, the x-axis drive, is provided by a second signal. When the oscilloscope is operated in what is called an x-y mode, the x-axis drive signal is a second input signal. This produces an x-y display of one signal against another, such as in creating Lissajous patterns. However, typical oscilloscope usage, which is the focus here, is to plot or display signal amplitude (y) against time on the x axis. This is done by using a ramp signal generated within the oscilloscope to provide the x-axis or horizontal drive. The ramp signal used is often referred to as the horizontal sweep signal. The duration of this ramp and how it is triggered are key factors in providing the desired time-calibrated display of the signal being input to the oscilloscope.

As shown in Fig. 1(a), triggering information is obtained at the signal input stage. The setup of the triggering and horizontal systems also determines how the signal is displayed. This is illustrated in Fig. 2.

The trigger system settings determine the point on the input signal that causes triggering to occur. Triggering starts sweep generation by the horizontal system. The sweep signal is a linear ramp that drives the display trace left to right across the display at a constant sweep speed. The duration of this ramp, and thus the horizontal sweep speed, are determined by the oscilloscope's time-base setting. This provides horizontal time calibration of the display.

In single-shot triggering, the trigger is manually armed by pressing a trigger arm button. One single-sweep display occurs when the input signal crosses a preset trigger level. There are no further displays after that until the trigger is manually rearmed and another triggering event occurs. The single-shot mode is intended for use in acquiring single events such as a laser pulse, a sonar ping, or a mechanical impact signal.

A repetitive triggering mode is used for acquiring repetitive signals such as sinusoids. This is the triggering mode shown in

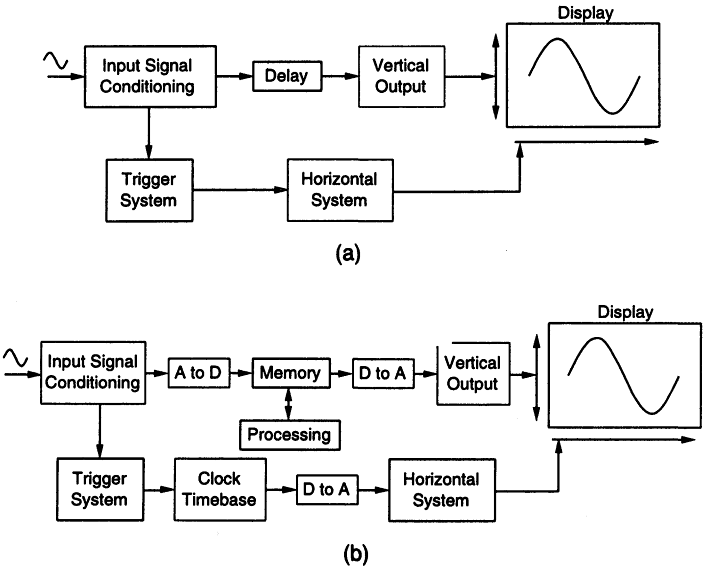

FIG. 1. Block diagram of (a) an analog oscilloscope and (b) a digital storage oscilloscope (DSO). The DSO has the same analog oscilloscope front-end requirements for signal conditioning and triggering.

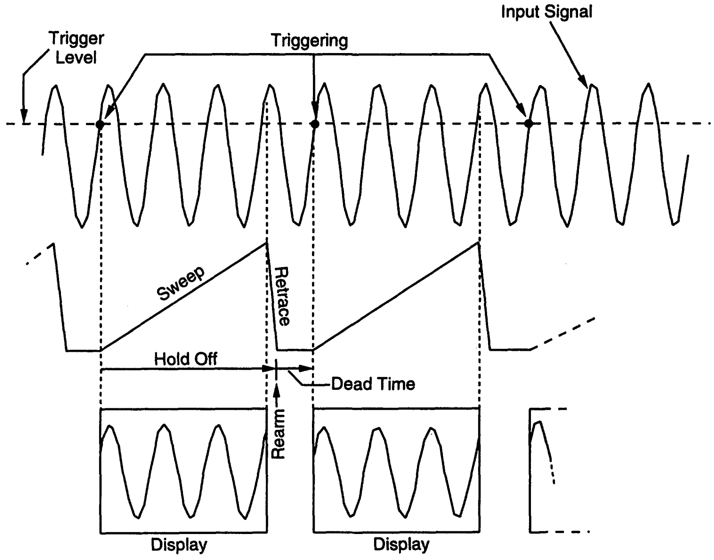

FIG. 2. A trigger level and triggering conditions are set up to determine the beginning point of waveform acquisition and display. Triggering also starts the sweep ramp for driving the display trace horizontally.

Fig. 2. Note that a sweep, and thus a display, are generated when the input signal reaches the trigger level setting. Once the sweep starts, further triggering is held off until sweep retrace is completed. At this point, the triggering circuitry is automatically rearmed. The next sweep (and display) then occurs when the input signal again crosses the trigger level.

The display on an analog oscilloscope is created by driving an electron beam across the phosphor-coated screen of a cathode ray tube (CRT). The input signal drives the CRT's vertical deflection plates to move the beam vertically, and the triggered sweep ramp (or other signal) drives the CRT's horizontal deflection plates to move the beam horizontally. The beam electrons strike and excite the CRT phosphor, causing it to emit light along the path traced by the electron beam.

In the case of single-shot triggering, the phosphor is excited by a single pass of the electron beam. However, the faster the beam is traveling (higher sweep speeds), the less the excitation and the dimmer the trace. The limit where portions of the displayed trace are no longer visible defines the CRT's writing speed. Thus, for viewing single-shot events on an analog oscilloscope, it is important to have a high–writing-speed CRT.

For repetitively triggered events, such as illustrated in Fig. 2, CRT writing speed is less of a concern. This is because the repetitively triggered sweeping of the beam regularly reexcites the phosphor in the trace path. As a result, repetitively triggered wave forms provide bright traces even when acquired at extremely fast sweep speeds.

It is important to note that the wave-form display process is analog and occurs in real time. That is, the actual analog signal being acquired is used directly to create the display trace. Thus, changes in the input signal are immediately reflected on the oscilloscope display in real time, as the signal changes actually occur. This is a key advantage when using the oscilloscope as a monitoring aid in making amplitude or timing adjustments on signals.

Another advantage is that momentary wave form disturbances, such as amplitude noise or time jitter, are also easily distinguishable. Such momentary or random signal disturbances cause corresponding deviations from the predominant trace path. Over multiple triggered traces, the result is less intense traces surrounding the more intense trace of the statistically dominant trace path. This intensity variation provides a subjective indication of signal noise statistics.

The real-time aspect of analog oscilloscopes can be a disadvantage, too. Since the display is a real-time display, transitory signal changes may fade from view before they can be studied. In the case of single pulses or other transient signals, the trace is a single brief flash across the screen. If the CRT's writing speed is not sufficient, there may be no trace at all. At the other extreme, a very low-frequency wave form may appear only as a bright dot moving slowly across the screen.

Many of these real-time display problems have been addressed through variations in CRT technologies. High-persistence phosphors have been used, for example, to slow trace fading in single-shot or low-frequency applications. Trace viewing time has been extended even more by use of storage meshes behind the CRT's phosphor. Another alternative is the use of CRT photography to capture transitory real-time displays for more detailed study.

1.2 Digital Storage Oscilloscopes

The digital storage oscilloscope (DSO) was developed to answer some of the shortcomings of analog oscilloscopes. Primarily, the DSO digitizes the input signal and stores it in digital memory. The key advantage is that the stored wave form can be easily reconstructed on the display at any time, even long after the actual analog signal is gone.

For transient events, the DSO essentially freezes the event on screen for detailed study. By contrast, single-shot capture of transient events with an analog oscilloscope provides only a brief trace flash on the display. Any detailed study of such analog wave-form displays must usually be done via a photograph of the display.

For any signal—single-shot or repetitive—digital storage offers the advantages of detailed analysis. For example, the mean value, root mean square value, or any other signal parameter can easily be computed from the stored values of the digitized signal. With appropriate computational support, advanced analysis techniques can also be applied. This can include performing fast Fourier transforms, convolution, correlation, or any other analytic process that can be programmed.

While the digital storage and processing of a DSO offer numerous advantages, there can also be some disadvantages. Understanding both the advantages and disadvantages relative to analog oscilloscopes is an important part of oscilloscope selection. However, before making a digital vs analog selection, it is important to consider the general wave-form capture requirements that apply to both.

1.3 General Wave-Form Capture Requirements

All oscilloscopes, regardless of their type, have an analog signal input system. This is necessary since the real world is analog. Even the digital signals used in digital systems are, in actuality, analog signals; they are time-continuous voltages that are simply level switched to represent digital data.

Consequently, whether considering an analog oscilloscope or a DSO, the first issue is the analog signal input requirements. This includes not only the oscilloscope's input signal conditioning but also the effects of probing or sensing.

1.3.1 Bandwidth and Rise Time Oscilloscopes are most commonly specified in terms of frequency bandwidth—e.g., a 200-MHz oscilloscope, a 200-MHz DSO. The bandwidth specification refers to the maximum-frequency sinusoid that can be acquired and displayed without significant signal attenuation. In other words, a 200-MHz oscilloscope can be expected to display any sinusoid up to 200 MHz without significant signal attenuation.

In the case of nonsinusoidal signals, the bandwidth specification must be interpreted in terms of the highest frequency component of significance in the signal being acquired. For example, repetitive nonsinusoidal wave forms, such as a square-wave signal, are made up of the fundamental frequency and some combination of harmonics. In general, such signals must be preserved out to the fifth harmonic for reasonably accurate observations and measurements. Thus, acquisition of a 40-MHz square wave would typically require a 200-MHz (5 × 40 MHz) oscilloscope to preserve signal amplitude and shape characteristics.

In many applications, the key consideration is measurement of a signal's rise time or some other timing aspect. For such applications, the oscilloscope's input bandwidth specification needs to be converted to a rise-time specification. According to Tektronix (1993a), the expression for bandwidth/rise-time conversion is

$$T_r = 0.35/f_{BW}, \qquad (1)$$

where T_r is rise time and f_{BW} is frequency bandwidth. Thus, the rise-time specification for a 200-MHz oscilloscope is 0.35/(200 MHz) = 1.75 ns. This expression can be derived from the Fourier transform relation between a Gaussian pulse's rise time and bandwidth. It provides a good approximation for most systems having a constant delay vs frequency.

An oscilloscope's rise time should be faster than the signal rise time being measured. How much faster depends on the measurement accuracy desired. The graph in Figure 3 provides a means of determining the necessary rise time for a desired accuracy. For example, if the oscilloscope's rise time is 3 times the rise time being measured (3:1 rise-time ratio), a 5% measurement error can be expected.

1.3.2 Probing Effects The type of probe or sensor used with the oscilloscope must also be considered as part of the overall measurement system. This is because the probe's impedance causes circuit-loading effects.

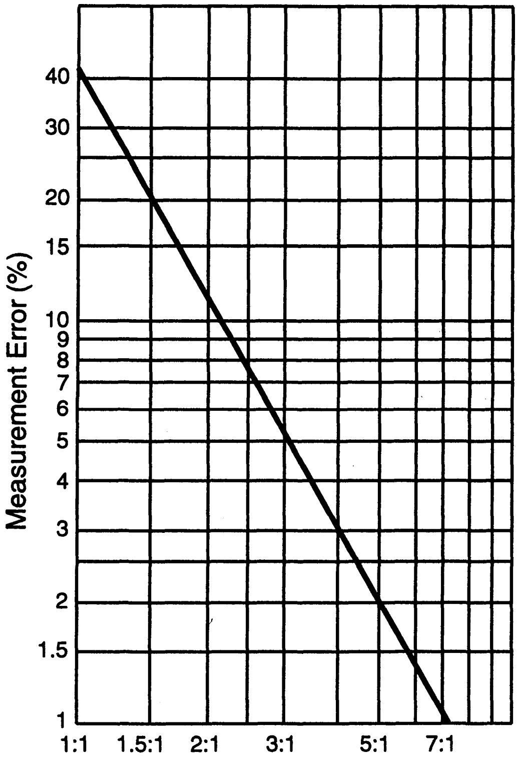

FIG. 3. Chart for determining rise-time measurement error. The amount of error depends on the ratio of the oscilloscope's rise time to the rise time being measured. A 3:1 ratio corresponds to 5% error.

For signal frequencies below 5 kHz, resistance is the dominant circuit-loading element. To minimize resistive loading, the probe used should have a resistance that is at least two orders of magnitude greater than the impedance of the circuit or sensor output being measured.

As frequencies progress above 5 kHz, probe inductance and capacitance have increasing loading effects. There are several steps that can be taken to reduce this reactive loading. To minimize inductive effects, the probe should be securely grounded with as short a ground lead as possible. To reduce capacitive effects from the probe, an attenuator probe (e.g., 10× attenuation) can be used. (Essentially, added resistive attenuation at or near the probe tip reduces the shunting effects of stray capacitance in the probe body and probe cable to the scope input.)

Additionally, the probe used should be adjusted to compensate for variations in the oscilloscope's input capacitance. Probe compensation is a simple procedure that is described in most oscilloscope manuals. Yet it is also one of the most often overlooked procedures, the result of which can be serious measurement errors, as reported by Tektronix (1993b).

Probes, like oscilloscopes, have rise-time and bandwidth limitations. As a result, probe selection must also be made to ensure adequate bandwidth or rise time for the signals to be measured. However, the probe's bandwidth or rise time cannot be considered alone. This is because the probe is an integral part of the oscilloscope's or DSO's input system.

Thus, the overall input system rise time must be considered in terms of the following relationship:

$$T_{r(\text{system})} = \sqrt{T^2_{r(\text{scope})} + T^2_{r(\text{probe})}}. \qquad (2)$$

The system rise time computed by Eq. (2) can be re-expressed as a system bandwidth using Eq. (1).

The key point to be realized from Eq. (2) is that inappropriate probe selection can significantly degrade the input bandwidth of an oscilloscope or DSO. To avoid this, manufacturers of high-quality instruments generally optimize their instruments for specific probe models. As reported by Tektronix (1993b), oscilloscope manufacturers often specify oscilloscope bandwidth at the probe tip when specific probe models are used.

1.3.3 Transient vs Repetitive Even with sufficient bandwidth or rise time, it is still possible that the instrument will not be able to provide an adequate display of the acquired signal. The classic example of this is in acquiring transient wave forms such as static discharges, mechanical impacts, and other one-time events.

When acquired with an analog oscilloscope, the transient signal causes a single-sweep trace across the display screen. For slow transients, the trace speed is slow enough that ample energy is imparted to the screen phosphor for a brief, but visible, trace in normal room light. On faster transients, the faster trace speed imparts less energy to the screen phosphor and the trace is dimmer.

As transient speed (and thus single-sweep trace speed) increases, a point is reached where the visual writing speed of the analog oscilloscope's display is exceeded. When this occurs, the trace is no longer visible in normal room light. However, the trace may still provide enough phosphor excitation to be visible through use of a viewing hood or via single-shot display photography. When the transient and its trace speed exceed the display's photographic writing speed, the trace is too dim for capture even with specialized photographic techniques.

In general, the photographic writing speed limit of an analog oscilloscope is significantly less than the bandwidth and horizontal sweep-speed limits. This means that the transient wave-form viewing capabilities will be substantially less than the repetitive wave-form viewing capabilities. The exception to this is microchannel plate (MCP) display technology. MCP oscilloscopes provide trace intensity multiplication of about 1000 times, as reported by Gustafson *et al.* (1985). This MCP intensity amplification is usually sufficient for single-sweep viewing up to the oscilloscope's rise-time specification at bandwidths of as much as 1 GHz.

With DSOs, display writing speed is not an issue. This is because the display trace does not have to be a real-time representation of the acquired signal. Instead, the signal is digitized and stored in memory, and then a display is generated from the stored wave-form data. As a result, both transient and repetitive signals can be displayed with equally clear and bright displays. Moreover, because the display is reconstructed from memory, transients are no longer a brief flash on the display, but are frozen on-screen for easy viewing.

The DSO's real-time sample rate is the limitation for capturing and displaying transient signals. Many DSOs use equivalent-time sampling for capture of repetitive wave forms up to the DSO's bandwidth limit. However, equivalent-time sampling, as will be discussed later, is a method of using lower real-time sample rates to create, effectively, high-speed sampling on repetitive wave forms. For single-sweep transient capture, the limit is always the actual real-time sampling rate.

Certain types of DSOs use real-time sampling exclusively to allow capture of transients up to the DSO's bandwidth and rise-time limit. Such DSOs are generally designed specifically for transient signal capture and are often referred to as transient digitizers.

The limitation on transient capture imposed by real-time sampling is essentially the time resolution provided by the sample rate. Similarly, the maximum equivalent-time sample rate imposes the upper limit on repetitive wave-form capture with a DSO. By comparison, analog oscilloscope limits for transient wave form capture are the display's writing speed and the bandwidth/rise-time specification for repetitive wave forms.

There is one other special limitation that needs to be considered regarding repetitive wave forms. This is the limitation of viewing very slow wave forms on analog scopes. Subhertz wave forms must be acquired on the lowest sweep-speed settings. As a result, the display on an analog oscilloscope will be just a bright dot moving across the screen. For such cases, there are two solutions for viewing a full trace of the slowly changing signal. One solution is to use an analog display storage oscilloscope or other high-persistence display technology. The other solution is to use a DSO to digitize the signal and re-create a full trace from memory.

2. RESOLUTION AND ACCURACY

Resolution and accuracy are sometimes confused in discussing oscilloscopes. In many cases they are wrongly taken to be synonymous.

Accuracy is the degree of conformity to an accepted standard. Resolution is the ability to distinguish differences. Thus, measurements between different things cannot be more accurate than the ability to resolve the differences. Consequently, to take full advantage of accuracy, there must be at least enough resolution to match accuracy and preferably more.

2.1 Analog Display Resolution

Analog oscilloscopes display wave forms against a calibrated display graticule. Generally, this graticule consists of eight major vertical divisions by ten major horizontal divisions. Each division is one centimeter square.

Typical spot sizes for the beam trace representing an acquired signal will range from 1/25 to 1/50 of a division, as reported by Tektronix (1992). The spot size can resolve half of a trace width. Therefore, the vertical display resolution is one part in 400 to one part in 800, while horizontal resolution is one part in 500 to one part in 1000. This is adequate for most on-screen measurement needs. Also, many analog oscilloscopes now have measurement cursors, or crosshairs, that can be positioned on the display to simplify waveform time and voltage measurements. It should be remembered, however, that such analog cursors are actually measuring screen position. Therefore, the cursors must be carefully positioned on the wave-form trace for accurate wave-form measurements.

2.2 Digital Storage Resolution

Digital storage oscilloscopes operate by sampling the input signal and digitizing the sample values. Thus, the time resolution of the stored signal data corresponds to the sampling interval (Δt), which is the reciprocal of the acquisition sampling rate.

DSO resolution may also be expressed in terms of record length. When a signal is captured with a DSO, a block of samples is taken for digitizing and storage. The number of stored samples for any given signal is referred to as the record length. Typical DSO record lengths are 512 and 1024 samples, although longer records are often available. A record length of 1024 samples implies a horizontal resolution of one part in 1024.

Vertical resolution corresponds to the digitizing resolution, which is one part in 2^B, where B is the number of digitizing bits. An 8-bit digitizer, for example, provides an amplitude resolution of one part in $2^8 = 256$; a 10-bit digitizer provides one part in $2^{10} = 1024$.

2.3 Accuracy

Oscilloscopes and DSOs have a variety of accuracy specifications. The most important of these include the amplitude accuracy of the vertical system and the time-base accuracy of the horizontal system.

Amplitude accuracy is simply the degree of accuracy to which a signal amplitude can be measured using the oscilloscope or DSO. In other words, how accurately can the amplitude of a 1-V, peak-to-peak sinusoid be measured. A fairly typical accuracy is 5%, which corresponds to one part in 20. This is well within the basic vertical resolution requirement cited above in 2.1 and 2.2 (resolution is greater than accuracy).

Time-base accuracy refers to ramp or clocking accuracy in reflecting a calibrated time horizontally across the display. In analog oscilloscopes, this is most directly related to the linearity of the ramp signal that drives the horizontal sweep. This is critical since the ramp horizontally drives the display, and any ramp nonlinearity translates to an effective speeding or slowing of the represented time. High-performance oscilloscopes address this by keeping sweep nonlinearities to 3% or less.

In DSOs, a ramp is often used to drive the horizontal sweep of the display system. The accuracy of this ramp is also important for measurements made directly from the display. However, since the display is reconstructed from digital memory, rather than real-time acquisition, it is not necessary to use as wide a range of ramp speeds as in analog oscilloscopes. Instead, DSO timing accuracy is based on the clocking accuracy of the digital time base used to drive sampling.

2.4 Digital Time-Base Accuracy

Digital time bases are generally driven by crystal-controlled clocks. This provides greater long-term accuracy and stability than the real-time methods of analog oscilloscopes.

In a DSO, the digital time base clocks the occurrence of signal sampling. The stability and accuracy of the clock determine the accuracy of where samples fall relative to each other on the signal. This is particularly important for equivalent-time sampling techniques since a complete sample record is built up over many signal repetitions. The longer it takes to build such a record, the more dominant clock instability and drift become in placing samples relative to each other and to the signal.

It is important to note that the sample interval (Δt) is assigned to the stored signal record as a single number. This sample interval is the reciprocal of the sample (or clock) rate. Thus, instabilities in actual clock rate result in a deviation of sample placement relative to sample interval. As indicated in Fig. 4, not only does this create a timing error, but it also results in a sample amplitude error for changing signal levels.

3. MEMORY AND RECORD LENGTH

DSOs, by definition, require memory for storage of the digitized wave form. However, it is common today for analog oscilloscopes to have digital memory, too. In analog oscilloscopes, this memory is used for storing front-panel setups for easy recall. Most DSOs offer similar setup storage and recall features. The advantage is that, once a complex measurement setup has been made, it can be stored in memory. Then, at the press of a few buttons, the stored settings can be recalled from memory for automatic setup of the oscilloscope or DSO.

A typical memory specification is the number of front-panel setups that can be stored in the DSO or oscilloscope. Another memory specification is the number of wave forms that can be stored in memory. The latter specification is exclusive to DSOs since analog oscilloscopes do not allow wave-form storage.

The number of wave forms that can be stored by a DSO is a function of available memory and the wave-form record length. As pointed out in previous discussion, record length is the number of stored samples used to represent the digitized wave form. The longer the record length (e.g., 1024 samples vs 512 samples), the greater the memory requirement for each stored wave form.

In some DSOs, record length is selectable. Thus, selecting a shorter record length allows more wave forms to be stored. On the other hand, a longer record length provides greater time resolution, but uses more wave-form memory, allowing fewer wave forms to be stored in a given memory size.

Also, memory can be partitioned differently in various DSOs. In some cases, there is fixed partitioning, allowing a fixed number of wave forms and front-panel setups to be stored. In other cases flexible partitioning allows trade-offs between the number of wave forms and setups stored.

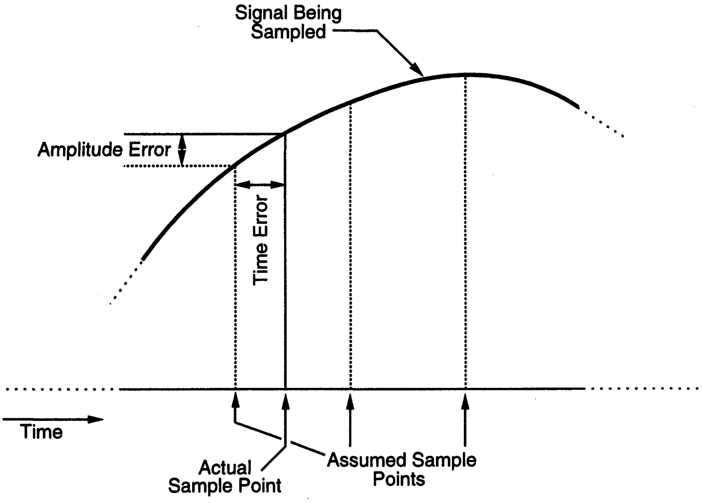

FIG. 4. Sample clocking inaccuracy results in two types of error. One is error in time placement of the sample. This results in a sample amplitude error that varies on the signal slope being sampled.

The key point is that, while memory and wave-form record length are important, the way memory is used is equally important. Applications requiring storage of numerous wave forms and few setups need memory partitioning in favor of wave forms. Applications requiring numerous front-panel setups generally benefit from memory partitioning in favor of setup storage.

4. ANALOG-TO-DIGITAL CONVERSION

Sampling and digitizing are the basic steps in analog-to-digital conversion (ADC) of wave forms. Up to this point, ADC has been discussed in a general sense. In reality, there are numerous ADC methods available. Each method has different advantages and limitations for wave-form acquisition and storage.

4.1 Digitizing Rate

The term "digitizing rate" is sometimes used in place of "sampling rate." To be correct, sampling rate is the rate at which amplitude samples are taken, and digitizing rate is the speed of converting an amplitude sample to a digital value. Thus digitizing and storage of an amplitude sample value must be completed before the next sample arrives for digitizing.

In terms of wave-form representation, the digitizing or sampling rate must be fast enough to define the wave form adequately. In the strictest sense, ADC must, at minimum, meet the Nyquist sampling rule. The Nyquist rule states that there must be two samples per cycle for the highest frequency of significance in the wave form being sampled.

For example, consider the case where the highest frequency of significance in a 20-MHz wave form is the fifth harmonic. Then, according to the Nyquist rule, the wave form must be sampled at a rate that is twice the frequency of the fifth harmonic. This would be a sampling rate of 200 MHz for the fifth harmonic of a 20-MHz wave form.

For most purposes, it is easier to think of sampling rate in terms of the DSO's bandwidth. At a minimum, the Nyquist sampling limit should be twice the DSO's bandwidth. For a 200-MHz DSO, this corresponds to a 400-MHz sampling rate at minimum. However, that also means that a 400-MHz sinusoid would be acquired with only two samples per cycle. While two samples per cycle may be adequate for mathematical description of the sinusoid, it is inadequate for graphical display of a recognizable sinusoid. Because of this, many DSOs use oversampling to provide more samples per cycle at the bandwidth limit. The effects of various numbers of samples per cycle on graphical representation are shown in Fig. 5.

4.2 Real Time and Equivalent Time

Real-time ADC means that all wave-form amplitude samples are taken, digitized, and stored in real time, as the wave form occurs. This is the ADC method necessary for capturing single-shot events. Samples are taken one after the other, in sequence, as the event transpires.

The difficulty with real-time ADC is the rates needed for adequate oversampling of the DSO's bandwidth. For example, with a 200-MHz DSO, oversampling at just 5 times the bandwidth means an ADC rate of 1 GHz. While 1-GHz and higher real-time ADC rates are certainly achievable, the technology is not inexpensive. Moreover, such high rates are not necessary when dealing with repetitive wave forms.

Repetitive wave forms can be repetitively acquired in a triggered mode (see Fig. 2). Since the wave-form repetitions are acquired over and over, a few samples can be taken at different points on each triggered acquisition. Over many triggered acquisitions, enough samples can be accumulated for a complete record of the wave form. This concept is illustrated further in Fig. 6. Essentially, the resulting composite of wave form samples is an equivalent-time representation of what would be achieved with a very fast real-time sampling rate.

Equivalent-time DSOs can capture repetitive wave forms with significant oversampling, even at their bandwidth limit. This is done economically by using low real-time sample rates and the correspondingly less-expensive ADC technology. For example, a 1-MHz real-time ADC can be used to achieve equivalent-time rates of hundreds of megahertz and even gigahertz for capturing repetitive wave forms. This assumes, of course,

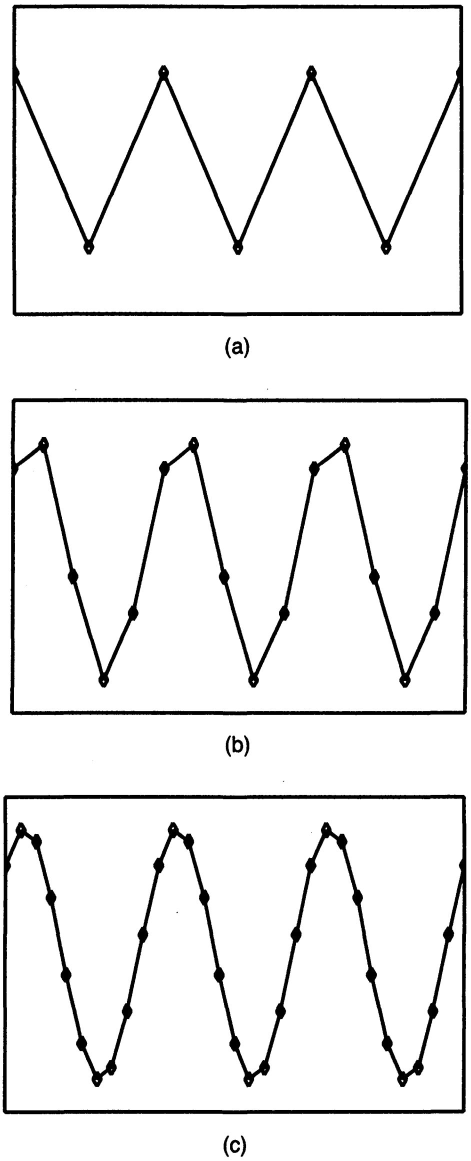

FIG. 5. The effects of various numbers of samples per cycle in accurate portrayal of a sinusoid—(a) two samples per cycle, (b) six samples per cycle, (c) 12 samples per cycle.

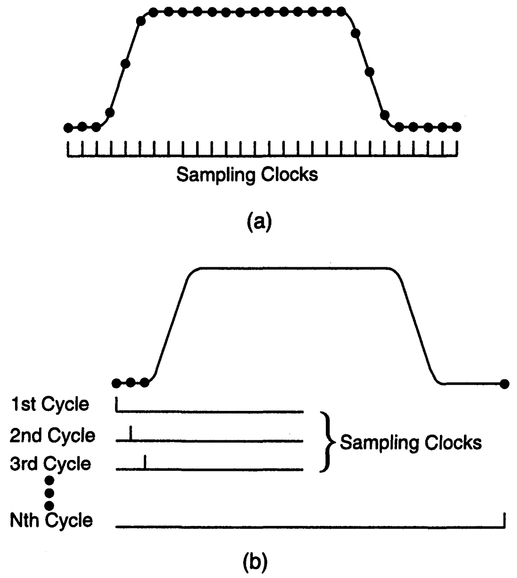

FIG. 6. Comparison of sampling methods. (a) In real-time sampling, samples are taken in sequence as the wave form actually occurs. (b) In equivalent-time sampling, samples are accumulated from numerous triggered acquisition cycles. For example, a 512-point record may take 512 acquisitions for complete sampling.

adequate analog bandwidth in the oscilloscope circuitry preceding the ADC.

There are some important cautions, however, when considering equivalent-time DSOs. Some DSOs with high equivalent-time capabilities gain their economic edge by using the lesser technology of very low real-time digitizing rates. This results in a very low single-shot capture capability for transients since single-shot capability is always limited to the real-time sample rate. Also, with a low real-time rate, full equivalent-time sampling can take longer because more repetitive acquisitions are necessary to build up a full wave-form sample record. Finally, any wave-form jitter or amplitude variations will have a degrading effect on the accuracy and appearance since the final record is a composite of many acquisitions over time. However, degradations from random effects can be reduced through the process of signal averaging.

4.3 Converter Types

A variety of converter types have been developed to meet various speed, resolution, and economic requirements. The major categories of converter types used in DSOs are successive approximation, flash conversion, charge coupled devices (CCDs), and scan conversion.

4.3.1 Successive Approximation These converters compare the input signal sample level to the output of a digital-to-analog converter (D to A). A bit-by-bit conversion is made starting with the most significant bit (MSB) and ending with the least significant bit (LSB).

Since each analog sample is digitized bit by bit, there is a trade-off between conversion speed and digital resolution (e.g., 8-bit vs 10-bit). For higher resolutions, longer conversion times must be accepted. To overcome the conversion-time trade-off, equivalent-time sampling methods are almost always used with successive approximation. However, the real-time conversion rate is still an important consideration for overall wave-form acquisition time and for any single-shot capture needs.

4.3.2 Flash Conversion These converters use a binary string of resistive dividers and comparators. The number of divider resistors and comparators is equal to the binary resolution of the converter. For example, an 8-bit converter would use an eight-level string of dividers and comparators.

The analog sample is applied to the top of the divider string, and the comparators output the corresponding binary levels in parallel. Since the conversion to all bits takes place in parallel, the method is quite fast, hence the name "flash" conversion.

However, there are several trade-offs to consider in flash conversion. One trade-off is that for higher resolution, more resistive elements and comparators must be strung together. This translates to greater converter complexity and expense. Also, the resistive divider string must be carefully designed to compensate for changing values at higher frequencies. Designing a high-performance flash converter is not a trivial task. Still, flash conversion offers an economical method for fast equivalent-time DSOs with real-time rates that are substantially higher than those using successive approximation.

4.3.3 Charge Coupled Device (CCD) A CCD is actually a very fast analog sampler and not a digitizer. Essentially, the CCD consists of a set of input cells, a memory section, and a set of output cells.

The key is that the CCD takes in analog samples at a high rate and transfers them to the memory section. The analog samples are held in memory and can then be read out and digitized at a slower rate, by successive approximation for example.

The advantage of the CCD technique is that high real-time sample rates can be achieved at modest cost. As reported by Tektronix (1992), a 100-MHz sample rate, 1-K record length, and 8-bit vertical resolution can be achieved at a modest cost compared to other methods used to achieve the same performance level.

4.3.4 Scan Conversion Scan converters typically provide the highest available real-time performance. As a result, they are only used in the class of DSOs referred to as transient digitizers.

A scan converter is basically a double-ended cathode-ray tube (CRT). One end provides a writing beam similar to that in a conventional analog oscilloscope CRT. However, instead of writing the wave-form trace onto the phosphor of a viewing screen, the trace is written onto a semiconductor target in real time. The target holds the trace, usually in the form of charge in a diode array. The reading beam at the other end of the CRT then scans the target and reads out the stored trace. This reading process can be done at a slow rate, allowing digitizing to be done by one of the more economical digitizing processes.

During scan conversion (reading of the target) no further wave-form information can be captured. However, this usually does not present a problem in transient wave-form capture since transients are infrequent occurrences.

4.4 Vertical Quantizing

Vertical quantizing is often referred to as quantizing noise. It is a function of digitizing, and thus occurs regardless of the method of digitizing.

Quantizing occurs when the analog value of a sample does not correspond exactly to one of the available digital levels. Since the digitizer cannot represent the analog level exactly, it must default to the closest digital level above or below.

This quantizing process has the effect of adding noise to the captured signal, hence the term "quantizing noise." The amplitude of this quantizing noise (or error) depends on the vertical resolution of the digitizer. An 8-bit digitizer, because of its lower resolution, causes higher quantizing noise amplitude than a 10-bit digitizer.

Quantizing noise is unavoidable. However, under certain circumstances, it can be significantly reduced, as reported by Ramirez (1985). This reduction occurs when repetitive wave forms are signal averaged by a processor having greater resolution than the digitizer. The result of such averaging can be that 8-bit digitizing can be cleaned up to be equivalent to 10-bit or even 12-bit digitizing.

4.5 Effective Bits

Digitizer resolution is generally stated as static resolution. That is, an 8-bit digitizer provides 8 bits of resolution in digitizing a dc voltage level. It also will generally provide 8-bit resolution for slowly changing wave forms. However, jitter, sampling uncertainty, and other effects begin to have a greater influence as wave-form frequency increases. These effects manifest themselves as increased noise on the digitized signal.

Since increased noise from sampling uncertainty is digitizing noise, it can, in effect, be categorized as quantizing noise. Thus, a higher quantizing noise translates to a lower digitizing resolution. This means that an 8-bit digitizer can actually appear to be of much lesser resolution when digitizing higher frequency signals. For example, at 75% of its sample rate limit, an 8-bit digitizer may appear to effectively be a 5-bit digitizer.

As mentioned previously, random noise effects can be overcome by signal averaging when repetitive wave forms are being acquired. Signal averaging cannot be done on single-shot or transient waveform acquisition. As a result, most transient digitizers have effective-bits specifications for different points across their bandwidth. In general, the higher the effective-bits specification, the higher the transient digitizer's quality.

5. DISPLAY TECHNIQUES

Digitized wave forms are stored in memory as an array of discrete amplitude values. These discrete values are then processed to present a visual display representing the original analog wave form. How this display is created is a matter of preference as well as a matter of how various types of wave forms should be represented for accurate interpretation.

5.1 Dot Displays

Dot displays are the simplest of all displays. These consist of simply displaying each sample value from memory as a dot. The vertical position of the dot represents amplitude and the horizontal position represents time.

In truth, the dot display is the most accurate representation of the acquired wave form. This is because the dots are direct plots of the acquired samples, and the acquired samples are the only recorded wave-form data. What happens between samples is speculation because no wave-form information was acquired between samples.

In practice, dot displays can be horribly confusing. This is shown in Fig. 7, where several sinusoids of different frequencies are represented by dot displays. The problem is that, when the dots are moved closer together horizontally, the eye is tricked into picking out different wave-form patterns. Generally, the eye picks out lower-frequency

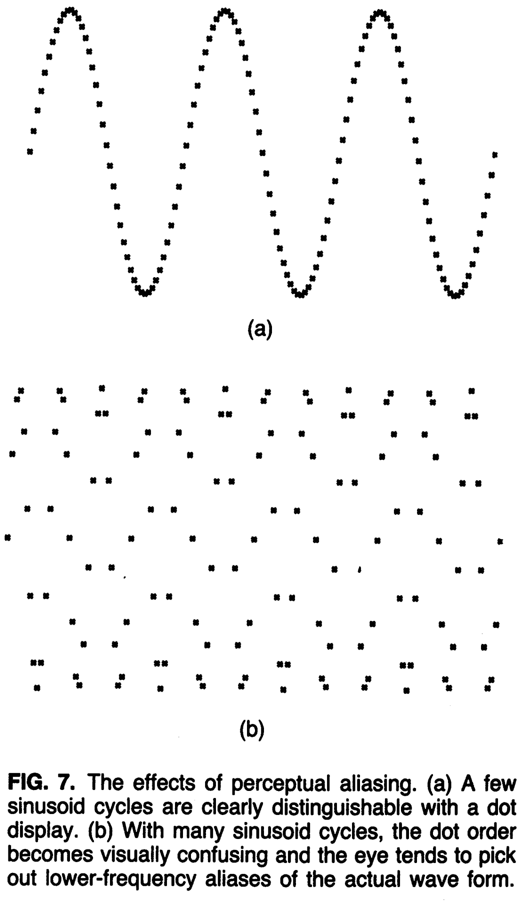

FIG. 7. The effects of perceptual aliasing. (a) A few sinusoid cycles are clearly distinguishable with a dot display. (b) With many sinusoid cycles, the dot order becomes visually confusing and the eye tends to pick out lower-frequency aliases of the actual wave form.

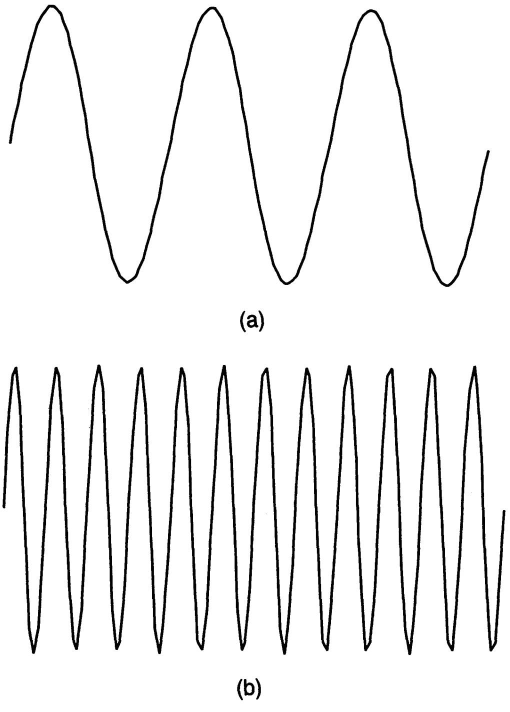
wave forms than actually represented by the dots. This effect is referred to as perceptual aliasing.

5.2 Interpolated Displays

To avoid perceptual aliasing, most DSOs provide interpolated displays. Most often the interpolation is linear. That is, a dot display is transformed by connecting the dots in time order with straight lines.

The effect of straight line interpolation is shown in Fig. 8. Note that, in comparison to the dot displays of Fig. 7, interpolated displays eliminate any confusion about the actual wave form path.

Linear interpolation provides a very close approximation of the actual wave shape for wave forms composed primarily of linear segments—e.g., square waves, ramps, triangular waves. For wave forms that follow nonlinear forms, such as sinusoids, other forms of interpolation may be preferred. Not surprisingly, sine interpolation is the most common form used in DSOs after linear interpolation. This is because sine interpolation provides a closer approximation for smooth wave forms.



(a)

(b)

FIG. 8. Linear interpolation or vector display. When a dot display is straight-line connected in dot order, wave forms are easier to distinguish. Compare (b) here to (b) in Fig. 7.

5.3 Peak Detection and Enveloping

Peak detection and enveloping are both special methods of handling samples to reveal special wave-form situations. Peak detection, in general, ensures capture of wave-form peaks or spikes that many times are not captured with ordinary sample processing. Enveloping is somewhat different and allows an envelope of maximum wave-form excursions to be captured.

With ordinary sample processing, the wave-form record is filled with samples taken at equally spaced points in time (Δt). The time spacing, or Δt, corresponds to the display-time window (total horizontal sweep time) divided by the displayed record length. For example, say that the DSO's sweep-speed setting is 0.01 s/division. For a 10-division horizontal display, this corresponds to a display-time window of 0.1 s. Thus, with a displayed record of 1024 sample points, the sample spacing (Δt) is 0.1 s/1023 = 0.97752 μs.

The problem with ordinary sampling is that short-duration details, such as a noise spike, can easily fall between samples and be missed. The likelihood of this happening increases with the greater sample spacing that accompanies acquisition of slower wave forms.

Peak detection minimizes the loss of small details, such as spikes, that could fall between samples. The method involves always sampling at full speed regardless of the sweep-speed (time base) setting. With a 100-MHz real-time sample rate, this corresponds to a fixed sample interval (Δt) of 1 ns. However, on longer time windows this results in far more samples than there is record length storage. A 0.1-s window with a Δt of 1 ns corresponds to 100,000,000 samples. For a stored record length of 1024 samples, only selected samples are stored and the excess samples are discarded.

For peak detection, the maximum-amplitude sample in any stored sample interval is retained for the stored wave-form record. This is illustrated in Fig. 9. The result is that for any sweep speed, no matter how slow, there is a very high probability of capturing wave-

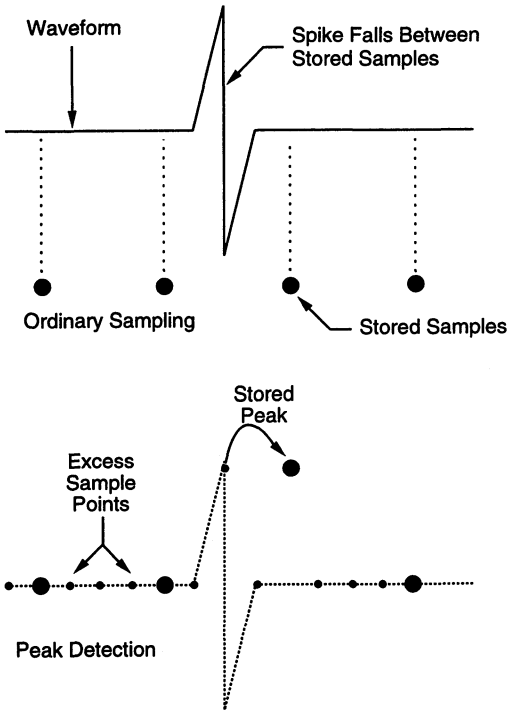


FIG. 9. Peak detection. With ordinary sampling, narrow wave-form spikes may occur between samples and may not be captured. Peak detection uses oversampling and picks the maximum valued sample for storage. This guarantees at least one sample on narrow spikes.

form peaks (or spikes) as narrow as the smallest sample interval. In the case of 100-MHz maximum sampling, this is referred to as 1-ns peak detection since peaks to 1 ns wide can be detected.

The key benefit of peak detection is that there is always an indication that signal spikes exist, even when operating at the slowest sweep speed. With this knowledge, a higher sweep speed can be used for more detailed capture and examination of the spikes. Without the initial indication provided by peak detection, signal spike problems could easily be missed.

Enveloping, another very useful process, can be implemented with or without peak-detection sampling. When implemented in conjunction with peak detection, enveloping is far more sensitive to minor wave-form changes.

Basically, enveloping involves the use of two stored wave-form records. One is used for maximum sample values and the other for minimum sample values. Over multiple wave-form acquisitions, an envelope display is created of maximum and minimum excursions of the wave form. Such an envelope display is very useful for detecting and studying jitter, drift, or other wave-form variations over time.

5.4 Pre- and Post-Trigger Displays

The majority of the displayed trace on an analog oscilloscope is a post-trigger display. It is the trace of the wave form occurring in time immediately after the trigger point (refer to Fig. 2).

In some oscilloscopes, a trigger hold-off feature allows the display to be delayed to a selected time after the trigger point. This is useful for viewing wave-form activity that occurs some time after a selected triggering point or triggering event. For example, the firing pulse for a laser could be used as a trigger, and trigger hold-off could be used to study laser activity some time after the firing pulse.

Often, it is important to see wave-form activity prior to the trigger point. This is referred to as pretrigger acquisition. Pretrigger acquisition is provided in some analog oscilloscopes by placing a fixed delay line in the signal path after the trigger-system pick-off point [refer to Fig. 1(a)]. This allows the displayed signal trace to include a portion of the signal occurring prior to the trigger point. The duration of this pretrigger portion of the display is equal to the time delay of the inserted delay line.

The pretrigger portion of the display shows wave-form activity prior to the trigger point. This is quite useful, for example, in capturing the starting point of pulses or transient wave forms. However, in analog oscilloscopes, delay-line pretriggering may not be sufficient for many needs. This will be especially true when the trigger level must be set high in order to avoid false triggers on noise or other aberrations (see Fig. 10).

DSOs get around the analog limits to pretrigger length in a fairly simple manner. This involves continuously sampling the input signal and shifting the samples through the record in memory. The segment of samples that is locked into memory as a stored wave-form record is determined by triggering on

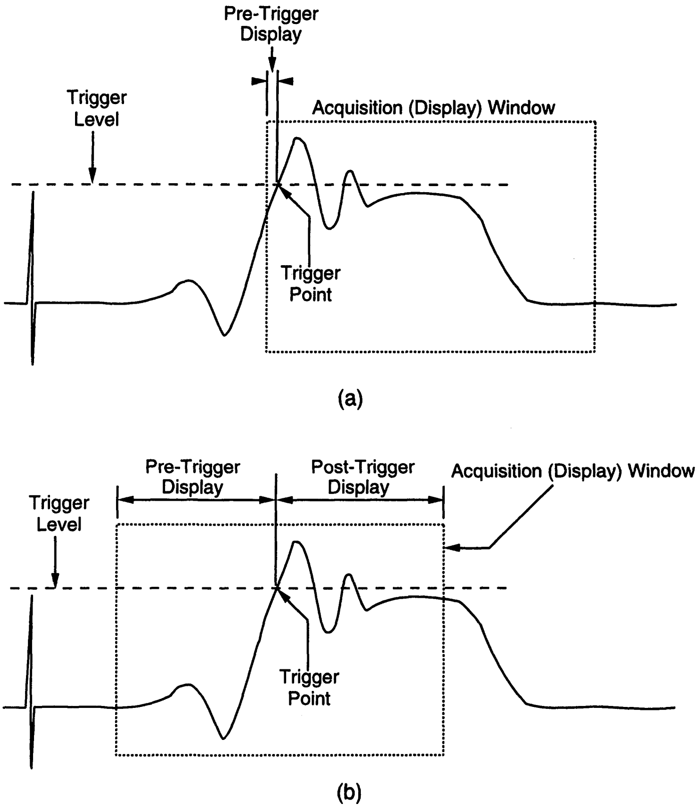

FIG. 10. Pre- and post-triggering. (a) Analog oscilloscopes use a fixed delay line to provide a small amount of pretrigger display. (b) Digital storage oscilloscopes can provide varying amounts of pre- and post-triggered wave-form information. This allows triggering above noise while still displaying the entire leading edge of a pulse.

the wave form and the amount of time that has been selected for pre- or post-triggering.

For example, let us say the DSO has been set up to provide half the display as pretrigger information and the other half as post-trigger information. The DSO is continuously acquiring samples and shifting them through memory while waiting for the triggering event. At the moment triggering occurs, samples existing in memory represent a record of 100% pretriggering information. Since the example setup calls for a record of 50% pretrigger and 50% post-trigger samples, the DSO continues acquiring samples after triggering until half a record length of post-trigger samples is in memory. At this point, the samples are frozen in memory as a wave-form record of half pretrigger and half post-trigger information, as shown in Fig. 10.

There are several key benefits to the adjustable pre- and post-triggering offered by DSOs. The first benefit is that trigger levels can be set high on the wave form to avoid false triggers, and the full wave form can still be viewed by using pretriggering to include the wave-form starting point. Another key benefit or use is the ability to look well ahead of the triggering point or event to study activity leading up to the triggering event. An example of the latter use would be study of charge buildup, corona, or other effects preceding high-voltage arcing.

6. USEFUL STORAGE BANDWIDTH AND RISE TIME

Previous discussion mentioned bandwidth and rise time as key specifications in selection and analog oscilloscope. The same analog specifications also apply to the signal input circuitry of a DSO. This is necessary for accurate presentation of the analog signal to the sampling and digitizing circuitry. Additionally, there are various other factors that affect the usefulness of the digitized signal display. Dot displays and perceptual aliasing are two of the factors already discussed.

Rather than trying to interpret the interactions of analog bandwidth and rise time and other various digitizing effects, combined figures of merit have been established for overall DSO evaluation. These figures of merit are referred to as useful storage bandwidth and useful storage rise time.

6.1 Useful Storage Bandwidth

In general, useful storage bandwidth (USB) is defined as follows for dot displays:

$$f_{\mathrm{USB}} = (\text{maximum digitizing rate})/25. \tag{3}$$

The value of 25 in the above relationship is the number of samples per cycle generally required for visual recognition of wave shapes on a dot display. For linearly interpolated display (vector connection of dots), the divisor value can be changed to 10.

6.2 Useful Storage Rise Time

With a DSO, the displayed rise time depends upon where samples fall on the actual rising wave-form transition. With a vector-interpolated display, the maximum rise-time errors on the DSO display closely follow the form of an analog oscilloscope's errors when the analog system has a rise time of 1.6 sample intervals. As a result, useful storage rise time (T_r) can be defined as follows:

$$T_r = (\text{minimum sample interval}) \times 1.6. \tag{4}$$

The above figure of merit applies to the worst-case error for rise-time measurement on a DSO vector display.

7. SIGNAL PROCESSING

One of the more powerful possibilities of a DSO is the ability to provide a wide variety of wave-form processing and analysis capabilities. Since the stored wave forms are essentially a series of numbers, virtually any kind of numerical analysis can be performed. Whether or not such analysis is available as a built-in feature depends on the particular DSO.

Most DSOs do provide measurement cursors for reading out the amplitude and time values of stored wave forms. Additionally, most DSOs provide the simpler built-in analysis functions such as wave-form maximum, minimum, average, and rms (root mean square) values.

High-end DSOs generally provide all of the simpler built-in functions as well as one or more advanced built-in functions. Some of the advanced functions that might be provided are briefly discussed below.

7.1 Save-on-Delta

Save-on-Delta is a function that relies on first storing an envelope of expected wave-form limits. Depending on the DSO implementation, the upper and lower limit traces can be generated manually or by downloading data to the DSO.

Once the upper and lower limit data, or envelope, is in place, Save-on-Delta acquisition of an actual wave form can begin. During acquisition, each sample of the wave form is compared to the upper and lower limit envelope. If the acquired samples do not violate the limits envelope, the wave form is not saved. If any sample does violate the limits envelope, the wave form is saved.

This acquisition mode is very useful for catching intermittent or infrequent wave-form conditions. A DSO can be left unattended in Save-on-Delta mode for as long as needed to capture limit-violation wave forms.

7.2 Averaging

Averaging can be applied to repetitively acquired wave forms to provide improvements in signal-to-noise ratio (SNR). Whenever possible, averaging should be applied to improve measurement accuracy.

The usual form of averaging is to select a number of acquisitions to be averaged—for example, 64 averages. Averaging then takes place by acquiring the first wave form. A second wave form is then acquired and automatically added to the previous wave form. This acquisition and summing of amplitude samples continues until the specified number of wave forms has been acquired and summed. The summed wave forms are then divided by the specified averaging number.

The result of averaging is that randomly occurring events (noise) on repetitively acquired wave forms become reduced, as reported by Ramirez (1985). When averaging is done at computation resolutions exceeding the digitizer's amplitude resolution, the effects of quantizing noise can also be reduced. This can result in a higher effective measurement resolution on the averaged wave form.

7.3 Integration and Differentiation

Stored wave forms can be integrated or differentiated using various numerical analysis routines. Typically integration and differentiation are done in a point-by-point (two point) process.

Integration is simply the process of calculating the rectangular area represented by a pair of points and summing those areas. The result of such integration provides a point-by-point plot of energy contained under the wave-form curve.

Differentiation is simply the point-by-point slope of a wave form. This is useful for defining break points on wave forms. A particularly useful application, as reported by Ramirez (1985), is in acquiring the impulse response of electronic circuits. Since a step voltage is easier to generate and control as a stimulus signal, a circuit step response is easier to acquire in most cases. When acquired with a DSO, the step response can be differentiated to provide an impulse response display.

7.4 Fast Fourier Transform

The classical Fourier transform is an analog method of transforming a time-domain signal to the frequency domain. This allows detailed analysis of a signal's frequency content. The discrete Fourier transform (DFT) is the classical numerical analysis approach to obtaining Fourier transform data. The fast Fourier transform (FFT) is simply a computationally efficient method of computing the DFT.

Some DSOs contain a built-in FFT algorithm. This allows acquired wave forms to be transformed from time-series displays to frequency-spectrum displays.

7.5 Convolution and Correlation

Convolution and correlation functions are very easy to compute in the frequency domain. For those DSOs having an FFT algorithm, the additional steps of providing convolution and correlations are often taken.

Convolution is a key computation used in transfer-function analysis. Correlation has many uses in signal identification and matching.

8. MEASUREMENT AUTOMATION

Since most oscilloscopes today are digitally controlled, they offer the opportunity for measurement automation. One form of automation has already been mentioned. That form is push-button storage and recall of instrument front-panel setups. Another form of automation just discussed is the signal processing capabilities that can be provided as built-in functions of DSOs.

Both forms of automation can be taken another step further by interfacing the instrument to a computer. When this is done, the automation resources are vastly expanded through software programming, disk storage, and setup and wave-form information transfers between the computer and instrument.

8.1 Interfacing Techniques

The basis for most stand-alone instrument interfacing today is the General Purpose Interface Bus (GPIB) as defined by the IEEE-488 specification. A single GPIB loop can contain up to 16 devices. One of the devices must be the GPIB controller (a personal computer for example), which leaves a potential of 15 devices for GPIB control. These devices can be DSOs, programmable analog oscilloscopes, arbitrary wave-form generators, power supplies, or any other type of GPIB instrumentation.

Another popular form of instrument interfacing is through an RS-232 port. This has become popular because most personal computers come standard with one or more RS-232 ports. The actual interfacing is still usually via the GPIB standard, but it is accomplished through RS-232/GPIB translation in the instrument's interfacing hardware and firmware.

RS-232 interfacing has another important advantage in that it is compatible with telephone modems. This allows an instrument to be remotely located and accessed through telephone lines and modem connection. If an RS-232/GPIB controller is used at the remote site, an entire GPIB instrument system can be remotely accessed and controlled over a single phone line.

8.2 Software Considerations

There are two key considerations in looking at software for automation applications. One consideration is the instrument interfacing and control software. The other is the wave-form handling and analysis software.

Most GPIB instrument manufacturers provide software drivers for their specific instrument models. These drivers are usually created so that they can be linked as modules into standard software platforms, such as BASIC or UNIX. A more important consideration, however, is command and syntax consistency across various instruments. If the manufacturer does not follow some form of codes and formats standard in creating drivers for various instruments, control of multiple instruments can become extremely complex.

After instrument control and wave-form transfer to the computer, there is the consideration of wave-form processing. This can be done by writing programs from the ground up using BASIC, C, or any other popular software platform. However, a tremendous amount of work can be saved by using any of several available wave-form processing packages. These packages provide specialized wave-form processing capabilities and often include many advanced analysis features such as FFT, convolution, correlation, modal analysis, and so forth. Essentially, once the acquired wave forms have been transferred to a computer, the analysis possibilities are endless.

9. CONCLUSION

Virtually any wave-form capture and analysis need can be met by one of the analog oscilloscopes or DSOs on the market today. The primary issue is matching application needs to a specific instrument type. This includes the following major steps:

1. Defining analog bandwidth and rise-time requirements.
2. Determining whether analog display or stored wave-form display is best for the application. Generally, digital storage is preferred for very slow wave forms, transient wave forms, or any wave form where substantial measurement or analysis is necessary. Analog oscillscopes are preferred for real-time wave-form viewing needs, such as in making circuit adjustments, and for multi-GHz transient recording.
3. Determining digital resolution in terms of both amplitude (digitizing resolution) and record length (generally longer records are needed for fast-rise, slow-decay wave forms).
4. Specifying sampling technique and rates—real time for single-shot transients and equivalent time for repetitive waveforms.
5. Wave-form storage requirements. Built-in instrument storage may be adequate for applications focused on a few wave forms, but large quantities of wave-form data usually require external storage (e.g., interfacing to a computer).
6. Considering the benefits that might be derived from the automated instrument control and advanced analysis techniques available through computer interfacing.

Careful consideration of the above issues in terms of specific application requirements will lead to a set of specific wave-form acquisition needs. This set of specific needs provides a clear definition of the specific instrument requirements for the application. This matching the tool to the job—rather than bending the job to fit an existing tool—leads to greater success in quickly obtaining useful measurement and analysis results.

It is important, however, to realize that both analog and digitizing oscilloscope technologies are marching to a quick pace and often leapfrog each other. This makes it risky to formulate any set of rules that dictates exclusive use of one technology over another for any given application need. Thus, evaluation of measurement needs against available oscilloscope technologies is an ongoing process.

As far as future trends are concerned, it is almost always safe to say that acquisition bandwidths and speeds will continue to increase. Also, with the digital age in full bloom, both analog and digitizing oscilloscopes are offering an expanding array of automation and measurement processing features. As a sidelight to this, industry observers speculate from time to time that oscilloscopes will eventually be compressed to a card that plugs into a personal computer. Current industry trends, however, suggest that the opposite is actually happening. More and more specialized computing power is being compressed into oscilloscopes. Whatever course future implementations take, the key oscillographic concepts will remain the same—acquisition, processing, and display of wave forms.

GLOSSARY

Aliasing: A condition where one frequency takes on the appearance of another frequency. In sampling, a minimum of two samples per cycle is required to avoid aliasing. In dot displays, perceptual aliasing can be prevented by connecting the dots in their correct time order.

Bandwidth: The continuous band of frequencies passed or transmitted by a device without undue attenuation. The bandwidth or pass-band edges are often defined as the points where amplitude becomes attenuated by 3 dB (half power).

Cathode-Ray Tube (CRT): A vacuum-tube display device consisting of an electron beam, an electronic drive and deflection system, and a phosphor-coated display screen. The deflection system traces the electron beam across the phosphor coating on the back of the screen causing luminescence of the phosphor along the beam path for a visible display of the trace on the front of the screen.

Equivalent-Time Bandwidth: The highest attainable bandwidth using equivalent-time sampling (one-half the equivalent-time sample rate).

Equivalent-Time Sampling: Any wave-form sampling method where a full wave-form record is built up over multiple, repetitive acquisitions of a wave form. Equivalent-time sampling allows capture of high-speed repetitive wave forms while using lower speed sampling and analog-to-digital conversion. Equivalent-time sampling cannot be applied to the capture of single-shot, transient wave forms.

Fast Fourier Transform (FFT): An efficient computer algorithm for computing the discrete Fourier transform of sampled waveform data. Time-domain samples are converted to frequency-domain data or vice versa.

Persistence: In reference to CRT phosphors, the property of persisting in light emission after excitation has ceased. Oscilloscope traces fade more slowly with high-persistence phosphors than with low-persistence phosphors.

Probe: Device used to sense or pick up signals and convey them to an instrument for observation or measurement. Voltage probes are commonly used with oscilloscopes, but current and temperature probes are generally available, too. In many cases, the probe is used to pick up the output of another sensor such as a strain gauge or accelerometer.

Probe Compensation: Adjustment of probe capacitance so that the probe attenuates all input signals equally across a range of frequencies.

Real-Time Bandwidth: The highest attainable bandwidth using real-time sampling (one-half the real-time sample rate).

Real-Time Sampling: Any wave-form sampling method where samples are taken sequentially in real time as the wave form actually occurs. Real-time sampling is required for the capture of single-shot, transient events and is equally applicable to the capture of any other class of wave form (repetitive, random, etc.).

Record Length: The number of samples acquired and stored as a digitized representation of a wave form.

Rise Time: The time required for the leading edge of a pulse to rise from 10 to 90% of its final value.

Sweep Speed: The speed at which the CRT display's electron beam is driven horizontally across the screen. Sweep speeds are usually in terms of seconds per display division, providing a time-calibrated display.

Time Base: In oscilloscopes, an electronic sweep or clocking system used to provide time-calibrated acquisition and display of wave-form information.

Triggering: The process where selected wave-form conditions cause acquisition of the wave form to begin.

Trigger Hold Off: A period of time when triggering is prevented. This is usually done to prevent a second trigger during the horizonal sweep period. Trigger hold off may also be used to provide a delayed sweep, allowing acquisition to occur at a selected period of time after the triggering event.

Trigger Point: The point on a wave form that causes triggering of wave-form acquisition.

INTRODUCTION

Osmosis [from the Greek *ōsmos*, the action of pushing, derived from *ōthein*, to push (Morris, 1981)] is the phenomenon resulting from the tendency of a pure solvent to diffuse into a solution separated from the solvent by a membrane that is permeable only to the solvent (Atkins, 1990). Many important examples of osmosis are found in nature. Osmosis drives the transport of oxygen and carbon dioxide across capillary walls separating blood from air in the lungs. Fresh fruit will shrivel when placed in contact with strong sugar solutions, and dried fruit can swell in contact with water as a result of osmosis (Marick, 1969). The delicate balance of chemical substances inside living cells is maintained, in part, by osmosis. Furthermore, osmosis has been exploited scientifically as a sensitive probe of molecular weight of natural and synthetic macromolecules (Tanford, 1961). Reverse osmosis is an important industrial process for making drinking water from saltwater. A feed stream such as brackish water or seawater, is contacted with a membrane that is permeable to water but impermeable to microorganisms, colloids, dissolved salts, and organic species. The feed stream is pressurized to force permeation of pure, drinking-quality water across the membrane (Bhattacharyya and Williams, 1992). In the 1940s, the concept of artificial kidney dialysis was demonstrated and has become widely used to prolong the lives of people suffering from renal failure (Kessler and Klein, 1992). This technology is based on the osmotic transport of metabolic waste products from blood into a saline solution. The blood and saline solution are separated by a membrane that is permeable to the waste products.

Osmosis can be observed by separating a solution of sugar water from pure water by a semipermeable membrane made of a material such as cellulose, which permits small water molecules to permeate through the membrane but does not allow permeation of the larger solute molecules (in this case sugar) (Atkins, 1990). At the start of the experiment, the osmometer shown in Fig. 1(a), containing a sugar-water solution, is dipped into a bath of pure water to a depth such that the sugar solution in the tube is at the same level as

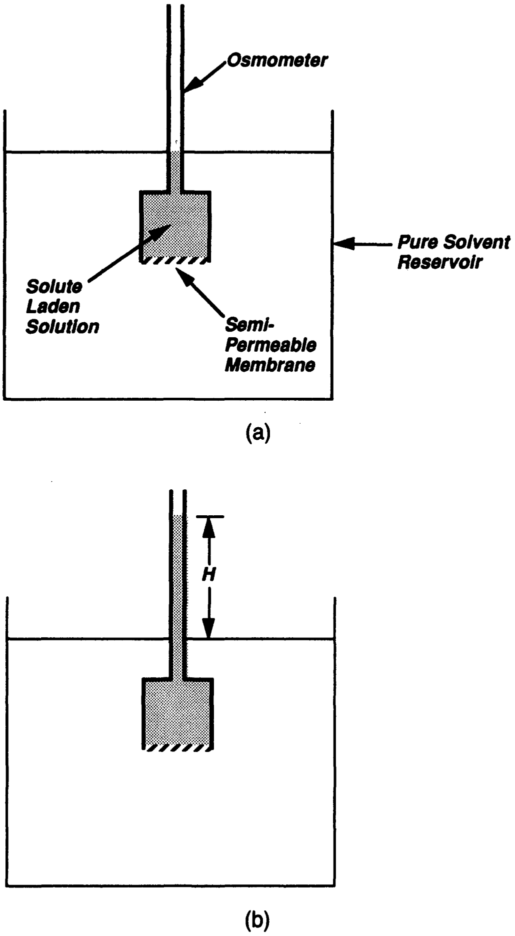

FIG. 1. Schematic of experiment to detect osmotic pressure of sugar water solution.

the pure water. As time proceeds, pure water diffuses across the semipermeable membrane into the solute-containing solution. As the pure water enters the sugar-water solution, it raises the level of the solution in the tube, and the pressure of the solution at the membrane face increases. Figure 1(b) illustrates the system at equilibrium, when there is no net transfer of solvent across the membrane, and the pressure of the sugar-water solution is higher than the pressure of the pure water in contact with the membrane. The value of the pressure difference across the membrane is $(\rho - \rho_{\text{air}})gH$, where ρ is the solution density, ρ_{air} is the density of air in the tubes above the solvent and solution, g is the average gravitational acceleration, and H is the difference between the level of sugar water in the capillary above the sugar-water reservoir and the level of pure water. This pressure difference is the osmotic pressure π.

Osmotic pressure is a thermodynamic property of a solution related to the solvent chemical potential in the solution (Denbigh, 1981). The experiment described in Fig. 1 is, therefore, an operational method for determining osmotic pressure, but the definition of osmotic pressure does not rely on the presence of a membrane or a bath of pure solvent. Like freezing point or boiling point temperatures, it is an intrinsic property of the solution. In this regard, the osmotic pressure does depend on solute concentration and nature since it is the presence of the solute that depresses the solvent chemical potential below its value in pure solvent. This chemical potential decrease, in turn, leads to experimentally observable manifestations of osmotic pressure (such as the increase in the height of solution in the capillary column described above). To provide some perspective of the magnitude of the osmotic effect, Table 1 presents values of osmotic pressure for several systems of interest. In this table, the increase in solution osmotic pressure with increasing solute concentration is observed.

1. MOLECULAR AND THERMODYNAMIC DESCRIPTION OF OSMOSIS

1.1. Molecular Basis of Osmosis

The presence of a solute in a solution can depress the solvent chemical potential by diluting the solvent (i.e., the solvent mole fraction is less in the solution than in pure solvent) (Denbigh, 1981). When a reservoir of solution is separated from pure solvent by a semipermeable membrane, the solvent chemical potential difference between the two solutions is a driving force for molecular diffusion of solvent from the solvent reservoir across the membrane into the solution. As solvent diffuses across the membrane, a pressure difference between the two reservoirs is established. The magnitude of this pressure difference increases until the solvent chemical potential in the solution is exactly equal to the chemical potential of the pure solvent. The equality of solvent chemical potential on both sides of the membrane is the criterion

Table 1. Typical values of osmotic pressure at 25 °C (Riley, 1990).

Solute	Concentration (mg/L)	Concentration (mol/L)	Osmotic pressure (bar)
NaCl	2 000	0.034 2	1.57
NaCl (isotonic solution)[a]	9 050	0.155	7.85
NaCl	35 000	0.60	27.4
Brackish water	2 000–5 000	0.034–0.086	1.0–2.7
Seawater	32 000		23.4
Sucrose	1 000	0.002 92	0.072
Dextrose	1 000	0.005 5	0.14

[a] Isotonic with mammalian plasma (Woodbury 1965).

for thermodynamic equilibrium (Denbigh, 1981). At equilibrium, there is solvent exchange between the two reservoirs due to molecular diffusion, but there is no net transport of solvent from one side of the membrane to the other. The pressure difference across the membrane at equilibrium is defined as the osmotic pressure.

1.2. Thermodynamic Analysis of Osmosis

The chemical potential μ_0 of a solvent in a solution at temperature T and pressure P relative to the chemical potential of pure solvent at the same temperature and pressure may be expressed as (Denbigh, 1981)

$$\mu_0 = \mu_0^0 + RT \ln a_0, \tag{1}$$

where μ_0^0 is the chemical potential of the pure solvent at temperature T and pressure P, R is the gas constant, and a_0 is the solvent activity. If the solution pressure is increased from P to $P + \pi$, the solvent chemical potential becomes

$$\mu_0 = \mu_0^0 + RT \ln a_0 + \int_P^{P+\pi} \bar{v}_0 dP, \tag{2}$$

where $\bar{v}_0$ is the partial molar volume of solvent in the solution (Prausnitz, 1969). Solvent in a solution will be in equilibrium with pure solvent when

$$\ln a_0 = -\frac{1}{RT} \int_P^{P+\pi} \bar{v}_0 dP. \tag{3}$$

The osmotic pressure π is, therefore, the pressure that must be applied to the solution to raise the solvent chemical potential in the solution to its pure-solvent value. The solvent partial molar volume is, to a very good approximation, independent of pressure (Denbigh, 1981), and therefore the osmotic pressure may be written as

$$\pi = -(RT/\bar{v}_0) \ln a_0. \tag{4}$$

1.2.1 Osmotic Pressure of an Ideal, Nonionic Solution The thermodynamic activity of solvent in an ideal solution is related to the solvent concentration as

$$a_0 = x_0, \tag{5}$$

where x_0 is the mole fraction of solvent (Denbigh, 1981). The reference state for chemical potential chosen for Eq. (1) is pure solvent and, accordingly, the solvent activity is 1.0 when the mole fraction of solvent is 1.0. As the solvent is diluted by solute, the solvent mole fraction and, in turn, activity decrease, which leads to a decrease in the solvent chemical potential according to Eq. (1). The solvent partial molar volume is equal to the pure-solvent molar volume in an ideal solution (Prausnitz, 1969). For an ideal solution, therefore, Eq. (4) becomes

$$\ln x_0 = -\pi \hat{v}_0/RT, \tag{6}$$

where $\hat{v}_0$ is the pure solvent molar volume. For dilute solutions containing a single solute,

$$\ln x_0 = -\pi \hat{v}_0/RT = \ln(1 - x_1) \approx -x_1, \tag{7}$$

where x_1 is the solute mole fraction. The solute mole fraction is the number of moles of solute, m_1, divided by the total number of moles of solvent and solute in the solution,

m_{tot}. In dilute solution, the total volume of solution, V, is not appreciably different from the product of m_{tot} and $\hat{v}_0$. In this case, Eq. (7) reduces to

$$\pi V = m_1 RT. \qquad (8)$$

Equation (8) is the van't Hoff equation for the osmotic pressure of a dilute ideal solution (Atkins, 1990). The similarity of this result with the ideal gas law illustrates the analogy between an ideal solution and an ideal gas (Atkins, 1990). Experimental determinations of the osmotic pressure of dilute solutions, which led to the empirical formulation of Eq. (8) well before its derivation from thermodynamic principles, inspired van't Hoff to develop the theory of ideal solutions based on the analogy with ideal gases (Mason, 1991). From Eq. (8), the osmotic pressure in an ideal solution is directly proportional to the number of solute molecules in the solution but does not depend upon the chemical nature of the solute.

Osmometry, the technique of using osmosis to determine the molecular weight of macromolecular species, has been widely practiced. To illustrate the sensitivity of osmotic pressure to solute molecular weight, Eq. (8) may be rewritten as follows:

$$\pi / c_1 = RT/M_1, \qquad (9)$$

where c_1 is the solute concentration (mass of solute/volume of solution) and M_1 is the solute molecular weight (g/mol). Experimentally, osmotic pressure is determined as a function of solute concentration at fixed temperature because, in real solutions, π / c_1 may not be independent of c. By plotting the ratio π / c_1 vs c_1 and extrapolating to infinite dilution (i.e., $c_1 \rightarrow 0$), RT/M_1 and, in turn, solute molecular weight may be determined. An example of using this technique to determine the molecular weight of a polymeric solute is presented later in this article.

1.2.2 The Influence of Solute Molecular Weight on Colligative Properties Solution properties such as the osmotic pressure of an ideal solution, which depend on the number, but not the chemical nature, of solute molecules in solution, are called colligative properties (Atkins, 1990). Other colligative properties, such as boiling point elevation, freezing point depression, and vapor pressure lowering, may be measured to determine solute molecular weight (Billmeyer, 1984). However, solution osmotic pressure is often the most practical colligative property to measure for high–molecular-weight solutes such as polymers. For example, Table 2 presents the coefficients characterizing the sensitivity of colligative properties to solute concentration when a high–molecular-weight solute is dissolved in benzene. For a solute molecular weight of 10 000 g/mol and a solute concentration of 0.1 g/cm^3, for example, the osmotic pressure would be 2.8 mm of benzene,

Table 2. Effect of solute molecular weight on colligative properties of a benzene solution. The pure-solvent normal freezing point is T_f. The freezing point depression is ΔT_f. The pure-solvent density and molar enthalpy of fusion are given by ρ and ΔH_f, respectively. The pure-solvent normal boiling point and enthalpy of vaporization are T_b and ΔH_v, respectively. The osmotic pressure coefficient and vapor pressure depression coefficient were estimated at 20 °C. The solute is assumed to be involatile. Moreover, it is presumed to be insoluble in solid benzene since these ideal freezing-point depression calculations are based on the assumption that the liquid containing the solute is in equilibrium with pure frozen solvent.

M_1 (g/mol)	Osmotic pressure coefficient (mm benzene cc/g)	Cryoscopic coefficient (K cc/g)	Ebullioscopic coefficient (K cc/g)	Vapor pressure depression coefficient (mm Hg cc/g)
	$\frac{\pi}{c_1} = RT\frac{1}{M_1}$	$\frac{\Delta T_f}{c_1} = \frac{RT_f^2}{\rho \Delta H_f}\frac{1}{M_1}$	$\frac{\Delta T_b}{c_1} = \frac{RT_b^2}{\rho \Delta H_v}\frac{1}{M_1}$	$\frac{\Delta p_d}{c_1} = p_0^* \hat{v}_0 \frac{1}{M_1}$
1 000	280	5.8	3.2	6.7
10 000	28	0.58	0.32	0.67
100 000	2.8	0.058	0.032	0.07
500 000	0.56	0.012	0.006 5	0.013
1 000 000	0.28	0.005 8	0.003 2	0.006 7

which is easily measurable using an apparatus similar to the one presented in Fig. 1. In contrast, the freezing point depression of benzene would be only 0.058 °C, the boiling point elevation of benzene would be even less, 0.032 °C, and the vapor pressure depression would be 0.067 mm Hg, a difference which would be difficult to detect experimentally.

1.2.3 Osmotic Pressure of a Solution Containing Several Solutes If there are N chemically distinct solutes in an ideal solution, the solvent activity in the solution is still given by Eq. (5). However, Eq. (7) must be replaced by

$$\ln x_0 = -\frac{\pi \hat{v}_0}{RT} = \ln\left(1 - \sum_{i=1}^{N} x_i\right) \approx -\sum_{i=1}^{N} x_i, \tag{10}$$

where x_i is the mole fraction of component i. If the solution is dilute, the total number of moles in the solution is approximately equal to the number of moles of solvent and, consequently, Eq. (10) becomes

$$\pi = RT \sum_{i=1}^{N} \frac{c_i}{M_i}, \tag{11}$$

where c_i and M_i are the concentration and molecular weight of solute species i. Using for the total solute concentration the definition

$$c = \sum_{i=1}^{N} c_i, \tag{12}$$

Eq. (11) becomes

$$\frac{\pi}{c} = \frac{RT}{c} \sum_{i=1}^{N} \frac{c_i}{M_i} = \frac{RT}{\bar{M}_n} \tag{13}$$

where $\bar{M}_n$ is the so-called number average molecular weight, which is defined as the mass of solute divided by the number of moles of solute molecules (Billmeyer, 1984). Osmotic pressure and, in fact, all colligative properties provide a measure of the number average molecular weight of solutes (such as polymers). Other relationships describing ideal-solution colligative properties may be generalized to solutions containing species of different molecular weight by replacing the solute concentration c_1 and solute molecular weight M_1 in the equations in Table 2 by the total solute concentration c and number average solute molecular weight $\bar{M}_n$, respectively.

1.2.4 Osmotic Pressure of a Dilute Ideal Electrolyte Solution The solute in many solutions of practical interest is an electrolyte (e.g., salt in saltwater or proteins in cells). The dissociation of the electrolyte must be accounted for in determining the osmotic pressure of the solution, since the number of individual solute molecules will change depending on the degree of dissociation of the electrolyte. This section presents the analytical fundamentals of osmotic pressure of electrolyte solutions.

If an electrolyte undergoes dissociation according to

$$M_{\nu_+}A_{\nu_-} \leftrightarrow \nu_+ M_{z_+} + \nu_- A_{\nu_-}, \tag{14}$$

where n_+ and n_- are the number of cations and anions, respectively, formed by dissociating one molecule of the parent electrolyte $M_{\nu_+}A_{\nu_-}$ into n_+ cations M_{ν_+} of charge z_+ and n_- anions A_{ν_-} of charge z_-, then the mole fraction of solvent in the solution is given by

$$x_0 = \frac{1}{1 + (M_0/1000)(n_+ + n_- + n_u)}. \tag{15}$$

The molality of dissolved cations (i.e., the number of moles of dissolved cations per kilogram of solvent) is n_+, n_- is the dissolved anion molality, and n_u is the molality of dissolved electrolyte that is undissociated. M_0 is the molecular weight of solvent in units of g/mole. Many electrolytes are dissolved in water, and Eq. (15) ignores the influence of hydronium and hydroxyl ions, which are always present in such solutions. If the electrolyte concentration is low (below approximately 0.01 molal) and the pH is markedly acidic or basic (i.e., $p\text{H} < 4$ or $p\text{H} > 10$), then Eq. (15) must be rewritten as follows to include the number of hydroxyl and hydronium ions in the solution (Tanford, 1961):

$$x_0 = \frac{1}{1 + (M_0/1000)(n_+ + n_- + n_u + n_{\text{OH}^-} + n_{\text{H}^+})}. \tag{16}$$

The remainder of this discussion is limited to cases where the concentrations of hydroxyl and hydronium ions are low relative to the concentration of electrolyte components. The following discussion must be modified accordingly if this assumption is not valid.

If n moles of parent electrolyte are added to 1 kg of solvent, the electrolyte concentrations are related by the following equation:

$$n = n_u + n_+/\nu_+ = n_u + n_-/\nu_-. \tag{17}$$

This relationship insures that the solution is electrically neutral (i.e., that the number of positive charges in the solution is exactly equal to the number of negative charges in the solution) (Atkins, 1990). The dissociation of the electrolyte is characterized by an apparent equilibrium dissociation constant, K, which is defined as (Denbigh, 1981)

$$K \equiv \frac{n_+^{\nu_+} n_-^{\nu_-}}{n_u} = \nu_+^{\nu_+} \nu_-^{\nu_-} \frac{\alpha^{\nu_+ + \nu_-}}{1 - \alpha} n^{\nu_+ + \nu_- - 1}, \tag{18}$$

where α is the fraction of parent electrolyte which dissociates ($\alpha \equiv 1 - n_u/n$). Values of K are tabulated for many electrolytes in standard references (e.g., Weast, 1979). As the tendency for the solute to undergo dissociation increases, the K value increases and vice versa. In aqueous solutions, the dissociation constant varies over an enormous range. For example, the dissociation constant of $(HPO_2)^{2-}$ to H^+ and $(PO_4)^{3-}$ is 2.2×10^{-13}, while K for hydriodic acid (HI) is approximately 10^{11} (Atkins, 1990).

The solvent activity of an ideal solution containing an electrolyte is equal to the solvent mole fraction, as before, and the osmotic pressure of an electrolyte solution is obtained by combining Eqs. (10) and (15) to give

$$\begin{aligned}\pi &= \frac{RT}{\hat{v}_0} \ln\left(1 + \frac{M_0}{1000}(n_+ + n_- + n_u)\right) \\ &\approx \frac{RT}{\hat{v}_0}\frac{M_0}{1000}(n_+ + n_- + n_u) \\ &= RT\frac{\rho_0}{1000} n[1 + \alpha(\nu_+ + \nu_- - 1)],\end{aligned} \tag{19}$$

where ρ_0 is the pure solvent density.

1.2.5 Osmotic Pressure of Dilute Ideal Protein Solutions Osmometry is a useful tool for characterizing the molecular weight of proteins such as hemoglobin, bovine serum albunim, and ovalbumin (Tanford, 1961). Proteins are macromolecules containing both weakly acidic and weakly basic structural elements. At low pH, they may carry a positive charge as high as +10 to +20 (measured in units of the charge of a proton) per 10 000 Da [1 Da (dalton) = 1/16 of the mass of an oxygen atom] (Tanford, 1961). As pH increases, weakly acidic groups on the protein chains acquire a negative charge, and the net charge of the protein molecule decreases. At very high pH, a protein molecule can carry a net negative charge of −10 to −20 per 10 000 Da (Tanford, 1961). The pH at which the protein has a net charge of zero is called the isoelectric point.

If protein molecules carrying a net charge of Z per molecule (measured in units of the charge of a proton) are dissolved at a concentration of n_p moles of protein per kilogram of solvent in a solution containing n moles of a fully dissociated electrolyte MA ($n_+ = n_- = 1$) per kilogram of solvent, the concentration of protein molecules will be related to the cation and anion concentration in the solution by (Tanford, 1961)

$$Zn_p = n_- - n_+ + (n_{OH^-} - n_{H^+}). \tag{20}$$

Equation (20) represents the condition for electrical neutrality. In many practical situations, the terms in parenthesis, which represent the effect of water ionization on electrical neutrality, may be neglected since hydroxyl and hydronium ion concentrations are often orders of magnitude lower than cation and anion concentrations. Ionization of water is therefore neglected in the following discussion. The protein molality of the solution would be n_p, the molality of cations would be n, and the molality of anions would be $n + Zn_p$.

The chemical potential of a fully dissociated electrolyte in solution is customarily written as the algebraic sum of the anion and cation chemical potentials. This convention is used since the individual anion and cation chemical potentials cannot be measured separately as a consequence of the requirement that the bulk solution remain electrically neutral (Denbigh, 1981). In a solution containing a polymer electrolyte (such as the protein solution described above), the chemical potential of a polymer molecule would represent, therefore, the chemical potential of the macromolecular ion plus the chemical potential of $|Z|$ small ions of opposite charge (Tanford, 1961). In order to define a chemical potential for macromolecular ions that more nearly reflects the properties of only the macromolecular component, Scatchard has suggested that the polymer electrolyte solution be viewed as comprised of the following three neutral pseudocomponents (Tanford, 1961):

- Component 0, solvent;
- Component 1, n_p moles of protein ions + $Zn_p/2$ moles of anions (A^-) − $Zn_p/2$ moles of cations (M^+);
- Component 2, neutral salt (MA).

Using these definitions, the chemical potential of component 1 will be equal to the algebraic sum of the chemical potential of the protein ions plus $Z/2$ times the difference between the chemical potentials of the anions and cations. For small ions, the difference in chemical potentials between cations and anions is believed to be very small (Tanford, 1961). Therefore, the chemical potential of component 1 in the mixture would be representative of the chemical potential of only the macromolecular ions.

Using Scatchard's convention, the concentrations of macromolecular ions, cations, and anions are given by (Tanford, 1961)

$$\begin{aligned} n_p &= n_1 \\ n_+ &= n_2 - Zn_1/2 \\ n_- &= n_2 + Zn_1/2. \end{aligned} \tag{21}$$

In these expressions, n_2 is the molality of neutral salt MA, and n_p is the polymer molality. The concentrations of anions and cations, expressed as molalities, are given by n_- and n_+, respectively. The polymer is added to the solution as $M_{|Z|}P$ if the polymer is negatively charged or as PA_Z if the polymer is positively charged. The total number of ions per kilogram of solvent is $n_p + 2n_2$. The solution can be formed experimentally by adding n_p moles of polymer and $n_2 - Zn_p/2$ moles of neutral salt to 1 kg of solvent. Note that to use this convention of component definition, the concentrations must be such that the number of moles of neutral salt added, $n_2 - Zn_p/2$, is positive.

The osmotic pressure of such a solution is given by an extension of Eq. (19) (Tanford, 1961):

$$\begin{aligned} \pi &= \frac{RT}{\hat{v}_0} \ln\left(1 + \frac{M_0}{1000}(n_+ + n_- + n_p)\right) \\ &\approx \frac{RT}{\hat{v}_0}\frac{M_0}{1000}(n_+ + n_- + n_p). \end{aligned} \tag{22}$$

1.2.5.1 Donnan Equilibrium. Living cells contain charged protein molecules and salt ions in an aqueous solution called plasma. The cells, which are bathed in a salt-containing, aqueous interstitial fluid, are impermeable to protein but permeable to the small salt ions. The presence of the protein inside the cell results in an unequal partitioning of the small ions between the inside and outside of the cell. This effect, called Donnan equilibrium, plays a central role in cell metabolic functions related to, for example, the propagation of nerve impulses (Woodbury, 1965). It is also of great importance in maintaining an osmotic pressure balance critical to the operation of living cells such as red blood cells, which contain proteins (hemoglobin) and are permeable to water and small ions such as Na^+, K^+, Cl^-, etc. (Tanner, 1959).

To develop a quantitative understanding of the Donnan effect, consider two solutions in contact via a membrane which is permeable to small ions and solvent but not to macromolecules. The solution on side I contains n_p^{I} moles of macromolecular ions, such as protein molecules, and $n^{\mathrm{I}} - Zn_p^{\mathrm{I}}/2$ moles of neutral salt per kilogram of solvent. The solution on side II of the membrane contains n^{II} moles of neutral salt per kilogram of solvent. The small cations and anions (always in equal amounts) can migrate across the membrane. At equilibrium, the chemical potential or, equivalently, activity of the neutral salt must be the same on both sides of the membrane. The activity may be expressed as the product of the constituent ion activities (Denbigh, 1981):

$$a = a_+a_-. \tag{23}$$

The condition of thermodynamic equilibrium requires that

$$a_+^{\mathrm{I}}a_-^{\mathrm{I}} = a_+^{\mathrm{II}}a_-^{\mathrm{II}}. \tag{24}$$

In a dilute solution, ion activity is taken to be equal to ion molality (e.g., $a_+^{\mathrm{I}} = n_+^{\mathrm{I}}$). Thus, the concentrations of small-molecule cations and anions on each side of the membrane are related by (Tanford, 1961)

$$n_+^{\mathrm{I}} n_-^{\mathrm{I}} = n_+^{\mathrm{II}} n_-^{\mathrm{II}}. \tag{25}$$

When combined with the electroneutrality condition expressed by Eq. (20), the concentration of ions may be written as

$$\begin{aligned}(n_+^{\mathrm{II}})^2 &= n_+^{\mathrm{I}}(n_+^{\mathrm{I}} + Zn_p)\\ (n_-^{\mathrm{II}})^2 &= n_-^{\mathrm{I}}(n_-^{\mathrm{I}} - Zn_p).\end{aligned} \tag{26}$$

From Eq. (26), the cation concentration will be higher on side II of the membrane than on side I and the anion concentration will be lower on side II if the macromolecular ions are positively charged (i.e., $Z > 0$) and vice versa if $Z < 0$. The difference in osmotic pressure between the solution containing the macromolecular ions and the solution without macroions is (Tanford, 1961)

$$\Delta\pi \equiv \pi^{\mathrm{II}} - \pi^{\mathrm{I}} = -\frac{RT}{\hat{v}_0}\ln\left[\frac{1 + (M_0/1000)(n_+^{\mathrm{I}} + n_-^{\mathrm{I}} + n_p)}{1 + (M_0/1000)(n_+^{\mathrm{II}} + n_-^{\mathrm{II}})}\right]. \tag{27}$$

1.2.6 Effect of Solution Nonideality on Osmotic Pressure Solvent activity in a nonideal solution is not equal to the mole fraction of solvent as shown in Eq. (5). Rather, the activity is written as the product of a convenient concentration scale (i.e., mole fraction, molality, volume fraction, etc.) and an activity coefficient γ_0, which characterizes the departure of the system from ideality (Prausnitz, 1969).

Many theoretical and empirical models are available for activity coefficients (Reid *et al.*, 1977). For uncharged polymer solutions, a widely used model is due to Flory and Huggins. In this model, the volume fraction of solvent in the solution is the concentration scale. The Flory–Huggins model yields the following expression for the solvent activity (Prausnitz, 1969):

$$a_0 = \phi_0 \exp\left[\left(1 - \frac{1}{r}\right)(1 - \phi_0) + \chi(1 - \phi_0)^2\right], \tag{28}$$

where ϕ_0 is the solvent volume fraction; χ and r are model parameters. The parameter χ characterizes the total intermolecular interaction energy between the molecules in the solution relative to the total intermolecular interaction energy for the pure components (Freeman, 1992). Good solvents have χ values less than 0.5; poor solvents have χ values greater than 0.5. A solvent for which χ is equal to 0.5 is called a theta solvent for the polymer (Billmeyer, 1984). The ratio of the polymer molecular volume to the solvent molecular volume is characterized by r, which is often set equal to the ratio of molar volumes of polymer and solvent. For high-molecular-weight polymers, $1/r$ is often negligibly small (Prausnitz, 1969).

Using the Flory–Huggins model, the following expression may be obtained for the osmotic pressure of a dilute, high-molecular-weight, polydisperse polymer solution (Young and Lovell, 1991):

$$\frac{\pi}{c} = \frac{RT}{\bar{M}_n}\left[1 + \frac{\bar{M}_n}{\hat{V}_0\rho_p^2}(\tfrac{1}{2} - \chi)c\right], \tag{29}$$

where ρ_p is the polymer density and, as in Eq. (12), c is the total polymer concentration. As indicated by Eq. (29), the ideal solution expression for the osmotic pressure [i.e., Eq. (13)] is recovered in the limit as polymer concentration goes to zero or as the Flory–Huggins χ parameter goes to $\frac{1}{2}$.

To characterize deviations from ideality that are not accurately described by the Flory–Huggins theory, Eq. (29) is often written as a power series (or virial series) in concentration (Tanford, 1961):

$$\frac{\pi}{c} = \frac{RT}{\bar{M}_n}[1 + Bc + Cc^2 + \ldots], \tag{30}$$

where the coefficients B and C are the second and third virial coefficients, respectively. The second virial coefficient can be written in term of the Flory–Huggins interaction parameter as (Young and Lovell, 1991)

$$B = \bar{M}_n(\tfrac{1}{2} - \chi)/(\hat{V}_0\rho_p^2). \tag{31}$$

Experimental osmotic pressure data for the polymer nitrocellulose in several solvents are presented in Fig. 2. The data presented in Fig. 2 are well represented by truncating Eq. (30) after the term containing the second virial coefficient. In thermodynamically good solvents, such as acetone, the second virial coef-

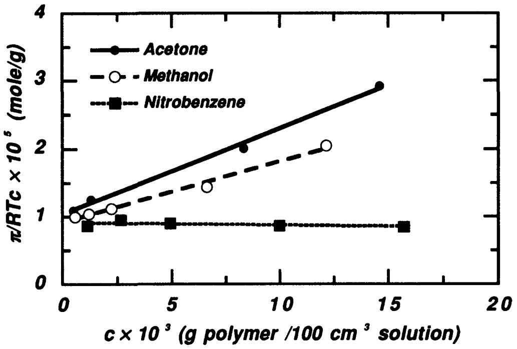

FIG. 2. Influence of solvent on results of osmotic pressure experiment to determine number average molecular weight of nitrocellulose.

ficient is large and positive, and the ratio of osmotic pressure to polymer concentration increases with increasing polymer concentration. The osmotic pressure in this nonideal solution depends, therefore, on both the number of solute molecules and the chemical nature of the solute (or, more precisely, on the interactions between the solute and solvent). In a thermodynamically poorer solvent, such as methanol, the sensitivity of π/c to polymer concentration is reduced. In a very poor solvent, such as nitrobenzene, the ratio π/c is almost insensitive to polymer concentration, indicating a χ value of approximately 0.5 or, equivalently, a vanishing second virial coefficient. When π/c is independent of polymer concentration, the solution is ideal, and the osmotic pressure depends only on the number of solute molecules, not on their chemical nature.

In systems containing electrolytes, activity coefficient models are available in the literature to account for nonideal solution behavior (Atkins, 1990). As described in Eq. (23), the activity for an electrolyte solution is typically written as the product of the constituent ion activities as (Tanford, 1961)

$$a = a_+ a_- = n_+ n_- \gamma_\pm^2, \tag{32}$$

where $\gamma_\pm$ is the mean activity coefficient for the cations and anions. A widely used model for the activity coefficient is given by the extended Debye–Hückel law (Atkins, 1990):

$$\log(\gamma_\pm) = -\frac{A|z_+ z_-|}{1 + BI^{1/2}} I^{1/2}, \tag{33}$$

where A and B are constants, and I is the ionic strength of the solution. The value of A is 0.509 $(\text{kg/mol})^{1/2}$ for an aqueous solution at 25 °C, and, in general, A is a function of the temperature and dielectric constant of the solution (Tanford, 1961). B is typically treated as an adjustable constant. The ionic strength of the solution is given by

$$I \equiv \tfrac{1}{2} \sum_i z_i^2 n_i, \tag{34}$$

where the summation extends over all different ions in the solution, and z_i and n_i are the charge and molality, respectively, of ion i (Tanford, 1961). This model can account for activity coefficients at concentrations as high as 0.1 mol/kg. There is no available theory for solutions which are substantially more concentrated (Atkins, 1990).

An example of osmosis in biological systems is presented in Fig. 3, which illustrates the dependence of hemoglobin osmotic pressure on hemoglobin concentration in water. As shown by the dashed line in Fig. 3, the osmotic pressure is not a linear function of hemoglobin concentration above approximately 7 g/(100 cm³), indicating that hemoglobin solutions are nonideal above this concentration.

As a practical application of the material presented in Sec. 1.2.5, it is interesting to note that at the concentration of hemoglobin in the blood [33 g/(100 cm³)], the osmotic pressure inside red blood cells due to hemoglobin is approximately 0.5 bar (380 mm Hg) (Lightfoot, 1974). The osmotic pressure of the serum proteins in contact with red blood cells is, on

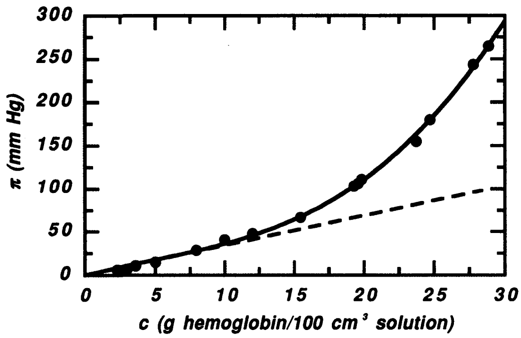

FIG. 3. Osmotic pressure of a hemoglobin solution at 0 °C. The dashed line indicates ideal solution behavior. (Lightfoot, 1974.)

average, 25 mm Hg (Lightfoot, 1974). The cell wall cannot support this large difference in osmotic pressure arising from the substantial difference in intracellular and intercellular protein concentration. Therefore, an opposing imbalance in electrolyte concentration is maintained which compensates for the unequal protein concentrations inside and outside the cell wall (Lightfoot, 1974).

2. EXPERIMENTAL METHODOLOGY FOR THE DETERMINATION OF OSMOTIC PRESSURE

Osmotic pressure may be determined directly using two broad classes of devices: static osmometers and dynamic osmometers (Young and Lovell, 1991). In both types of osmometers, the osmotic pressure is determined as a function of concentration [solute concentration is commonly less than 20 g/L (Young and Lovell, 1991)] at fixed temperature. The extrapolation of the ratio of π/c to zero concentration gives $RT/\bar{M}_n$, and the solute number average molecular weight may be computed directly.

In a static osmometer, the osmotic pressure is determined by measuring the equilibrium pressure difference across a membrane separating two solutions containing different concentrations of solute. A schematic of a static osmometer is presented in Fig. 4. Older static osmometers (e.g., Pinner–Stabin osmometers) have large cell volumes (3–20 cm^3) on either side of the membrane (Young and Lovell, 1991). Small-bore capillaries are used for the tubes above the cell. The use of small capillaries decreases the amount of solvent which must permeate through the membrane before the attainment of equilibrium. Normally, the amount of solvent added to the solution during the equilibration time does not significantly change the solute concentration (Young and Lovell, 1991). Modern static osmometers (e.g., Knauer and Wescan osmometers) have small cell volumes (on the order of 0.3–2 cm^3) and large membrane areas to minimize equilibration times (typically 30–60 minutes) (Young and Lovell, 1991). Pressure differences between the two sides of the membrane are typically monitored indirectly using pressure transducers (Billmeyer, 1984). Osmotic pressure is sensitive to temperature, and so temperature is typically controlled to ±0.01 °C (Young and Lovell, 1991).

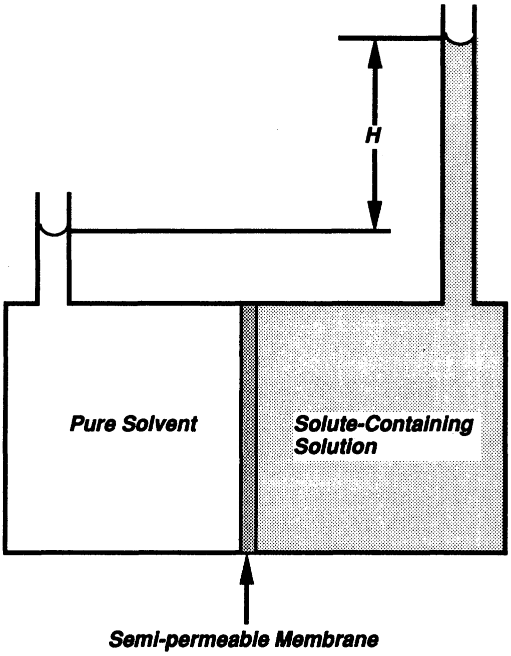

FIG. 4. Schematic of osmometer.

In a dynamic osmometer, the flow of solvent across the membrane is monitored, and a hydrostatic pressure just sufficient to prevent solvent flow through the membrane is applied to the solution (Young and Lovell, 1991). This hydrostatic pressure is the osmotic pressure of the solution.

Number average molecular weights between approximately 5×10^3 and 5×10^5 Da can often be determined to an accuracy of approximately 1% (Rodriguez, 1989). Real membrane materials are not completely impermeable to solutes. Most osmometer membrane materials are based on cellulose, and at molecular weights below 5×10^3 Da, many solutes can permeate through the membrane and will not, therefore, contribute to the observed osmotic pressure of the solution (Rodriguez, 1989; Young and Lovell, 1991). For this reason, membrane osmometry can seriously overestimate the number average molecular weight of samples containing a large number fraction of low–molecular-weight species. Above a molecular weight of approximately 5×10^5 Da, the osmotic pressure of the solution is very small, and the precision of the technique is limited, therefore, by the precision with which small pressure differences (between the two chambers connected by the membrane) can be determined (Billmeyer, 1984).

3. APPLICATIONS

3.1. Reverse Osmosis

The role of osmosis in industrial separation technologies such as reverse osmosis, dialysis, and electrodialysis are described in several review articles (Bhattacharyya and Williams, 1992; Eykamp and Steen, 1987; Kessler and Klein, 1992; Klein *et al.*, 1987; Kulkarni *et al.*; 1992, Strathmann, 1992). In reverse osmosis (also called hyperfiltration), two solutions of different solute concentrations are separated by a semipermeable membrane. The objective of the separation is to drive solvent (e.g., water) from a region of high solute concentration (e.g., seawater) across the membrane to a region of low solute concentration (e.g., fresh water). In order to transport solvent from the high–solute-concentration side to the low–solute-concentration side of the membrane, the solvent chemical potential on the high-concentration side must be raised to a value that is above the solvent chemical potential on the low–solute-concentration side. A hydrostatic pressure applied to the high–solute-concentration side of the membrane is typically used to increase the solvent chemical potential on the high–solute-concentration side of the membrane and drive solvent transport.

At steady state, the flux of solvent across the membrane is given by (Bhattacharyya and Williams, 1992; Kessler and Klein, 1992)

$$J_0 = A(\Delta p - \sigma\Delta\pi), \tag{35}$$

where σ is the Staverman reflection coefficient (defined below), J_0 is the solvent flux (volume of solvent permeating membrane per unit membrane area per unit time), A is the solvent permeability constant, Δp is the impressed hydrostatic pressure difference across the membrane, and $\Delta\pi$ is the osmotic pressure difference across the membrane (Bhattacharyya and Williams, 1992). Theoretical models are available to predict the dependence of the solvent permeability constant on material parameters (such as solvent diffusion coefficient and solubility in the membrane) and membrane thickness (Bhattacharyya and Williams, 1992).

At a solvent flux equal to zero, the Staverman reflection coefficient σ is the ratio of the applied pressure difference Δp to the osmotic pressure difference $\Delta\pi$ across the membrane. If σ is equal to 1, then the hydrostatic pressure difference that must be maintained across the membrane to prevent solvent flow due to osmosis is equal to the osmotic pressure difference between the two solutions. In this limit, the membrane is completely impermeable to solute. If the membrane is permeable to solute, the pressure difference needed to maintain zero solvent flux is less than the osmotic pressure difference predicted based on bulk solute concentrations and σ is, accordingly, less than 1 (Bhattacharyya and Williams, 1992).

The importance of osmosis in membrane separations such as reverse osmosis can be understood from Eq. (35). The osmotic pressure difference $\Delta\pi$ must be overcome by an applied hydrostatic pressure difference across a membrane to transport solvent through the membrane and, for example, desalinate water. If the osmotic pressure difference across the membrane is large, the applied hydrostatic pressure difference will be large which, in turn, increases the cost of the technique. From Table 1, the osmotic pressure of seawater is approximately 20 times that of brackish water. Consequently, reverse osmosis, which is very competitive economically with other technologies (such as multistage flash distillation, multiple effect evaporation, ion exchange, and electrodialysis) for brackish water desalination, is much less competitive for seawater desalination (Riley, 1990).

The desalination of water is the most widely known application of reverse osmosis. However, in addition to desalination of water, reverse osmosis is applied in the food industry to concentrate products such as milk, in the paper industry for the concentration of lignosulfonates, and in the chemical process industries to concentrate and recover a variety of industrial solutes (Eykamp and Steen, 1987).

3.2. Dialysis

Dialysis (*q.v.*) is a separation process in which a feed solution is passed across a semipermeable membrane that is permeable to solvent and small solutes in the feed but impermeable to large macromolecules in the feed (Klein *et al.*, 1987). Unlike reverse osmosis, dialysis membranes are designed to encourage the passage of small solute molecules while retaining only the species of highest molecular weight in the mixture. An important application of dialysis is hemodialysis. In this process, blood containing small–molecular-weight metabolic waste products is passed across a membrane that is permeable to the low–molecular-weight wastes but impermeable to higher–molecular-weight blood proteins (Klein *et al.*, 1987). This application has sparked the development of dialysis for use in industrial separations such as the desalting of cheese whey solids and the reduction of alcohol content in beer (Klein *et al.*, 1987). Dialysis based upon the Donnan effect described earlier is being tested in applications such as the softening of feedwater to reverse-osmosis membrane units and the removal of toxic or otherwise harmful cations from industrial wastewater streams (Klein *et al.*, 1987).

3.3. Electrodialysis

Electrodialysis involves the use of electrically charged membranes. An electric field is applied across the membrane to separate ionic solutes from an aqueous feed stream (Strathmann, 1992). The membranes used in such devices are ion selective (that is, they allow positively charged ions to permeate while excluding negatively charged ions or vice versa). The principal commercial applications of electrodialysis are desalination of water, the production of table salt (Strathmann, 1992), desalination of food such as cheese whey and sugar, and the production of chlorine in so-called "chlor-alkali cells" (Lonsdale, 1982).

GLOSSARY

Chemical Potential: An intensive thermodynamic function that is defined, mathematically, as the derivative of the extensive thermodynamic functions of internal energy, enthalpy, Gibbs free energy, and Hemholtz free energy with respect to the amount of one component in a mixture. More importantly for osmosis, the condition of chemical equilibrium between two or more phases is established when each substance has an equal value of its chemical potential in all phases into which this substance may partition. Difference in the chemical potential of a substance that may partition between two phases is the origin or driving force for the diffusion of that substance from a region of high chemical potential to a region of lower chemical potential.

Dalton (Da): A standard unit of molecular weight. One dalton is 1/16 the mass of an oxygen atom.

Dialysis: A separation process in which a feed solution is passed across a semipermeable membrane that is permeable to solvent and small solutes in the feed but impermeable to large macromolecules in the feed. Small solute molecules are separated from the feed solution in this process.

Electrodialysis: A separation process involving the use of electrically charged membranes and the application of an electric field across the membrane to separate ionic solutes from an aqueous feed stream.

Isotonic Solution: A solution that has the same osmotic pressure as a reference solution. The reference solution in biomedical applications is typically mammalian plasma.

Molality: The molal concentration of a solute. A one molal solution contains one mole of solute molecules per kilogram of solvent.

Osmotic Pressure: Operationally, the excess pressure that must be placed on a solution separated by a semipermeable membrane from a reservoir of pure solvent to prevent any net mass transport of solvent through the membrane. It is a thermodynamic property of the solution and is a measure of the depression in the solvent chemical potential due to the presence of solute molecules.

Osmometry: The analytical technique for measuring the osmotic pressure of a solution.

Reverse Osmosis: (Also called hyperfiltration) a separation process in which a solution at high pressure is passed across a semipermeable membrane that is permeable to solvent but impermeable to solute. The result is a concentration of the solute in the feed stream to the unit and the production of a stream of pure solvent that has permeated through the membrane.

Semipermeable Membrane: A membrane that is permeable to solvent molecules but impermeable to solute molecules.

INTRODUCTION

The term "packaging" is used to describe the methods and structures by which electronic components are interconnected to make a functional system. The interconnection package must perform several key roles. It must provide mechanical support for the components as well as protection from damage due to handling. Sensitive active components such as transistors and integrated circuits must be protected from the external environment. The package must distribute power to active devices and remove the heat generated by them as well as providing for all required signal interconnections between components. Packaging technology is the set of designs, materials, and processes of which the interconnection packages are made.

In the earliest electronic systems, individual components, such as resistors, capacitors, tubes, and laser semiconductor devices, were interconnected by soldering their terminals or plugging them into sockets with connections made by discrete wires. As the complexity of electronic systems increased, denser and denser interconnection packages were required to reduce cost and save space as well as to increase the overall system performance. Printed circuit cards were introduced to interconnect discrete components efficiently, and integrated circuits allowed many active devices to be placed and interconnected on a single silicon chip. Nevertheless, the increasing complexity of electronic systems required ever more sophisticated packaging technology. Today, powerful computers utilize hundreds of thousands or even millions of circuits, and many systems are designed in such a way that their performance depends as much on packaging technology as on chip technology.

Modern packaging technology is a complex field concerning the fabrication of many different mechanical, electrical, and thermal structures using many different metals, polymers, glasses, and ceramics, which are formed in a wide variety of processes and which are optimized for both cost and performance. This article describes the principles and materials considerations of importance to packaging. It explains how integrated circuit chips are connected to the interconnection package and the various types of simple and complex packages in use today. Since only a general description can be provided here and the details are very important in the engineering of different packaging technologies, the reader is encouraged to refer to several recent books on packaging cited as references.

1. GENERAL PRINCIPLES

1.1 Interconnection Hierarchy

Complex systems consist of many levels of interconnections, as shown for a typical system in Fig. 1. The first-level package encapsulates the chip for protection from handling damage and the environment and provides metallic leads for power input as well as signal connections between chips. The simplest and lowest-cost package is a plastic or ceramic single-chip module (SCM). The chip-to-chip interconnections are then provided by the second level of packaging or multichip module (MCM), which may be a laminated plastic-based card or board (MCM-L) or a ceramic-based substrate (MCM-C), or a hybrid containing sequentially built thin-film wiring (MCM-D). For the highest-performance electrical interconnections between chips, bare chips are mounted on a multichip module that is then encapsulated as a whole, thus combining the first and second packaging levels.

1.2 Electrical Design

Signal interconnection between chip and package and between different packaging levels requires both making the number of required interconnections and providing the optimal electrical performance. The number of terminals required by a component is re-

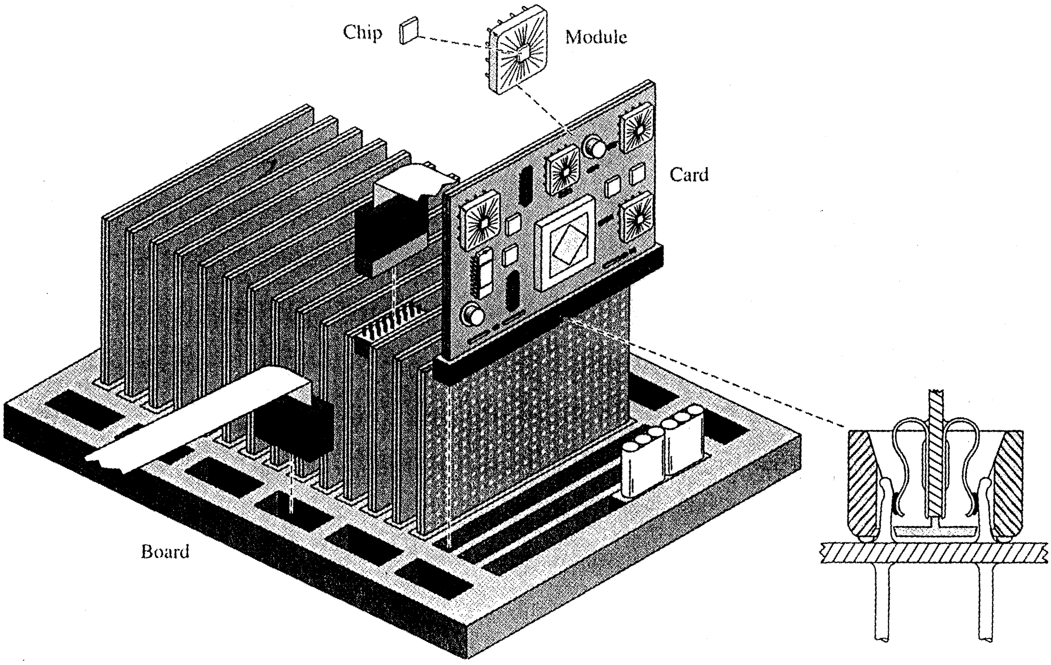

FIG. 1. Chips are mounted in single- or multiple-chip modules. The modules are soldered or pin attached to cards, which are plugged into connectors in a board. Cables connect signals between boards. (From Tummala and Rymaszewski, 1989, reproduced by permission.)

lated to the communication needed between this component and the rest of the system. A useful design guideline was given in an empirical rule devised by E. Rent in 1960 (Radke, 1969):

$$I = bC^p,$$

where I is the number of input and output terminals (I/O), C is the number of circuits on a package, b is a constant equal to approximately 2, and p is approximately $\frac{2}{3}$. In recent years, the degree of functionality contained in a package component has increased, requiring fewer interconnections to the next level than predicted by the original Rent's rule, but the above formula with lower values of p is still useful (Seraphim *et al.*, 1989). Bipolar chips containing 5000–20 000 circuits require 200–400 signal I/O, and large multichip modules containing millions of circuits require thousands of interconnections. The larger the number of I/O terminals on a given package the greater will be the amount of interconnection wiring required on the next level of packaging.

The delay caused by signal propagation between chips often limits overall system performance. The resistance R, capacitance C, and inductance L of the package wiring are key to improved performance. Proper electrical design minimizes both signal delay and noise. For short nets the RC time constant determines the package delay. Over longer distances signals travel in transmission lines in cards, boards, ceramic modules, or thin-film wiring with typical dimensions shown in Fig. 2. These signals travel with the velocity $V = c/\sqrt{\epsilon}$, where c is the speed of light and ϵ is the insulator dielectric constant. The time delay T in traveling a distance l in the package is then

$$T = (l/c)\sqrt{\epsilon}.$$

This delay is minimized by shortening the distance signals must travel by using finer, denser wiring and by reducing the dielectric constant of the insulator. The impedance of the transmission line, Z_0, is $\sqrt{L/C}$ where L is the inductance and C the capacitance per unit length. Z_0 is typically 40–80 Ω. In addition, the transmission-line designs shown in Fig. 2 contain parallel planes of wires, and the dimensions are chosen to reduce cross-coupling noise between lines to typically <10% of the signal amplitude by minimizing mutual inductance and interline capacitance.

	Card/board	Ceramic module	Thin-film wiring
W	150–100	80	10–25
t	30–50	25	3–15
h	270–430	100	5–15
h_1	500–1200	300	20–36
s	500–400	400	25–75
ϵ	4.4–4.0	5–10	3–3.5
Z_0 (Ω)	80	50	40–50

FIG. 2. Cross section of transmission lines with typical dimensions (in micrometers). The term ϵ is the insulator dielectric constant and Z_0 the characteristic impedance.

Power must be distributed to the chips on an MCM by low-resistance power planes to minimize voltage drops across the package. When many drivers, N, are switched simultaneously on the chip, a noise voltage ΔV is induced on the chip reference voltage, related to the rate of driver current switching, di/dt, by the effective package inductance L_{eff}:

$$\Delta V = NL_{\text{eff}}\frac{di}{dt}.$$

The package must provide low enough L_{eff} to keep ΔV below typically 10–20% of the supply voltage. The low inductance is achieved by making the connection between the chip and power distribution planes as short as possible.

1.3 Materials Characteristics

Package structures are made from a wide variety of materials (Harper, 1991; Minges, 1989). The characteristics of some typical conductors and insulators are given in Tables 1 and 2. The most important properties are the electrical conductivity of metals, the dielectric constant of insulators, the thermal conductivity of the heat dissipation structures, and the relative thermal expansion coefficient of dissimilar materials that are bonded or joined together.

Table 1. Properties of insulator materials.

Insulator	Dielectric constant	Thermal expansion coefficient (10^{-7}/°C)	Thermal conductivity W/m°K
SiC	42	37	270
Si	11.7	27	170
Alumina	9.4	66	20
AlN	8.8	33	230
BeO	6.8	68	240

Mullite	6.2	45	10
Diamond (CVD)	5.7	23	1500
Glass-ceramics	4–8	30–50	5
Epoxy-glass (FR-4)	4.7	110–150	0.2
Borosilicate glass	4.0	30	5
Epoxy-Kevlar (60%)	3.6	60	0.2
Polyimides	3–3.5	70–500	0.2
Benzocyclobutene	2.6	350–600	0.2
Polytetrafluoroethylene	2.2	200	0.1

Since the resistance of a conducting element increases with length but is inversely proportional to cross-sectional area, different types of interconnection make trade-offs between dimensions and resistivity to optimize performance. Copper is the conductor of choice for all interchip wiring because of its low resistivity and its superior chemical stability to silver; however, because of relative ease of fabrication higher-resistivity metals are often used, particularly in ceramic packages. Joining metals such as solders or brazes have high resistivity but are used for short, wide-area connections. Kovar is used for pins because of its mechanical properties, while the relatively large size of pins allows the use of a high-resistivity metal.

Since the performance of the package improves with lower dielectric constant and shorter wiring lengths, new materials or processes have been introduced to improve performance. Low-ϵ glass-ceramics have been developed to replace the more common alumina ceramic. Thin-film copper wiring (which produces the highest wiring density) is made with polymer insulators.

The thermal conductivity of plastics is relatively poor and heat is conducted away from high-power chips by ceramic or metal heat spreaders to air- or water-cooled heat sinks.

Electronic packages are comprised of dissimilar materials bonded or joined together, which expand at different rates on heating. The thermal cycles that occur during fabri-

Table 2. Properties of conductor materials.

Conductor	Electrical resistivity (10^{-6} Ωcm)	Thermal expansion coefficient (10^{-7}/°C)	Thermal conductivity W/m K
Alloy 42 (42% Ni, 58% Fe)	70	43	16

Silver	1.6	197	418

cation or when systems are turned on and off result in stresses and/or strains which are proportional to the difference in thermal expansion coefficients of the different materials and the change in temperature. These stresses can result in fatigue failure such as delamination at interfaces of a multilayer structure, solder cracking, and metal fatigue. The design of a package for maximum reliability requires the choice of materials with as closely matched thermal expansion coefficients as possible given the fabrication and electrical design requirements.

2. CHIP-TO-PACKAGE INTERCONNECTIONS

2.1 Wirebonding

Wirebonding is the most common chip connection technology. Wires are directly and individually bonded to the input/output pads on the perimeter of the chip and then bonded to the package. The bonding process is ultrasonic, thermocompression, or thermosonic bonding applied by mechanical tools. The wires are aluminum (with 1% Si) or aluminum alloys or gold and are 25–38 μm in diameter for signal and as much as 125–150 μm in diameter for power connections if required. Chip pads can be placed on a 100–150-μm pitch, thus allowing several hundred I/O from large chips. Wirebonding is most commonly used with molded plastic SCMs (described below).

2.2 Tape Automated Bonding (TAB)

Tape automated bonding or TAB was developed as a highly automated technique for high-volume packaging of individual chips with relatively few connections, although it has evolved to accommodate over 300 I/O terminals. The TAB process begins with a continuous tape up to 70 mm or more wide as shown in Fig. 3(a). The tape is processed in a reel-to-reel method and contains sprocket holes for movement and alignment as shown in the figure. The tape is made of stable plastics such as polyimides, polyesters, etc., and contains copper conductors patterned using photolithographic techniques and metal etching processes. In order to isolate electrically the metal patterns associated with a given chip, mechanical punching is used. The plastic tape is either etched or prepunched to form a window in which the metal leads extend beyond the tape so that they can be bonded to chips containing metal bumps on their I/O pads. The bonding of all leads is done simultaneously in a thermocompression bonding process in an inner-lead bonding tool shown in Fig. 3(b). In this tool the chip is placed with its aluminum or gold bumps facing up. The TAB tape is placed over the chip with the inner lead bonds aligned to the metal bumps. A heated metal tip or thermode then uses compression to form the bonds between leads and bumps. The chips are retained on the tape for subsequent testing, encapsulation (if desired), and burn-in followed by excising of the individual chip-lead packages from the tape. TAB is a chip connection technology that can be used as part of a molded plastic- or ceramic-based single-chip module, but it can also function as a first-level package if the chip is encapsulated in plastic on the tape and the outer TAB leads are bonded directly to the second-level package.

2.3 Solder-Bump Interconnections

Solder-bump chip connections, also known as controlled-collapse chip connection (C4) or flip-chip bonding, involves solder bumps deposited by metal evaporation in a dense area array on wettable metal terminals on the chip and a matching footprint of solder-wettable terminals on the interconnection package. The upside down chip is aligned to the substrate and all joints are made simultaneously by reflowing the solder. The high surface tension of the solder causes self-alignment. For a given chip size this technology allows the greatest number of interconnections. The small bump size results in very low inductance. In a typical application, 100-μm-diam bumps are placed on a 225-μm grid allowing space for 784 connections on a 6.5-mm square chip. An example of this technology is shown in Fig. 4. Smaller solder bumps and tighter grids resulting in thousands of connections have been demonstrated (Tummala and Rymaszewski, 1989).

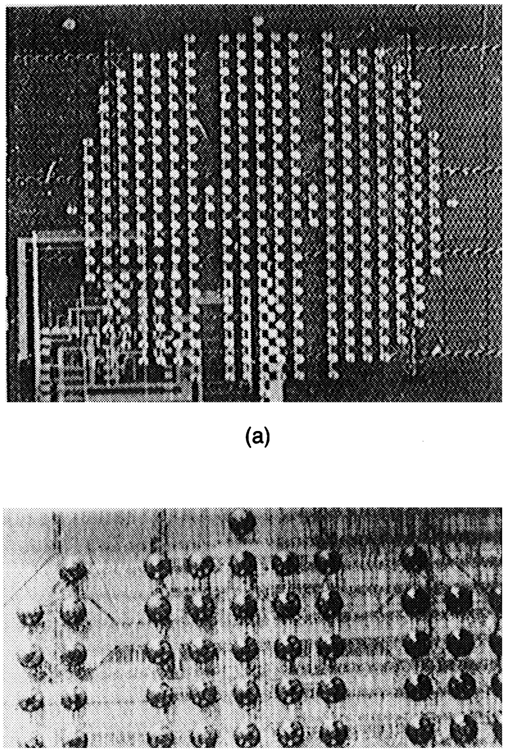
3. MOLDED PLASTIC PACKAGING

Transistors encapsulated in plastic appeared in the late 1950s, and because of the low cost and effectiveness of the technology, molded plastic packages are the most widely used single-chip modules today. They are called by many names such as dual in-line package (DIP), and variations like SIP and ZIP, the small outline package (SOP and SOJ), the plastic leaded chip carrier (PLCC), and plastic quad flat pack (PQFP), as well as others. Some of these are illustrated in Figure 5 where a cutaway view shows their basic construction. The lead frame is the supporting structure to which the chip is physically attached. Electrical connections are made by wirebonding and then the whole assembly is covered with a thermosetting molding compound (Goosey, 1985) in a transfer molding process.

3.1 Lead-Frame Materials

The most widely used metal for lead frames is Alloy 42 (42% Ni, 58% Fe), which has a thermal expansion coefficient closely matched to the Si chip, although its low thermal conductivity presents a problem for high-power chips since the lead frame is the main heat conduit away from the chip. To overcome the thermal limitation a variety of other lead-frame alloys are used (Tummala and Rymaszewski, 1989). The lead frames are 0.15–0.25-mm thick and are chemically etched or mechanically stamped from rolled strip stock. Chips are bonded to the lead frames by silicon/gold eutectic bonding or by use of silver-filled epoxy or polyimide adhesive paste. After encapsulation the leads are formed to special shapes for soldering to cards. In Fig. 5 the DIP leads are wider at the top than at the bottom, creating an integral standoff when



(a)

(b)

FIG. 4. (a) A 5000-circuit chip with 354 solder bumps in an area array; (b) a close-up view of solder bumps (courtesy of IBM Corp).

the leads are inserted into holes in cards. The PLCC leads shown in Fig. 5 have a "J bend" and the SOIC leads are "gull wing" shaped for surface-mount soldering.

3.2 Encapsulation Materials

Molding compounds are mixtures of materials optimized for a specific application. The most commonly used resin is cresol novolac epoxy, which has relatively low shrinkage on curing, low moisture absorption, chemical inertness, good adhesive properties, and a glass transition temperature of 150 °C. Other resins have glass transition temperatures between 125 and 200 °C. For applications requiring high heat resistance, low dielectric properties, and low-temperature properties silicone materials can be used. In addition to the resin, curing accelerators and curing agents, flame retardants, colorants, and inert fillers make up the molding compound. The filler comprises about 70% by weight and is needed to control shrinkage, improve thermal conductivity, and enhance thermal shock resistance. Powdered fused silica (SiO_2) is the primary filler used today. Nevertheless, the thermal expansion coefficients of molding compounds are typically (120–200) × 10^{-7}/°C. Care must be taken in the transfer molding process and the physical design of the chip, lead frame, and wire bonds to avoid stress-induced failures (Manzione, 1990).

4. PRINTED-CIRCUIT CARDS AND BOARDS

4.1 Structures

Printed-circuit technology is the lowest-cost method for interconnecting a large number of diverse components. The basic structure is shown in Fig. 6. The simplest cards are single sided and have wiring on only one surface. More complex cards are double sided and have wiring and components on both outside surfaces. The most complex cards have multilayer wiring and can support components on one or both outside surfaces. In cards and boards, plated copper wiring is connected between layers by plated through holes in a metal/polymer laminate. The plated through holes (PTH) are also used to mount chip carriers, passive devices, and connectors. The voltage reference planes distribute current, provide shielding, and control the impedance of the signal transmission lines. This basic structure is used to make a range of second-level packages, from inexpensive small cards containing one or two planes with signal linewidths of 1.0 mm and PTH diameter of 0.84 mm to high-cost, high-performance boards 600 × 700 mm in size and containing as many as 50 planes with signal linewidths of 0.05 mm and PTH diameter of 0.35 mm. Fig. 7 is a picture of a large card used in workstations.

4.2 Materials and Processes

The most common insulator is FR-4 (fire-retardant, epoxy-impregnated glass cloth), although polyimide-glass laminates are also used, and a variety of polymers and fillers are used for specific applications requiring low thermal expansion coefficient, low dielectric

constant, or high thermal stability (Seraphim *et al.*, 1989). High thermal stability is achieved with a number of polyimide materials. Low–dielectric-constant boards with very low dissipation at high frequencies are made of polytetrafluoroethylene (PTFE) (Goosey, 1985).

The fabrication process involves laminating copper on both sides of the insulating material (FR-4 or equivalent), drilling holes, and joining the two sides by electroless copper plating of the hole walls and surfaces. The copper wiring is then created by either a subtractive or an additive process. Both use photolithographic techniques to define a wiring pattern. In the subtractive process, the unwanted copper is etched away after through-hole plating. In the additive process, as the through holes are plated, copper is added in a pattern to the surface and finally coated with tin before the photoresist is removed and the base copper etched away. To construct a multilayer structure, partially cured "prepreg" (epoxy-glass laminate alone) is placed between each of the metallized double-sided laminates or cores to form a stack. Copper surface planes may be added and the entire stack laminated and treated as a core. Holes are drilled where desired to intersect internal copper pads joined to lines or voltage planes and the whole unit is plated again (Seraphim *et al.*, 1989).

5. CERAMIC PACKAGING

Ceramics are used to fabricate many of the chip carriers shown in Fig. 5. There are ceramic dual in-line packages (CERDIPS) and leadless chip carriers. While the shapes are similar to molded plastic packages, ceramic chip carriers are more rugged and have the

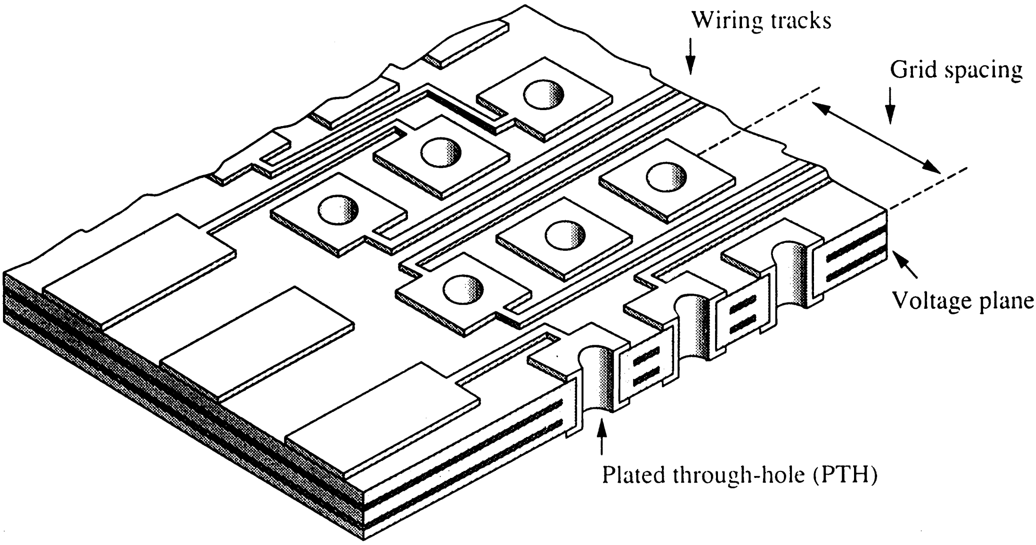

FIG. 6. Printed circuit card with two signal layers. There are two wiring tracks within the grid spacing (two lines per channel). (From Seraphim *et al.*, 1989, reproduced by permission.)

advantage that they can be made hermetic, i.e., the interior is totally isolated from the ambient atmosphere. Hermeticity is not achievable with plastic packages because of the gas permeability of plastics. Ceramic packages are sealed with metal or ceramic lids. Moreover, ceramics have thermal expansion coefficients well matched to semiconductors, thus reducing bonding stress, and they have relatively high thermal conductiv-

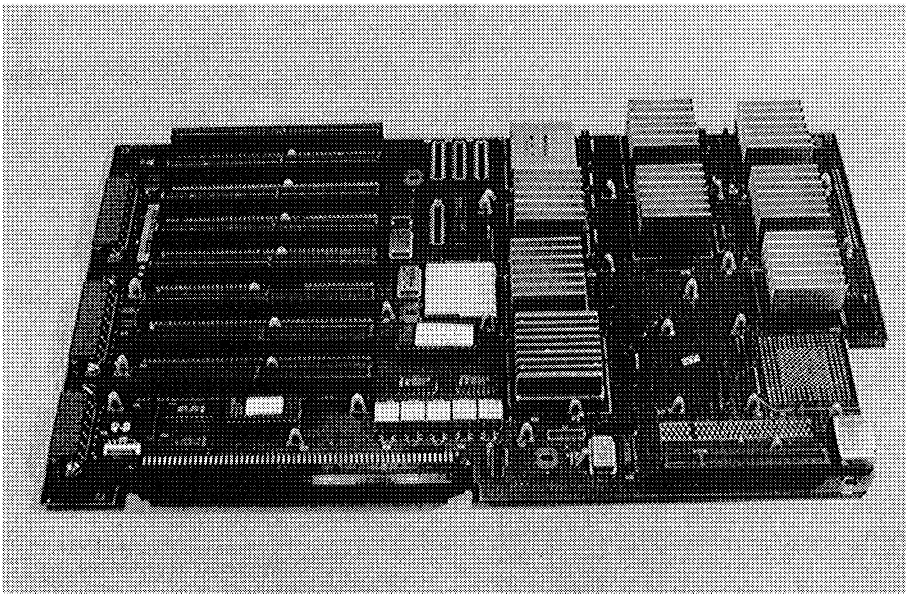

FIG. 7. This printed circuit card or "planar" is 250 × 420 mm^2 and interconnects the components of a workstation computer, including surface-mounted single-chip modules with heat sinks and connector blocks for additional small cards (courtesy of IBM Corp).

ity. In addition, the strength and rigidity of ceramics easily accommodate a large-area array of pins for dense interconnection to higher package levels.

5.1 Metal-on-Ceramic Packages

With the exception of the pin-grid array (PGA), the chip carriers in Fig. 5 have wirebond connections between chip and package I/O leads. In the ceramic PGA there is a single layer of metal on the ceramic surface to provide wiring between the components mounted on the PGA and make connections to the pins. This wiring is made by either thick- or thin-film processing. In the thick-film process, a screen or metal stencil is prepared with openings defining the circuit pattern. The screen is placed over the ceramic substrate. An ink paste containing metal particles is made to fill the openings in the stencil by use of a compliant blade or "squeegee" as in common silk-screen printing processes. The stencil is removed and the substrate is fired at high temperature, sintering the metal particles in the circuit pattern. In the thin-film process, metal is sputter deposited on the ceramic and patterned by photolithography and metal etching.

5.2 Multilayer Ceramic Substrates

Multichip ceramic substrates with multiple wiring layers are made by cosintering a ceramic and metal system. A powdered ceramic is mixed with solvents and organic binder polymer and tape cast and dried into a "green sheet," which is cut to size. Holes are punched for via interconnections and a thick-film metallization process used to fill the holes and define the circuit lines. After inspection the good sheets are stacked and laminated and then sintered at high temperature to form a solid body with metal conductors and ceramic insulation. Surface metals are overplated as required and pins brazed to bottom pads. Chips are mounted directly on the module, and it is hermetically sealed. An example is pictured in Fig. 8. The most complex ceramic MCMs today contain more than 60 layers of low-dielectric glass-ceramic with several hundred meters of cosintered copper wiring and are used to interconnect over a hundred chips.

5.3 Ceramic Materials

Alumina (Al_2O_3) is the most common ceramic in use. Thick-film processes typically employ 96% Al_2O_3, 3–3.5% SiO_2, and a small

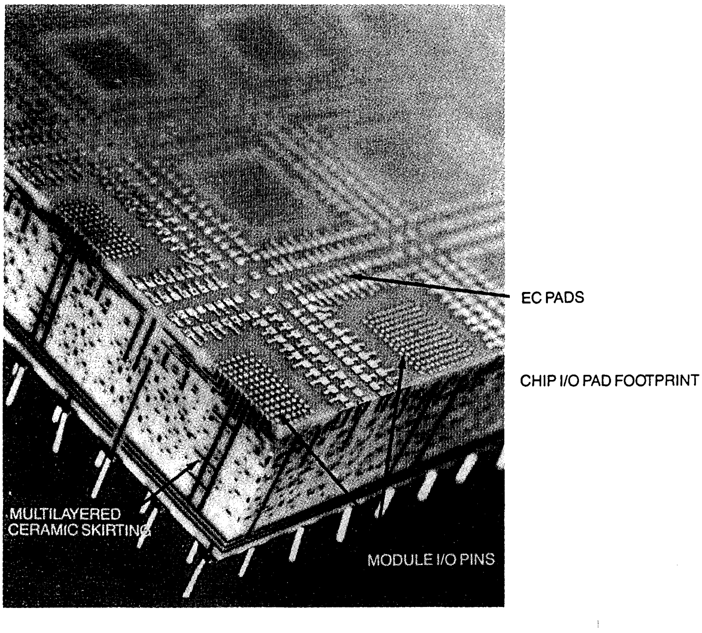

FIG. 8. Cross section of multilayer ceramic showing dense wiring (courtesy of IBM Corp., from Tummala and Rymaszewski, 1989, reproduced by permission).

amount of MgO and CaO. Other ceramics such as BeO, SiC, and AlN are used where higher thermal conductivity is desired, and glass-ceramics or mixtures of glass and ceramic that are compatible with copper metallization are used when a low dielectric constant is required for electrical performance. Since metals must be cosintered with the ceramic, the choice of metallization for a given ceramic is limited since the sintering temperature of the ceramic must be somewhat lower than the melting point of the metal. (Tummala and Rymaszewski, 1989).

6. THIN-FILM WIRING

Multilayer thin-film wiring is applied to the surface of a printed circuit card, ceramic package, or passive mechanical support where high performance, high density, and extreme compactness of interconnection wiring are required. The dimensions of transmission lines given in Fig. 2 indicate that roughly ten times as many wiring tracks can be made in a wiring layer using thin-film wiring as in thick-film card or ceramic wiring. Thus, roughly ten thick-film layers are equivalent to one thin-film layer in wirability, and thin-film layers are each only one tenth as thick.

6.1 Materials

The high electrical performance of thin-film wiring is due to the use of low–dielectric-constant insulators such as spray- or sputter-deposited borosilicate glass or quartz or, more commonly, polymers such as polyimides. Polyimides are chosen for their ability to form high-quality, defect-free thin films by spin or spray application and for high thermal stability, low moisture uptake, and good solvent resistance. Copper is the metal of choice, although aluminum and others are used. Since copper does not adhere well to polymers and can react with uncured material, very thin layers (≤1000 Å) of chromium, titanium, or other materials are placed between the copper conductor and the polymer to act as adhesion promoters and passivants.

6.2 Sequential Patterning

The very fine dimensions of thin-film wiring require sequential fabrication techniques; an example is given in Fig. 9. There are a variety of methods for metal and polymer deposition and patterning, and many different processes are in use. Metals may be deposited by evaporation, sputtering, electroless plating, or electroplating. They may be patterned using photolithographic techniques by wet etching as used in printed circuit cards, by plating in a resist pattern, or by lift-off processes used in making on-chip wiring. Polymer insulators may be patterned by wet chemical etching, reactive ion etching, or laser ablation, or they may be intrinsically photosensitive and directly patterned optically like a photoresist.

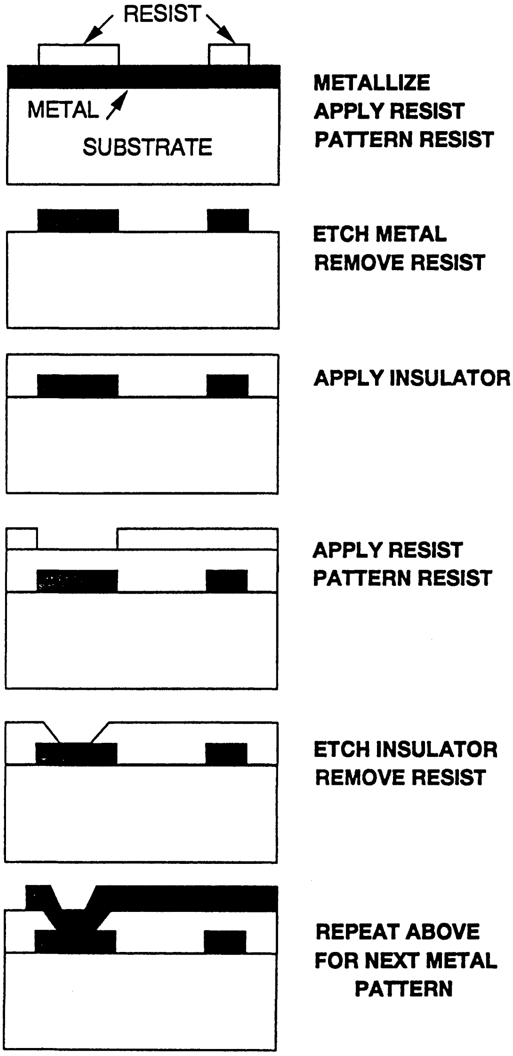

FIG. 9. Typical thin-film wiring fabrication process. In this figure, the sequential process flow is from top to bottom.

The choice of a particular patterning process for metal or polymer is dependent on cost and is often dictated by the aspect ratio (the ratio of height to width) of the most demanding feature required by the electrical design. Processes that are capable of forming high–aspect-ratio structures such as electroplating of a metal in a patterned photoresist or reactive ion etching of a polymer are generally more expensive than processes that can only form low–aspect-ratio structures such as wet etching of metals or polymers.

7. PACKAGE-TO-PACKAGE INTERCONNECTIONS

7.1 Pins

The most common interconnection method between first- and second-level packages is to solder the leads or pins of one component into the plated through holes of a card or board. Typically tin-lead eutectic solder (63% Sn, 37% Pb), which is liquid above 183 °C, is used in the wave soldering process shown schematically in Fig. 10. After flux is applied, the populated card is preheated and passed over a fountain of flowing solder where capillary forces cause the solder to fill the plated through holes.

In pin-grid array (PGA) and multilayer ceramic packages, pins are attached to the package before mounting on the card or board. In the simplest packages, pins are swaged into the package while more complex structures require pins that are brazed to pads on the bottom of the package. For multilayer ceramic packages, Ni/Au-plated Kovar pins are attached with eutectic Au-Sn (20% Au, 80% Sn) braze, which melts at 280 °C. Higher melting point (779 °C) but less expensive eutectic copper-silver braze or other materials are also used.

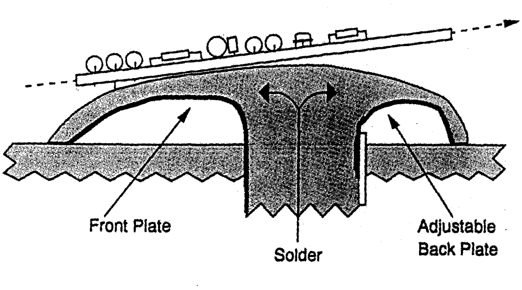

FIG. 10. Wave soldering (adapted from Seraphim *et al.*, 1989).

7.2 Surface-Mount Technology (SMT)

Relative to pin-in-hole mounting, surface-mount technology reduces package size and cost and improves board utilization. It does this by joining leads from components to the board surface on a finer pitch than the 2.54-mm hole spacing currently in use, thus allowing the whole board cross-sectional area to be used for wiring unobstructed by holes. Currently SMT connections are made with a pitch as fine as 0.3 mm, allowing several hundred perimeter bonding leads for a single chip module. Surface-mounted packages are either leadless or leaded chip carriers, some of which are shown in Fig. 5. For these packages a very short surface solder joint provides both electrical and mechanical connection between package and board. In leadless chip carriers, the solder must accommodate the shear strain caused by the relative displacement of package and board during thermal excursions. In leaded chip carriers, the strain is accommodated by elastic deformation of the leads. Since solder fatigue failure is a concern for SMT components, the contact metallurgy and intermetallic compound formation as well as the solder time and temperature cycle must be carefully controlled. Typically, eutectic Sn-Pb solder is applied by dipping or wave soldering, paste screening, or stenciling, plating, or application of preforms. The major joining techniques are wave soldering, vapor-phase reflow, infrared or hot-gas reflow, laser soldering, or hot-knife soldering. In vapor-phase reflow, the populated board with applied solder is placed in the saturated vapor of a boiling fluorocarbon. The vapor condenses on the board raising the temperature of all components to the fluorocarbon boiling point (typically 215 °C) thus reflowing the solder and joining all components simultaneously at uniform temperature.

While the vast majority of surface-mounted components are attached by solder, the use of conductive polymer adhesives is growing. Metal-particle–filled polymers such as epoxies form acceptable conductors in some applications. The principal metals used are silver, copper, or gold although silver/palladium alloys have been utilized (Goosey, 1985).

Highly loaded polymer films are isotropic conductors. Less highly loaded polymer films can be insulating until compressed between opposing metal pads. These materials form anisotropic "z-axis" conductive films and are finding increasing applications.

7.3 Connectors

A connector is a device to separate and reconnect electronic circuits repeatedly, and they come in many sizes and shapes. All involve the application of force by springs or other elements and a remakable low-resistance electrical contact surface. An example of a spring-loaded connector for a package with pins is shown in Fig. 11. The cross section of a card-edge connector is shown in Fig. 1, where spring-loaded contacts join to pads along both edges of a printed circuit card. Metal spring materials are most frequently beryllium copper or phosphor bronze, and interface contact metals are gold, palladium, or tin. The insulation that supports the metal contacts is most often an injection-molded plastic housing. Very high-density connectors are made from an area array of metal contact elements separated by a plastic insulator. The individual contact elements may be solid metal structures or shaped metal springs in a rigid plastic housing. The contact elements may also be metal structures in a compressible plastic medium that provides the contact force.

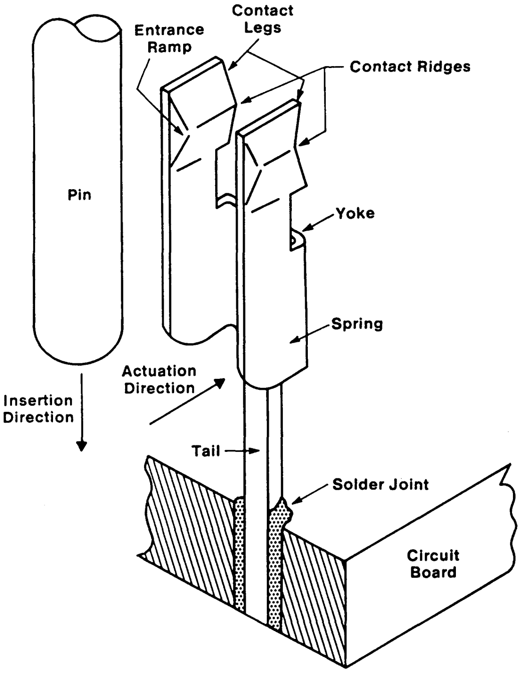

FIG. 11. Mechanical pin connector (from Tummala and Rymaszewski, 1989, reproduced by permission).

7.4 Cables

Cables are used to carry power, sense very low voltages or current, or transmit data over relatively long distances. Signal cables are flexible transmission lines containing a signal wire and a ground return conductor (a wire or shield, braid or continuous) separated by a dielectric and covered with a protective polymer jacket. Typical transmission lines are twin-lead, tri-lead, or coaxial. Since data are transmitted over long distances, the speed of transmission and the attenuation in the cable are important. For high speed, low–dielectric-constant polymers are used, and air is introduced to lower ϵ further. For example, expanded polytetrafluoroethylene has a dielectric constant of 1.3 so that signals travel at 88% of the speed of light. At high frequencies current flows in the skin depth, δ, on the outer surface of the inner conductor and the inner surface of the outer conductor. The skin depth δ is proportional to $1/\sqrt{f}$, where f is the frequency. Hence, the signal is attenuated by the skin-effect resistance and insulator dielectric loss. For low attenuation at high frequencies conductors are coated with silver or copper.

Electrical cables are used to interconnect packaged components within a system or for communication between systems. For short distances electrical cables can be used for high-speed data transmission, but for the highest data transmission rates or high-speed transmission over long distances, optical fiber cables are used. These cables consist of a graded-index SiO_2-based glass fiber in a protective plastic sheath. Optical fiber cables can carry data with minimal losses over several kilometers at rates in excess of Gbits/s.

8. HEAT TRANSFER

In order to maintain active device characteristics and ensure long lifetimes, semiconductor junctions must be maintained typically at 85 °C or less. The function of the package is to cool the chips by transferring the heat generated to an air or water reservoir or heat sink.

8.1 Thermal Engineering

The cooling structure of the package is characterized by the thermal resistance R, in °C/W, that it presents to a device generating heat Q (in watts, W), resulting in a temperature difference ΔT (in °C) between the device and the cooling fluid (a gas or liquid):

$$R = \Delta T/Q.$$

In low-power applications, R may be ~100 °C/W, but for densely packaged high-power chips, R must be engineered to be ≤ 10 °C/W. Heat is usually transferred to the cooling fluid by convection, which may be natural or forced (by a fan or pump) or due to boiling. The ability of the fluid to accept heat from area A (in m^2) is characterized by the heat transfer coefficient h (in W/m^2 °K):

$$Q = hA\Delta T.$$

Ranges of values for h are given in Table 3, but since h encompasses all the complex effects of convection, including fluid motion, fluid properties, and system geometry, the exact value for a particular cooling structure must be modeled and ultimately determined empirically.

8.2 Cooling Structures

Low-power electronic systems use natural-convection air cooling, but most computers use forced-air cooling, relying on circulating fans and finned metal heat spreaders as required to cool components. The multichip module packages require the most sophisticated cooling structures because they achieve high system performance by closely interconnecting many powerful chips. Figure 12 shows a few of the wide variety of structures in use. Depending on the thermal resistance required between the device and the cooling fluid, the heat may be removed from the chips through the interconnection package or from the back of the chip through various thermal structures such as solder, adhesives, paste, ceramic structures, metal plates, or metal pistons.

9. FUTURE CHALLENGES, EMERGING TECHNOLOGIES

Progress in package technology is characterized by steady evolutionary improvement of existing technology as well as revolutionary changes associated with new materials. For example, the outer lead bond pitch of surface-mount packages has continued to shrink over a 20-year period, and wiring density of cards and ceramic modules is increasing. There is ongoing work to reduce the dielectric constant of processable ceramics and polymers by introducing new materials. Other new materials such as synthetic diamond for thermal management could open new dimensions in packaging. But the key challenges to package technology will be, as always, to package new and ever more powerful systems at the lowest possible cost.

9.1 Optoelectronics

Optoelectronics devices and fiber-optic links are increasingly being used for high-bandwidth communications between electronic systems. While semiconductor devices used as transmitters (such as lasers and light-emitting diodes) and receivers can be interconnected and powered using the technologies described above, special package designs are required to couple the optical fiber to the semiconductor transmitter or receiver. For example, to avoid signal losses the alignment tolerance for single-mode fibers is about 0.5 μm. The coupling of fiber to device can

be accomplished by precision mechanical mounting (with or without lenses), an adherent butt joint, or thin-film optical waveguides (Tummala and Rymaszewski, 1989). Future systems may require dense arrays of fibers coupled to small high-speed semiconductor switches that include optical transmitters and receivers.

9.2 Electromagnetic Management

Future packaging technology must successfully handle processor chips running at frequencies of hundreds of megahertz and the electromagnetic emissions and interference associated with these systems. In addition, as wireless communication becomes dominant for portable systems, the fabrication of high-frequency transmitters and receivers of electromagnetic waves will become important. Electromagnetic field modeling, component placement, and shielding will become key aspects of package technology. The need for low-cost, light-weight, moldable shielding materials could open up a range of applications for conducting polymer materials.

9.3 Low-Power, Low-Cost, Light-Weight Systems

As semiconductor technology reduces device size and power and careful design puts more and more function on a single chip, potentially very low-cost, reasonably powerful systems will be possible. Package engineers will be increasingly challenged to build thin, light-weight, but very robust structures that provide signal interconnection, power distribution, and cooling for these future portable systems.

INTRODUCTION

Paleomagnetism is the study of the magnetization of rocks and sediments, and provides a record of the direction and intensity of the ancient geomagnetic field.

Paleomagnetism was a cornerstone of the "revolution" in the earth sciences that began in the 1950s and led to the development of the theory of plate tectonics. A series of landmark papers published in the 1950s on paleomagnetic data from Britain and North America provided the first land-based quantification of continental drift (e.g., Runcorn, 1956). Forty years on, paleomagnetism remains the primary means of reconstructing the relative positions of rock bodies in the geologic past (on scales from individual thrust sheets to entire continents). In addition, paleomagnetism has led to an improved understanding of the mechanisms for generation of the geomagnetic field, for secular variations, and for polarity reversals. The record of polarity reversals in rocks and sediments provides a unique means of global correlation, and has become the thread on which we hang our geologic time scales.

1. RELEVANT CHARACTERISTICS OF THE GEOMAGNETIC FIELD

About 90% of the geomagnetic field at the Earth's surface can be modeled by a dipole close to the center of the Earth. The nondipole components of the geomagnetic field contribute to the short-term (secular) variations of the field, and are responsible for the deviation of the north geomagnetic pole from the north pole (situated at the rotation axis of the Earth). It is generally accepted, on the basis of records for the last 10^5 years, that secular variation averages out over $\sim 10^4$ years. The time-averaged geomagnetic field is thought to approximate a geocentric axial

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

dipole field. This is of paramount importance to paleomagnetic studies because it allows us to predict the location of the ancient north pole relative to an observation point where the time-averaged field direction is recorded by ancient rocks or sediments.

The dipole component of the geomagnetic field has changed polarity numerous times in the geologic past. The present state of "normal" polarity has existed for about the last 780 000 years. Our template for the sequence of geomagnetic polarity reversals since about 150 Ma B.P. (before present) is based on magnetic anomalies from the oceans, which are produced by normally and reversely magnetized ocean crust formed at the mid-oceanic ridges. The so-called "seafloor spreading" process often occurred at rather constant rates over long periods of geologic time and spreading was usually symmetric either side of the ridge. For these reasons, the record of geomagnetic reversals in the ocean floor is often a faithful record of the sequence of polarity reversals through time. Statistical analysis of the reversal record since about 150 Ma B.P. indicates that there are too few short polarity intervals for a Poisson process; however, this may be attributed to the inadequacy of the record. It is generally considered that the lack of memory characteristic of the Poisson process is also a characteristic of polarity reversal history. Because of the dipole nature of the main field and the "geologically instantaneous" nature of the reversal process (the process takes about 3000 years), the record of individual reversals in rocks and sediments provides a unique global time marker, a unique means of global correlation.

2. ORIGIN OF MAGNETIZATION IN ROCKS AND SEDIMENTS

2.1 Magnetic Minerals

Iron oxide and iron sulfide minerals are the most common carriers of remanent magnetization in rocks and sediments. Titanomagnetites [$x\mathrm{Fe_2TiO_4} \cdot (1-x)\mathrm{Fe_3O_4}$] are present in many types of igneous and metamorphic rocks, and are therefore a detrital constituent in many sedimentary rocks. The titanomagnetites are ferrimagnetic at room temperature for values of x less than about 0.8. Many sediments, particularly deep-water pelagic limestones, contain magnetite ($\mathrm{Fe_3O_4}$) or low-titanium titanomagnetite that may be biogenic in origin, being derived from marine organisms, such as bacteria and some molluscs, which incorporate magnetite in their metabolism (see BIOMAGNETISM AND GEOMAGNETIC FIELD DETECTION BY ORGANISMS). Biogenic magnetite usually lies in the single-domain (SD) grain-size range, which is the optimal grain size for retention of magnetic remanence over geologically significant time intervals.

Titanohematites [$x\mathrm{FeTiO_3} \cdot (1-x)\mathrm{Fe_2O_3}$] are antiferromagnetic for $0 < x < 0.5$. The weak net magnetic moment in hematite (α-$\mathrm{Fe_2O_3}$) and titanohematites is due to a slight canting of the spin moments. Titanohematites are constituents in some igneous and metamorphic rocks. Hematite is a common constituent of sedimentary rocks and is an important carrier of magnetic remanence in clastic and chemical sediments. Hematite may occur in sediments as detrital "specularite" or as an authigenic pigment that grows during diagenesis.

Maghemite (γ-$\mathrm{Fe_2O_3}$) has the spinel structure of magnetite and the chemical composition of hematite. Maghemite is ferrimagnetic and has similar magnetic properties to magnetite. Maghemite is common as a low-temperature oxidation product of magnetite in both igneous and sedimentary rocks. It reverts to hematite at about 350 °C.

Goethite (α-FeOOH) is the most common iron oxyhydroxide mineral and is antiferromagnetic, the net moment being due to canting of spin moments. Goethite is an important product in low-temperature oxidation, particularly of iron sulfides, and is a constituent of manganese nodules and the Pacific red clays where it may precipitate directly from seawater.

Pyrrhotite (FeS_{1+x} where $x = 0$–0.14) is the most commonly occurring iron sulfide mineral that is ferrimagnetic. The ferrimagnetism is restricted to a limited compositional range ($0.1 < x < 0.14$). Pyrrhotite occurs in basic igneous rocks and can grow during sediment diagenesis in certain reducing environments. The most common iron sulfide mineral (pyrite, $\mathrm{FeS_2}$) is paramagnetic, and does not therefore carry magnetic remanence.

2.2 Natural Magnetization Processes in Rocks and Sediments

Thermal remanent magnetization (TRM) is the magnetization acquired by a magnetic mineral grain during cooling through its blocking temperature, above which the magnetic ordering of a grain is randomized by thermal energy. The blocking temperature is a function of grain size and composition and lies below the Curie (Néel) temperature. Igneous rocks cooling from magma generally acquire a TRM in the direction of the ambient geomagnetic field.

Chemical remanent magnetization (CRM) is produced by growth of a magnetic mineral grain through its blocking volume, below the blocking temperature of the grain. The blocking volume is the critical volume for a particular grain shape and composition, above which the grain can carry magnetic remanence. Magnetic mineral grains acquire a CRM as they grow through their blocking volume in the ambient geomagnetic field, and the direction of the CRM is usually maintained during further grain growth. CRM is an important mode of remanence acquisition during sediment diagenesis.

Detrital or depositional remanent magnetization (DRM) is an important magnetization process in sediments. Detrital or biogenic magnetic mineral grains with preexisting TRM or CRM can align themselves with the ambient field during deposition. The alignment occurs in the upper few centimeters of the soft sediment, and is therefore often referred to as postdepositional remanent magnetization (pDRM). The lock-in depth of DRM has been estimated experimentally and theoretically to be of the order of 10 cm, but will depend on grain size, porosity, sedimentation rate, and bioturbation depth.

Viscous remanent magnetization (VRM) is the remanence produced by a weak external field (such as the geomagnetic field) over a long period of time. VRM is an important source of secondary magnetization in rocks and sediments. The intensity of VRM is proportional to the logarithm of time that the sample experiences the weak field. The proportionality constant (viscosity coefficient) increases with temperature. Many rocks and sediments carry a VRM acquired during the present Brunhes interval of "normal" polarity of the geomagnetic field.

3. LABORATORY AND ANALYTICAL TECHNIQUES

The introduction of cryogenic magnetometers in the mid 1970s resulted in a significant reduction in magnetometer noise level, and opened up paleomagnetic research to a wider range of rocks and sediments (see Collinson, 1983). Modern cryogenic magnetometers can measure sample magnetization intensities as low as $\sim 10^{-5}$ A/m with sufficient precision for precise determination of paleomagnetic direction.

Rocks and sediments can become magnetized at any time during their history, and hence the natural remanent magnetizations (NRM) of rock and sediment samples are often the resultant of more than one magnetization component. TRM in igneous rocks and DRM in sedimentary rocks can usually be associated with the original cooling of the igneous rock or original deposition of the sedimentary rock and, in such cases, are referred to as "primary" magnetizations. Subsequent chemical alteration or heating of the rock can yield a CRM or TRM that would then be a "secondary" magnetization. VRM often has recent origin, having formed since the last geomagnetic polarity reversal. Laboratory techniques in paleomagnetism are designed to resolve the various magnetization components that constitute the total magnetization of the rock or sediment. The objective is usually to resolve the "primary" magnetization component, that associated with the formation of the rock or sediment. The age of the "primary" magnetization component can then be derived from the paleontological/radiometric age of the rock or sediment.

3.1 Demagnetization Techniques

The external field strength required to alter the magnetic remanence of a grain will depend on the coercivity of the individual grain, which is controlled by composition and grain size/shape. The dependence of coercivity on composition and grain size is utilized in *alternating-field* (AF) *demagnetization* to resolve the magnetization components carried by different grain populations. If the NRM of the sample is a composite of individual magnetization components that have distinct coercivity spectra, the AF method is suitable for resolving the individual components. The normal procedure is to demagnetize the sample progressively by a stepwise increase in peak alternating field, measuring the remaining magnetic remanence after each step. The range of peak alternating fields is typically 5–100 mT. For each demagnetization step, the sample is placed in a magnetically shielded coil and the alternating field is smoothly ramped down to zero in the absence of background field. Grain remanences with coercivity lower than the peak alternating field will be reoriented as the peak field is ramped down, and their contributions to the remaining remanence will cancel out. The net effect is to demagnetize these grains. As the peak alternating field is progressively raised, a larger proportion of the total magnetic grain population becomes demagnetized and ceases to contribute to the remanence of the sample. For a full description of the design of alternating-field demagnetizers see Collinson (1983).

The time required for magnetic remanence of a grain to decay in zero external field (the relaxation time) is a function of ambient temperature, grain size, and composition. The blocking temperature is the temperature at which the relaxation time falls within the time range of laboratory experiments ($\sim 10^3$–10^4 s). As the relationship between relaxation time and temperature is exponential, the exact length of the experiment does not, within reason, affect the observed blocking temperature. Two populations of magnetic grains with different origins, and therefore different compositions and/or grain sizes, might be expected to have distinct blocking-temperature spectra. This principle is utilized in *thermal demagnetization* to separate magnetization components carried by different magnetic grain populations. Normal practice is to heat the sample in progressive temperature increments (until the magnetization falls below the magnetometer noise level), allowing the sample to cool in field-free space after each heating increment. The remanence of all grains with blocking temperature less than the maximum temperature will become randomized as the sample cools in field-free space. The magnetization measured after each heating step can be used to determine the directions of magnetization components with distinct blocking-temperature spectra. For a description of the design of thermal demagnetizers, see Collinson (1983).

Leaching with hydrochloric acid can provide a means of selective destruction of magnetic grains. Such *chemical demagnetization* is applicable to siliceous rocks, particularly red sandstones, which contain a secondary magnetization due to authigenic growth of fine-grained pigmentary hematite. The dissolution rate of coarse-grained hematite of detrital origin is lower than that of the finer-grained pigmentary hematite of diagenetic origin, because of the difference in the ratio of surface area to grain volume. Leaching in 3–10 N hydrochloric acid, and remanence measurement at certain time intervals during the leaching, provides a means of resolving magnetization components with distinct "leaching spectra."

3.2 Analysis of Demagnetization Data

The most widely used method for analyzing changes in magnetization direction and intensity during demagnetization is the orthogonal projection, also referred to as the Zijderveld diagram (see Zijderveld, 1967; Dunlop, 1979; Collinson, 1983). This is a simple, but extremely useful, means of displaying the change in magnitude and direction of the magnetization vector during demagnetization. Straight-line segments on these plots indicate that the magnetization vector being removed has constant direction. This direction can be computed, and defined as a component of the magnetization. It is important to note that straight-line segments on orthogonal projections may not always represent single components. They may also represent composites of two or more components with identical demagnetization (coercivity, blocking, or leaching) spectra. The magnetization components cannot be resolved if the overlap in demagnetization spectra is too great. However, if the unblocking temperature spectra overlap, this does not necessarily mean that the coercivity spectra will overlap. The choice of demagnetization technique will be critical to whether the components of magnetization can be resolved.

The points on the orthogonal projection that define straight-line segments are commonly picked by eye. The component direction associated with a particular straight-line segment can then be computed by a least-squares technique (Kirschvink, 1980). This method gives a maximum angular deviation

(MAD) value, which provides an estimate of the goodness of fit of the straight line to the points on the projection.

In the special case when three magnetization components with overlapping demagnetization spectra are present, the Hoffman–Day method (Hoffman and Day, 1978) may help to resolve the component directions. The method involves plotting subtracted vectors on an equal-area stereographic projection, at each stage in the progressive demagnetization process. In a demagnetization interval characterized by two overlapping demagnetization spectra, the subtracted vectors will plot on a great circle between the two component directions. If three overlapping demagnetization spectra are present, the intersection of the two great circles can give an estimate of the direction associated with the component with intermediate blocking temperature, even though this component direction is not directly resolved by the demagnetization process. Orthogonal projection in this case would not resolve the intermediate component.

If two magnetization components with partially overlapping demagnetization spectra are present in the sample, the resultant vector will trace a great circle in stereographic projection as the overlapping interval is demagnetized (Halls, 1978). If one of the two components has dispersed directions, the great circles from individual samples will converge to give the direction of the undispersed component. The method is only applicable in the special case where one of the components is dispersed, as there will be no appreciable convergence of the great circles if both components have single directions. The dispersion of one of the components can occur in a number of situations. For example, the primary component in conglomerate clasts will be dispersed relative to the secondary component that postdates conglomerate deposition. In this case, the secondary component could be resolved by remagnetization circle analysis.

3.3 Statistics

When the the magnetization components for individual samples have been determined, the sample magnetization components are combined to produce a site mean direction. The site mean directions may then be combined to compute an overall mean direction.

The probability density function generally used in paleomagnetism to determine the mean and dispersion estimates is referred to as the Fisher distribution (Fisher, 1953). This distribution assumes circular symmetry about the mean direction. Each observation is considered as an independent unit vector, and the mean direction is determined by summing the Cartesian coordinates of each of the vectors. A resultant vector **R** of the distribution can be calculated as the vector sum of the vectors. The concentration parameter k for N vectors is calculated by

$$k = (N - 1)/(N - R).$$

For $k > 10$, the radius of the 95% circle of confidence, in which the true mean should lie at the 95% confidence level, can be calculated by

$$\alpha_{95} \sim 140^\circ/(kN)^{1/2}.$$

The use of Fisher statistics implies that the population of vectors has a Fisherian distribution, a condition that is often not satisfied. Although the Fisherian distribution is almost universally used as the basis for statistical treatment in paleomagnetism, the Bingham distribution is preferred by some workers as it is better suited to the bimodal (normal and reversed polarity) and azimuthal asymmetry which is inherent in paleomagnetic data (Onstott, 1980). When using Fisher statistics, each vector should be equally independent and it is therefore important to maintain the sample/site hierarchy.

3.4 Field Tests for the Age of Magnetization

As rocks and sediments can become magnetized at any time in their history, field tests that constrain the age of the magnetization are critical to any paleomagnetic study. The *fold test* involves the determination of dispersion of paleomagnetic vectors during unfolding of the structure, and therefore allows determination of the age of magnetization relative to the age of folding. The age of folding can usually be determined by stratigraphic constraints. The fold test is best suited to individual folds, although it can be adapted for regional use on tilted beds that are not part of a single structure. The test involves analysis of the dispersion of paleomagnetic vectors during progressive unfolding of the structure, by rotating the limbs of the structure to the horizontal about the strikes of the individual limbs. In cases where the structure has plunge, the plunge should be rotated to the horizontal prior to the rotation of the limbs about the strike. McElhinny (1964) used the ratio of the concentration parameter (k) before and after tilt correction to determine whether the fold test was positive (i.e., whether the magnetization was prefolding). Critical values of k_2/k_1 (k_1 and k_2 are values of k before and after tilt correction of the structure, respectively) are listed by McElhinny (1964) for vector populations of 2–20. In the last ten years, it has become increasingly apparent that magnetization components are sometimes coeval with deformation/folding. Statistical criteria for analysis of the dispersion of paleomagnetic vectors that are more rigorous and better suited to the progressive unfolding of structures have recently been introduced (e.g., McFadden, 1990).

The second category of field test is the *conglomerate test*, which can be applied to conglomerates, breccias, or agglomerates. If the magnetization component directions from the clasts are randomized, the magnetization component predates the formation of the clasts. The same magnetization component recognized in an adjacent *in situ* outcrop of the same lithology can then be considered to have age very similar to the stratigraphic age of outcrop. The test for randomness (Watson, 1956) can be applied to the vectors derived from the clasts.

The third category of field test is the *baked contact test* which can be applied to igneous intrusions and their thermally metamorphosed contact with the country rock (Wilson, 1962). If the igneous intrusion and the baked country rock carry the same magnetization component direction, and the country rock outside the aureole carries a different (preceding) magnetization, then this is considered to constitute a test for a "primary" TRM in the igneous body.

3.5 Identification of Carriers of Natural Remanence

Magnetic mineral phases tend to have characteristic modes of occurrence, and therefore, the identification of magnetic remanence carriers provides clues to the age of magnetization components. Recent advances in instrumentation have allowed complete magnetic hysteresis loops to be measured even on weakly magnetized sediments. For example, the alternating-gradient force magnetometer (μMAG) can be used to determine values of saturation magnetization (M_s), saturation remanence (M_{rs}), and coercive force (H_c) even on weakly magnetized limestones, giving good constraints on the magnetic mineral content of the sample. High-temperature experiments designed to determine Curie (Néel) temperatures, and low-temperature experiments designed to monitor transitions in magnetic behavior (Verwey and Morin transitions), are important means of determining the magnetic mineral content of rocks and sediments. However, in order to determine the carriers of natural remanent magnetization (NRM), the characteristics of the NRM itself must be determined as fully as possible.

As described above, progressive demagnetization is the standard procedure for determining the component content of the NRM. Thermal and alternating-field demagnetization characteristics indicate the blocking temperature and coercivity spectra, respectively, of NRM components.

Blocking temperature is a function of composition and grain size of the magnetic carrier. For single-domain (SD) grains of constant composition, the blocking temperature will be a function of grain size. Because of the large grain size of hematite at the SD/MD (single-domain to multidomain) threshold (~2 mm), the SD range for hematite covers most of the remanence-carrying grain sizes encountered in sediments. Therefore, in the case of hematite, blocking temperature is a useful guide to grain size. For titanomagnetites [$x\mathrm{Fe_2Ti0_4} \cdot (1 - x)\mathrm{Fe_30_4}$], the blocking temperature is a function of composition and grain size and shape. As x decreases, the Curie point increases almost linearly, and as blocking temperature cannot exceed the Curie point, the available blocking temperature range will increase as x decreases. For SD titanomagnetite grains of uniform shape and composition, the blocking temperature will be a function of grain volume/shape. The blocking temperature range in itself is not generally diagnostic of magnetic mineralogy, other than the fact that the maximum blocking temperature cannot exceed the Curie (Néel) point of the mineral composition. In the case of minerals with relatively low Curie (Néel) points, such as geothite (~120 °C), the blocking-temperature range is rather diagnostic because it is so restricted. Mineralogical changes as a result of heating during thermal demagnetization can obscure the blocking-temperature spectrum. For example, maghemite alters to hematite at about 350 °C, and iron sulfides will oxidize in air to form magnetite at about 300 °C.

The coercivities of remanence of hematite and geothite are typically about two and three orders of magnitude greater, respectively, than that of SD magnetite. For this reason, hematite and goethite magnetizations are very resistant to alternating-field (AF) demagnetization. For titanomagnetites, coercive force increases with x and with decreasing grain size. The grain-size effect will dominate in natural samples with fairly uniform composition.

4. APPLICATIONS OF PALEOMAGNETIC STUDIES

4.1 Paleomagnetic Poles and Continental Drift

The focus of the first modern paleomagnetic studies, carried out in the 1950s, was the documentation of continental drift. Deviating paleomagnetic data from European and North American rocks of the same age were shown to reflect the development of the North Atlantic Ocean since the formation of the rocks. As a result of the dipolar nature of the main time-averaged geomagnetic field, the paleolatitude of the rock body can be determined from the paleomagnetic inclination and the coordinates of the sampling site. It is customary to express a paleomagnetic direction recorded at a particular location as a virtual geomagnetic pole (VGP), determined assuming an axial geocentric dipole. Such paleomagnetic poles are a standard means of expressing paleomagnetic data, and the time-space distribution of paleomagnetic poles for a particular crustal block or continent is known as an apparent polar wander path (APWP). The APWP for a particular continent is an expression of the movement of the crustal block relative to the rotation axis of the Earth. True polar wander, the movement of the rotation axis relative to the entire lithosphere, is generally considered to be insignificant compared to apparent polar wander. Apparent polar wander paths are a principal means of reconstructing the relative position of crustal blocks in the geologic past and are continually updated by addition of new data. For a recent compilation of the APWPs for the major continents and the constraints that these data place on paleogeographic reconstructions, see Van der Voo (1993).

4.2 Tectonic Rotations in Mountain Belts

Paleomagnetic data have proved useful in documenting rotations of small-scale crustal blocks during deformation in mountain belts. One of the aims of geological studies in fold and thrust belts is the "palinspastic" reconstruction of the deformed belt by field mapping and seismic reflection studies of the subsurface structure. Such reconstructions require knowledge of the relative rotation of thrust sheets in the deformed belt. Paleomagnetic component directions that predate the deformation can be used to monitor these rotations. In zones of oblique convergence, large-scale vertical-axis rotations of thrust sheets relative to the adjacent stable continent have been recorded (e.g., Channell *et al.*, 1990). Clockwise and anticlockwise rotations are usually associated with dextral and sinistral shear, respectively, although the fault patterns that accommodate the observed rotations have not been well documented.

4.3 Magnetic Polarity Stratigraphy

Because of the dipole nature of the geomagnetic field, the recording of ancient polarity reversals in rocks and sediments provides a unique means for global correlation. No other type of event (isotopic, paleontologic, lithologic, or geochemical) recorded in rocks or sediments provides the same potential for precise global correlation. As our knowledge of the history of geomagnetic polarity reversal has improved, the geomagnetic polarity time scale (GPTS) has become central to our determination of geologic time. The template for the GPTS for the last 150 Ma is based on oceanic magnetic anomalies, which are produced by alternating zones of normal and reversed magnetized ocean crust formed at the mid-oceanic ridges. One of the roles of magnetic polarity stratigraphy is to correlate the GPTS to paleontologic events, radiometric ages, and isotopic events. Almost any stratigraphic study benefits from magnetostratigraphic data on account of the potential for precise global correlation, and for correlation to the GPTS and current geologic timescales (see King and Channell, 1991).

4.4 Secular Variation Magnetic Stratigraphy in Lake Sediments

"Magnetic stratigraphy" usually refers to magnetic polarity stratigraphy. Short-term "secular" variations of the geomagnetic field are generally considered to average out over intervals of about 10^4 years. Directional changes associated with secular variation provide a potential means of correlation in recent sediments. Whereas conventional polarity stratigraphy depends on the recognition of directional changes of remanent magnetization of about 180°, secular variations rarely exceed a few tens of degrees. Hence, sampling and measurement techniques in secular variation studies are particularly critical. The technique has been largely restricted to lake sediments because of their high sedimentation rates and relative lack of bioturbation. Most marine sediments are too bioturbated and have sedimentation rates that are too low for a high-fidelity record of secular variation. As secular variation is largely due to the nondipole components of the geomagnetic field, secular variations are not globally synchronous but can be used for local/regional correlation.

4.5 Rock Magnetic Stratigraphy

Rock magnetic stratigraphy involves the utilization of nondirectional magnetic properties of sediments as a means of correlation. The first rock magnetic parameter to be widely used for correlation was magnetic susceptibility. Magnetic susceptibility essentially monitors the concentration of ferrimagnetic minerals. The parameter provides a rapid means of sediment correlation, and is now a standard technique for correlation of lake and deep-sea sediment cores. The field of rock magnetic stratigraphy has broadened considerably in the last ten years with the use of magnetic parameters that are sensitive not only to magnetic mineral concentration but also to grain size and mineralogy. These techniques have been applied to the study of environmental changes in lake catchments by monitoring changes in magnetic mineralogy of the sediments (Thompson and Oldfield, 1986). Similar methods have been applied to marine sediments to study changes in sediment provenance and clastic/biogenic fluxes, which can often be related to paleoclimatic change (see King and Channell, 1991).

4.6 Insights into Geomagnetic Field Behavior from Secular Variation, Excursions, Polarity Transitions, Paleointensities, and Polarity Bias

Globally distributed secular-variation records provide a means of determining the history of drift of centers of secular variation, and hence establish the longevity of the westward drift observed in historical observatory records. The time-space configuration of the nondipole field revealed by detailed secular-variation-records will provide insights into geomagnetic field-generation mechanisms.

Brief departures of the geomagnetic field from the full polarity state (geomagnetic excursions) appear to have been recorded in the present normal-polarity interval (the Brunhes chron) at numerous locations, but many recorded excursions have not been documented at multiple sites and therefore cannot be firmly established as geomagnetic phenomena. The short duration ($\sim 10^3$–10^4 years) of geomagnetic excursions leads to difficulty in recording these phenomena in rock or sediment sections, as the rock/sediment record is usually episodic on these time scales. In addition, age control is often insufficient to establish unequivocal correlation for Brunhes excursions recorded at different locations. The best-documented excursion is from sediments at Mono Lake (California) where the excursion (dated at 27–29 ka B.P.) is followed by four successive recurrences of the excursion wave form (Lund *et al.*, 1988). An additional excursion at about 120 ka B.P. (Blake event) has been recorded at several locations in the Mediterranean region and in Atlantic cores. These and other records imply that the geomagnetic field exhibits a complete spectrum of behavior from high-amplitude secular variation to full polarity reversals. Brief polarity reversals that never stabilize, where the dipole field immediately reverts back to its initial polarity, have also been recorded. Detailed high-fidelity records of the process of polarity reversal, recorded in sediments with high accumulation rates, have tended to indicate that the dipole configuration of the field is maintained during the reversal process (Clement, 1992), and that the paleomagnetic pole follows preferred longitudinal paths during the reversal process.

Absolute geomagnetic paleointensity determinations in volcanic rocks generally utilize a method based on the so-called Thellier technique (Thellier and Thellier, 1959). The majority of the determinations are for the last few thousand years, and display considerable scatter due to short-term (secular) variation in geomagnetic intensity, nonrigorous experimental techniques, and use of unsuitable archaeological and volcanic materials. As volcanic eruption is discontinuous, the volcanic record of paleointensity is discontinuous. Each determination requires independent age control, and the uncertainties in these ages inhibit correlation to other paleointensity determinations.

More continuous paleointensity records for the last 100–140 ka have been obtained from deep-sea sediment cores (see Tauxe, 1993). These relative paleointensity records are obtained by normalizing the remanence (NRM) intensity using anhysteretic remanence (ARM), isothermal remanence (IRM), or susceptibility to compensate for variations in concentration of magnetic minerals. Good correlation of paleointensity records from widely spaced locations indicates that these data record the time-averaged dipole moment of the geomagnetic field, effectively averaging out secular variation. The scope of sediment paleointensity studies has been expanded back to 3.9 Ma B.P. by recent records from the equatorial Pacific (Valet and Meynadier, 1993). Several intriguing features appear in these records. Paleointensity lows in the Brunhes chron appear to correlate to short "polarity events" or excursions. Reversals tend to coincide with lows in the virtual axial dipole moments (VADMs), with abrupt increases immediately after reversal. The longer the duration of the polarity chron, the greater the abrupt increase in VADM at its base; and each polarity chron appears to be characterized by sawtooth decay of VADM leading up to the next reversal. This has led to the suggestion that the reversal frequency, and the occurrence of "polarity events" or excursions, are ultimately controlled by the intensity of the geomagnetic dipole moment, which also controls the stability of a particular polarity state.

As our record of polarity reversal history improves and is pushed back in time, we will be able to ascertain whether there is any long-term pattern or polarity bias in the record that may signify changes in convection in the Earth's core. Our present record is fairly complete for the last 150 Ma; however, this is a small fraction of the entire history of polarity reversal, which goes back at least 3000 Ma.

GLOSSARY

Anhysteretic Remanent Magnetization (ARM): The magnetic remanence produced in the laboratory by smooth decay of a strong alternating field in the presence of a weak direct field.

Apparent Polar Wander Path: The time-space distribution of paleomagnetic poles for a particular crustal block.

Blocking Temperature: The critical temperature above which the magnetic moment of a mineral grain becomes randomized by thermal energy. The relaxation time of the grain magnetization may increase from a few seconds to millions of years as the grain passes through its blocking temperature.

Blocking Volume: The threshold volume above which a grain can carry remanence at room temperature. Below this volume, the grain is superparamagnetic and the blocking temperature is below room temperature.

Coercivity of Remanence: The back field required to reduce a remanent magnetization to zero, after saturation.

Curie (Néel) Temperature: Temperature above which saturation magnetization is zero. It is a characteristic of a particular magnetic mineral.

Demagnetization: The process of progressive demagnetization of a magnetic remanence (using alternating fields, thermal, or chemical techniques). Progressive demagnetization is used as a means of resolving the component content of the remanence. The process is successful where the components have nonuniform responses to one of the demagnetization techniques.

Isothermal Remanent Magnetization (IRM): The magnetic remanence produced in the laboratory by temporary application of a strong direct (dc) field.

Magnetic Domains: Uniformily magnetized regions in a magnetic grain.

Magnetic Susceptibility: Measure of degree of magnetization of a substance in a weak direct field, equal to M/H (ratio of induced magnetization to applied field).

Multidomain Grain: A grain which contains more than one magnetic domain.

Natural Remanent Magnetization (NRM): The naturally occurring remanent magnetization of a sediment, rock, or mineral.

Normal Polarity: Polarity of the geomagnetic dipole field as of today.

Paleomagnetic Pole or Virtual Geomagnetic Pole (VGP): The pole calculated from a magnetization direction recorded at a particular location assuming that the geomagnetic field responsible for the magnetization direction was a geocentric dipole.

Reversed Polarity: Polarity of the geomagnetic dipole field opposite to that of today.

Secular Variations: Geologically short-term geomagnetic field variations, which are generally believed to average out in $\sim 10^5$ years.

Virtual Axial Dipole Moment (VADM): The magnetic moment of an axial geocentric dipole calculated from paleointensities observed at a particular location.

INTRODUCTION

Paramagnetism may be defined as the study of the properties of matter that are related to the existence of free magnetic moments. A primary manifestation of paramagnetism is a positive magnetic susceptibility, but there are many phenomena that are connected with the existence of free moments and we shall examine some of them in this article.

Michael Faraday was the first person to study systematically the magnetic properties of matter. This work was published in three volumes in London from 1839 to 1855 under the title *Experimental Researches in Electricity*, and it provides a fascinating glimpse into Faraday's great mind. Having subjected all kinds of substances (including rarefied gases and such common items as dry mutton and fresh beef) to the action of a powerful electromagnet (Faraday, 1846a), he concluded, "All matter appears to be subject to the magnetic force as universally as it is to the gravitating, the electric and [other] forces." (Faraday, 1846b). He observed that *all* substances respond to a magnetic field in one of two ways: They orient their long dimension either across the "lines of force," or alongside them. He called the first kind "diamagnetic" (see DIAMAGNETISM) and kept the term "magnetic" for the second. "Magnetic" was then a general term for substances that are attracted to the lodestone and to magnetic metals such as iron. Diamagnetic materials are repelled by a magnet. The word "paramagnetic" was coined in 1850 from the Greek prefix "para," which means alongside (as in parallel), to describe paramagnetic behavior. "Ferromagnetic" was used by W. Thomson (Lord Kelvin), also in 1850, in the expression "feebly ferromagnetic," which might have meant "paramagnetic." A clear distinction between "ferromagnetic" and "paramag-

netic" as they are used today was made by P. Curie in 1895.

The magnetic properties of matter are due primarily to the electrons. Nuclear magnetism is interesting in its own right, but it is of order 10^{-6} smaller than electronic magnetism and will not be considered here. Diamagnetism is a universal property of matter that follows from Lenz's law (see ELECTRODYNAMICS, CLASSICAL): All electrons contribute a diamagnetic moment that, omitting considerations of anisotropy, points in the direction opposite to that of the magnetic field. Paramagnetism on the other hand occurs only in materials that have spontaneous, randomly oriented moments in their ground state (with the exception of Van Vleck paramagnetism, which is discussed in Sec. 2.5). These moments tend to align themselves parallel to an applied field, but thermal agitation, or in the case of metals the exclusion principle, opposes that tendency and the net result is partial alignment along the field. This is paramagnetic behavior, which again may be subject to anisotropies.

Static paramagnetism, as all equilibrium magnetic phenomena, is quantum mechanical in origin. This follows from the Bohr–Van Leeuwen theorem (Van Vleck, 1932), which shows, in essence, that in classical systems all dependence of the Hamiltonian function on an applied magnetic field can be eliminated without affecting the values of thermodynamic averages. Our treatment will therefore be quantum mechanical, but nevertheless thinking along classical lines is still useful in providing physical insight. It is interesting that 30 years before quantum mechanics, Langevin (1905), by postulating the existence of magnetic moments, was able to derive the temperature dependence of paramagnetic susceptibilities that had been observed ten years earlier by P. Curie (Curie, 1905).

In this article, the paramagnetic properties of free atoms, of ionic salts containing metallic elements having partially filled shells, and of metals are considered. Some applications of paramagnetic substances, such as magnetic cooling, the maser, and the tunable spin-flip Raman laser, are also mentioned.

The basic concept in the theory of magnetism is that of the magnetic moment. In the next section, we define this and show that it is given by the derivative of the Hamiltonian with respect to the applied magnetic field. This property is used in Sec. 2.5 to calculate the thermal average of the moment per unit volume, and the susceptibility.

1. THE MAGNETIC MOMENT

The magnetic moment $\boldsymbol{\mu}$ of an electron is comprised of two parts, the orbital moment $\boldsymbol{\mu}_l$ and the spin moment $\boldsymbol{\mu}_s$. These two quantities will be defined, and the total moment $\boldsymbol{\mu} = \boldsymbol{\mu}_l + \boldsymbol{\mu}_s$ will be shown to satisfy the relation

$$\mu_\alpha = -\frac{\partial \mathcal{H}}{\partial H_\alpha}, \tag{1}$$

where $\mathcal{H} = T + V$ is the Hamiltonian function, the sum of the kinetic and potential energies, and α denotes a Cartesian component of the applied field $\mathbf{H}$ and of $\boldsymbol{\mu}$. Unless otherwise specified, the magnetic field will be taken in the z direction. The moments of individual electrons i are additive so that in many-electron systems, Eq. (1) is valid for the total moment, $\boldsymbol{\mu} = \Sigma_i \boldsymbol{\mu}_i$. To prove Eq. (1) in a one-electron system, the dependences of $\mathcal{H}$ on the orbital and spin moments will be considered separately.

1.1 Orbital Moment

The definition of the magnetic moment of a moving electron of charge $-e$ (note that e is positive) with respect to a point of origin is

$$\boldsymbol{\mu}_l = -(e/2c)\, \mathbf{r} \times \dot{\mathbf{r}}, \tag{2}$$

where c is the velocity of light $\mathbf{r}$ the position, and $\dot{\mathbf{r}}$ the velocity. The effect of an applied field $\mathbf{H}$ on the electron's motion is obtained by adding a vector-potential term (Van Vleck, 1932, Ch. I) to the momentum operator $\mathbf{p}$ in the Hamiltonian, thus:

$$\mathcal{H} \rightarrow (1/2m)[\mathbf{p} + e\mathbf{A}/c]^2 + V, \tag{3}$$

where $\mathbf{H}$ is derived from the vector potential $\mathbf{A}$,

$$\mathbf{H} = \nabla \times \mathbf{A}. \tag{4}$$

It is easily shown that the velocity is given by

$$\dot{\mathbf{r}} = (1/m)[\mathbf{p} + e\mathbf{A}/c], \tag{5}$$

and substituting for $\dot{\mathbf{r}}$ in Eq. (2) gives

$$\boldsymbol{\mu}_l = -(e/2mc)\,\mathbf{r} \times [\mathbf{p} + e\mathbf{A}/c]. \tag{6}$$

In atomic systems, it is convenient to use the symmetric gauge

$$\mathbf{A} = \tfrac{1}{2}\mathbf{H} \times \mathbf{r}, \tag{7}$$

and substitution of Eq. (7) into Eq. (3) followed by differentiation with respect to H gives, for a field in the z direction,

$$-\frac{\partial \mathcal{H}}{\partial H} = -\frac{e}{2mc}\left[(xp_y - yp_x) + \frac{eH}{2c}(x^2 + y^2)\right]. \tag{8}$$

The right-hand (r.h.) side of Eq. (8) is identical with the z component of $\boldsymbol{\mu}_l$ given by Eq. (6), and this proves Eq. (1) as far as the dependence on the orbital moment is concerned. The second term on the r.h. side of Eq. (8), proportional to H, is the induced diamagnetic moment, which always contributes a positive term to the energy. This term does not contribute to the paramagnetism of localized electrons and it will be neglected here. The first term, independent of H, is proportional to the z component of the orbital angular momentum. For non-s states, it represents a spontaneous, paramagnetic moment that, if the potential V is spherically symmetric, is free to take different orientations in space and hence to lower the magnetic energy.*

1.2 Some Definitions and Units

Before introducing the spin moment, it is convenient to give some definitions and establish a notation. We define the dimensionless angular momentum $\mathbf{l} = \mathbf{r} \times \mathbf{p}/\hbar$, where $\hbar$ is Planck's constant divided by 2π. The eigenvalues of the components l_α are integers ranging from $-l$ to $+l$ where l is the orbital quantum number. In the absence of the diamagnetic term, the orbital moment reduces to

$$\boldsymbol{\mu}_l = -(e\hbar/2mc)\,\mathbf{l}. \tag{9}$$

As $\mathbf{l}$ is dimensionless, it is natural to take as unit of magnetic moment the Bohr magneton $\beta = e\hbar/2mc$, which has the value 0.927×10^{-20} in centimeter-gram-second (cgs) units. The magnetomechanical ratio γ is the algebraic ratio of the magnetic moment to the angular momentum. For orbital motion, Eq. (9) gives the value

$$\gamma_{\text{orb}} = -e/2mc. \tag{10}$$

The magnetomechanical factor g' is defined as the absolute value of the ratio of magnetic moment in units of the Bohr magneton to the angular momentum in units of $\hbar$. For orbital motion, $g'_{\text{orb}} = 1$.

1.3 Spin Moment

The existence of an intrinsic electron spin angular momentum was postulated by Uhlenbeck and Goudsmit (1925) in order to explain the doubling of the optical spectral lines in the alkali atoms. The components of the spin vector $\hbar\mathbf{s}$ obey the angular momentum commutation rules, and in order to give a multiplicity of 2 to the optical spectra, the components of $\mathbf{s}$ must have magnitude $\frac{1}{2}$. To be consistent with the anomalous Zeeman effect (see below), the magnetomechanical ratio of the spin moment must have the value $2\gamma_{\text{orb}}$ with γ_{orb} given by Eq. (10), and hence the magnetomechanical factor of the spin moment must be twice that of the orbital moment, or $g'_s = 2$ (the more precise value, including radiative corrections is $g'_s = 2.0023$). With $g_s \equiv g'_s \cong 2$, the spin magnetic moment becomes $\boldsymbol{\mu}_s = -2\beta\mathbf{s}$ and the interaction of the total magnetic moment with an external field $\mathbf{H}$, called the Zeeman interaction, becomes finally

---

*This clear separation into a paramagnetic, H-independent moment and a diamagnetic moment linear in H is meaningful only when the electron's wave function is localized in space, as it is in atoms and molecules. The wave functions of electrons in energy bands (Bloch functions) extend over the whole volume of the sample, and the coordinates x and y can take on arbitrarily large values. The contributions of the two terms to the energy are then comparable, giving rise to the orbital diamagnetism of Bloch electrons, and it is simpler to deal directly with the complete Hamiltonian [Eq. (3)].

$$\mathcal{H}_Z = -(\boldsymbol{\mu}_l + \boldsymbol{\mu}_s)\cdot \mathbf{H} = \beta(\mathbf{l} + 2\mathbf{s})\cdot \mathbf{H}. \qquad (11)$$

Differentiation with respect to H gives Eq. (1).

1.4 The Moment in a Magnetic Field

In his investigations of the influence of a magnetic field on light propagating through glass, Faraday (1846c) had discovered that the field produces a rotation of the plane of polarization of plane-polarized light (the Faraday effect). Convinced that light and magnetism were related, he set out to find the effect of a magnetic field on the spectrum of a light source but was unable to reach a conclusion (as were other workers who tried in the following 50 years), primarily because the effect is very small and requires sensitive means of detection. Zeeman (1896) succeeded in showing that a magnetic field produces a definite broadening of the spectrum but he was not able to resolve the line splitting into what is now the familiar "Zeeman effect." From the different polarization properties of the center and edges of the broadened spectrum, he concluded that the line was split into three components. This observation was the first indication of the space quantization of angular momentum, even though it was still explainable by Lorentz's classical theory of a harmonically bound electron. Had Zeeman been able to resolve the broadened line, he would have found that it was not split into three (the normal Zeeman effect), but into a larger number of components, and this was no longer explicable by Lorentz's theory. The anomalous Zeeman effect, as this is called, depends in detail on the initial and final states of the emitting atom, and requires for its explanation that the spin moment have a magnetomechanical factor $g_s' \equiv g_s = 2$, and be coupled (by the spin–orbit interaction) to the orbital moment.

The Zeeman splittings determine the magnitude of the induced paramagnetic moment and of the susceptibility. Experimentally, the latter is determined by measuring the force exerted on the induced moment by an inhomogeneous field. In the Gouy method, this is done as follows. The specimen, in the form of a long thin rod of cross section A, is suspended between the vertical pole faces of an electromagnet with the field H at the center of the pole faces pointing horizontally. The specimen is midway between the poles but vertically off the magnet axis so that it is partly in the fringing field region where H has a gradient in the vertical direction x. If H is not too large ($H \lesssim 1$ T), the induced moment is proportional to H and the magnetization, which is the moment per unit volume M, can be written $M = \chi H$ where χ is independent of H. The force df_x exerted on the volume element $dv = Adx$ is

$$df_x = dm\,\frac{dH}{dx}. \qquad (12)$$

where $dm = \chi HAdx$ is the moment induced in the volume element. Substituting for dm and integrating Eq. (12) gives

$$f_x = \tfrac{1}{2}\,\chi A(H_{\max}^2 - H_{\min}^2), \qquad (13)$$

where $H_{\max}$ and $H_{\min}$ are the maximum and minimum values, respectively, of the field inside the specimen. Knowledge of A, $H_{\max}$, and $H_{\min}$ combined with a measurement of f_x determines the susceptibility.

The calculation of the paramagnetic susceptibility of free atoms is described in the next section. Knowledge of atomic paramagnetism provides the basis for analyzing the paramagnetic properties of solids.

2. ATOMIC PARAMAGNETISM

At a temperature T, the states that contribute to the paramagnetism are the ground state and those states that are within a thermal energy kT above it, k being Boltzmann's constant. A brief discussion of the structure of the atomic states is thus in order.

2.1 Atomic States

The electronic wave functions of many-electron atoms cannot be known exactly, and in order to classify and calculate them one makes use of a scheme based on perturbation theory and known as the central-field approximation (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES). This is as follows.

The total atomic Hamiltonian is split into three parts in order of decreasing magnitude,

$$\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 + \mathcal{H}_{so}. \qquad (14)$$

The term $\mathcal{H}_1$, the major part, is the sum over all electrons of the kinetic energy and of a suitably chosen spherical potential. $\mathcal{H}_1$ can be solved exactly in terms of one-electron orbitals (nl) of energy ϵ_{nl} where n and l are the principal and orbital quantum numbers (q.n.) respectively. The electrons are assigned the lowest energy levels in accordance with the Pauli principle, and they successively fill the (nl) shells, which can accommodate $2(2l + 1)$ electrons each. Filled shells have zero orbital and spin momenta and hence zero magnetic moment. Only atoms with partly filled shells are paramagnetic. The set of q.n.s (nl) that specify an eigenstate of $\mathcal{H}_1$ is called a configuration, and for paramagnetism it is sufficient to specify only the number of electrons in open shells. It is customary to use spectroscopic notation for the l values; thus $l = 0, 1, 2, 3, \ldots$ is written $s, p, d, f, \ldots$, etc. For example singly ionized iron, which has six electrons in the $3d$ and one in the $4s$ shells, is written $3d^6 4s^1$. Being the sum of one-electron energies ϵ_{nl} that are independent of "orientation" (i.e., azimuthal q.n.), the energy of a configuration that represents a partially filled shell is highly degenerate.

The effect of $\mathcal{H}_2$, which includes the electron–electron interaction minus an average one-electron potential that is included in $\mathcal{H}_1$, is to remove partially the orientational degeneracy of a configuration, thus splitting the configuration into "terms." Because $\mathcal{H}_2 < \mathcal{H}_1$, the mixing of configurations usually can be neglected. The total orbital ($\mathbf{L} = \Sigma_i \mathbf{l}_i$) and spin ($\mathbf{S} = \Sigma_i \mathbf{s}_i$) angular momenta, summed over all the electrons, commute with $\mathcal{H}_1$ and $\mathcal{H}_2$ and hence can be used to label the term states, each of which is associated with particular L and S values and has degeneracy $(2L + 1)(2S + 1)$. This classification scheme, which is based on the smallness of the spin–orbit interaction $\mathcal{H}_{so}$ [the last member of Eq. (14)], is known as Russell-Saunders coupling. Lastly, when $\mathcal{H}_{so}$ is taken into account, the degeneracy within each term is partially removed: Since $\mathcal{H}_{so}$, as well as $\mathcal{H}_1$ and $\mathcal{H}_2$, commutes with the total angular momentum $\mathbf{J} = \mathbf{L} + \mathbf{S}$, $\mathbf{J}$ is a good q.n. and the main effect of $\mathcal{H}_{so}$ is to split each term into multiplets (LSJ) with J running from $|L - S|$ to $L + S$. Each multiplet still has degeneracy $2J + 1$, and this is ultimately removed by an applied magnetic field that splits the multiplet into $2J + 1$ equidistant Zeeman levels. It is this splitting that causes the anomalous Zeeman effect. Because $\mathcal{H}_{so}$ does not commute with $\mathbf{L}$ or $\mathbf{S}$, the q.n.s L and S are now only approximate, and a multiplet (LSJ) may contain small admixtures of other multiplets ($L'S'J$) with $L' = L \pm 1$ and correspondingly $S' = S \mp 1$.

Multiplets having $J \neq 0$ possess a spontaneous moment while multiplets having $J = 0$ give rise only to an induced paramagnetic moment. The next two subsections describe how the lowest-energy term and the lowest multiplet belonging to that term are found.

2.2 Hund's Rules

Hund noted the empirical fact that the lowest-energy term of a configuration satisfies the following two conditions:

1. It has the largest S; and
2. if several terms have that same S value, it has the largest L among them.

Physically, these rules follow from the repulsive character of the electron–electron interaction: Concerning **1**, the Pauli principle keeps electrons of parallel spins apart from one another and hence lowers their mutual interaction energy. The larger the number of electrons with parallel spins, the larger the energy reduction. And concerning **2**, a large value of L allows the electrons to distribute themselves among a large number of orientations and thus to lower their energy even further.

Once the lowest term of a configuration is identified through Hund's rules, the ground state, which is the lowest multiplet level of that term, is determined by the spin–orbit interaction.

2.3 Spin–Orbit Interaction

An electron moving in an electric field $\mathbf{E}$ sees a magnetic field $\mathbf{H}_{orb} = \mathbf{v} \times \mathbf{E}/c$ proportional to the velocity $\mathbf{v}$. In the spherical potential of the atom, $\mathbf{E}$ is radial; hence $\mathbf{H}_{orb}$ is parallel to the orbital moment and there results a coupling between the spin and orbital moment of each electron i, given by

$$h_{so}(i) = \zeta_{nl} \mathbf{l}_i \cdot \mathbf{s}_i, \qquad (15)$$

where ζ_{nl} is the spin–orbit parameter of the shell (nl) obtained by integration over the square of the radial part of the corresponding wave function. The total spin–orbit interaction is $\mathcal{H}_{so} = \Sigma_i h_{so}(i)$.

By making use of the angular momentum commutation relations, it is shown that $\mathcal{H}_{so}$ commutes with **J** and that as a result of the Wigner–Eckart theorem it is equivalent, within the manifold of states belonging to the term (LS), to the operator

$$\mathcal{H}_{so} \rightarrow \Lambda \mathbf{L} \cdot \mathbf{S}. \tag{16}$$

The constant Λ is given by

$$\Lambda = \pm \zeta_{nl}/2S, \tag{17}$$

where the + and − signs apply respectively to configurations with less than half-filled and more than half-filled shells. In addition to the matrix elements of $\Lambda \mathbf{L} \cdot \mathbf{S}$, $\mathcal{H}_{so}$ has matrix elements between terms that differ in their (L,S) values by $\Delta L = \pm 1$, $\Delta S = \mp 1$, but this will not concern us here as their effect is usually small.

From Eq. (16), the multiplet energies with respect to the unsplit term energy are found to be

$$E_J = \tfrac{1}{2}\Lambda[J(J+1) - L(L+1) - S(S+1)]. \tag{18}$$

The energy difference between neighboring multiplets is thus proportional to the J value of the multiplet with the largest J,

$$\Delta E_J = E_{J+1} - E_J = \Lambda(J + l), \tag{19}$$

a relation that is known as the Landé interval rule.

It follows from Eqs. (17) and (18) that the ground multiplet state of a partly filled shell is $J = |L - S|$ or $J = L + S$ according to whether the shell is respectively less than or more than half-filled. Figure 1 shows the Hund's-rule ground term and the lowest multiplet for the different configurations d^n of a d shell. A similar figure, with maximum values $L = 6$ and $S = \frac{7}{2}$, would represent the $4f^n$ configurations of the rare earths (no confusion should arise between the superscript n and the principal quantum number n).

In the particular case of a shell that is half-filled, the ground state has $L = 0$, $S = J = (2l + 1)/2$, and the magnetic moment is entirely due to the spin with $g = 2$. A shell that is one electron short of being half-filled has a ground state $L = l$, $S = l$, and $J = 0$.

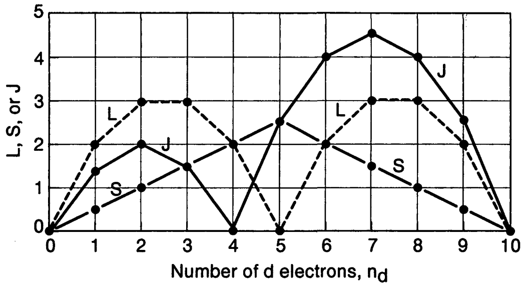

FIG. 1. Values of L, S, and J for the ground state of iron-group ions as the d shell is filled. Because of the change in sign of the spin-orbit constant Λ at $n_d = 5$, the values of J at a given L are higher for $n_d > 5$ than they are for $n_d < 5$. Only the values at integral n_d have physical meaning; the straight lines are a guide to the eye.

2.4 Landé *g* Factor

A magnetic field lifts the $(2J + 1)$-fold degeneracy of the multiplet states $|JJ_z\rangle$. Unlike the operator J_z, the magnetic moment $\beta(L_z + 2S_z)$ is not a constant of the motion, and in free ions it has matrix elements between multiplet states differing by $\Delta J = \pm 1$. However, the Zeeman interaction $\mathcal{H}_Z = \beta(\mathbf{L}_z + 2\mathbf{S}_z) \cdot \mathbf{H}$ is in practice much smaller than the spin–orbit interaction, and these off-diagonal matrix elements are usually unimportant. The Zeeman energies are then given by the expectation values of the magnetic moment over the $|JJ_z\rangle$ states,

$$\mathcal{H}_Z(JJ_z) = \langle JJ_z|\beta \mathbf{H} \cdot (\mathbf{L}_z + 2\mathbf{S}_z)|JJ_z\rangle \equiv g_J \beta H J_z, \tag{20}$$

where g_J is defined as the Landé g factor. The energy separation between consecutive levels is called the Zeeman splitting, equal in free atoms to $g_J \beta H$. The fact that these expectation values are proportional to J_z follows from the Wigner–Eckart theorem, which in systems having spherical symmetry requires the matrix elements of any vector operator (such as μ) over the states $|JJ_z\rangle$ to be proportional to those of the angular momentum itself. The coefficient of proportionality here is g_J.

The physical meaning of g_J can be seen in a semiclassical picture: The orbital and spin momenta, being strongly coupled by $\mathcal{H}_{so}$, precess around one another and around the direction of their resultant **J**. The magnetic moment precesses rapidly around **J** in the same manner, and since its components normal to **J** average to zero, it is only the component of $\boldsymbol{\mu}$ along **J** that couples to an external field. The term g_J is then obtained from the expectation value of this component in the direction of **J**,

$$g_J = \frac{\langle \boldsymbol{\mu} \cdot \mathbf{J} \rangle}{J(J+1)} \frac{1}{\beta}. \tag{21}$$

According to Eq. (21), g_J is the magnetomechanical ratio g' (as defined in Sec. 2.1) for the states of the (LSJ) multiplet. Explicit calculation of $\langle \boldsymbol{\mu} \cdot \mathbf{J} \rangle$ gives

$$g_J = \tfrac{3}{2} + \frac{S(S+1) - L(L+1)}{2J(J+1)}. \tag{22}$$

The proportionality factor in the Zeeman energies, Eq. (20), is traditionally called the spectroscopic splitting factor and denoted by g. From Eq. (20), g too is equal to g_J. The equality $g = g'$ is particular to spherical systems. For ions in solids, it will be seen in Sec. 4.4 that the two are in general different.

2.5 Magnetic Susceptibility

The magnetic susceptibility is defined as the derivative of the magnetization with respect to the applied magnetic field. At sufficiently low fields, the thermal average of the induced moment is linear in the field and the atomic susceptibility is a constant that can be calculated by expanding the energies of the low-lying states, n, to second order in the field. From Eq. (11),

$$E_n(H) = E_n^{(0)} - (\mu_z)_{nn}H + \sum_{n' \neq n} \frac{|(\mu_z)_{n'n}|^2}{E_n^{(0)} - E_{n'}^{(0)}} H^2, \tag{23}$$

where $E_n^{(0)}$ is the unperturbed energy and $\mu_z = -\beta(l_z + 2s_z)$. From Eq. (1) and the definition of the thermodynamic free energy, it follows that the paramagnetic moment is given by the negative of the derivative of the free energy with respect to H. The moments of atoms obey Boltzmann statistics, and hence for an assembly of N atoms per unit volume the magnetization $M(H,T)$ is given by

$$M(H,T) = -N\frac{\partial F(H,T)}{\partial H}, \tag{24}$$

where $F(H,T)$, the free energy per atom, is defined through

$$\exp\left[-\frac{F}{kT}\right] = \sum_n \exp\left[-\frac{E_n H}{kT}\right]. \tag{25}$$

The low-field ($\beta H \ll kT$) susceptibility follows from these relations and is given by

$$\begin{aligned}\chi(T) &= -N\left[\frac{\partial^2 F}{\partial H^2}\right]_{H\to 0} \\ &= N\left[\sum_n \left[\frac{(\mu_z)_{nn}^2}{kT} + 2\sum_{n'} \frac{|(\mu_z)_{n'n}|^2}{E_{n'}^{(0)} - E_n^{(0)}}\right] \cdot \exp\left(-\frac{E_n^{(0)}}{kT}\right)\right]\left[\sum_n \exp\left(-\frac{E_n^{(0)}}{kT}\right)\right]^{-1},\end{aligned} \tag{26}$$

where the states n and n' belong to the low-lying multiplets of the lowest term (LS).

The two terms in the numerator of Eq. (26) have different physical meanings: The first one is the contribution of a spontaneous moment that can orient itself in the external field. It exists only when n belongs to a multiplet having $J \neq 0$. The second one is a temperature-independent contribution of an induced moment known as Van Vleck paramagnetism (Van Vleck, 1932, Ch. 7). At low temperature, this term is important only when the ground multiplet has $J = 0$, but at temperatures comparable to the multiplet splitting* it makes a significant contribution even if $J \neq 0$. This is the reason for the discrepancies between the experimental and theoretical values of the effective magneton number in the cases of samarium and europium noted below (Table 1). In the induced moment, selection rules restrict the difference in the J values of the states n and n' to $\Delta J = \pm 1$.

A detailed account of the temperature variation of $\chi(T)$ is given by Van Vleck (1932, Ch. 9), and may be summarized as follows:

---

*Various units of energy are used in atomic physics, among them the kelvin (K), the wave number (cm^{-1}), and the electron volt (eV), which is equal to 1.6×10^{-19} J. In terms of the other units, 1 eV = 8065 cm^{-1} = 11 600 K.

Table 1. Effective magneton numbers p for trivalent rare-earth ions (near room temperature) [from Kittel (1986), p. 405].

1. At low temperatures, $kT \ll \Delta E_J$ where ΔE_J is the energy separation of the ground multiplet J from the next higher one, only the states of the ground multiplet are populated. Usually $J \neq 0$, in which case the second term of Eq. (26), which reduces to a constant $N\alpha$, is negligible. The matrix elements $(\mu_z)_{nn}$ are equal to $-g_J J_z \beta H$, and summation over J_z gives the well-known Curie susceptibility,

$$\chi = N g_J^2 J(J+1)\beta^2/3kT. \tag{27}$$

The factor $p = g_J\sqrt{J(J+1)}$ is called the effective magneton number and provides a convenient way to tabulate the experimental data. Table I shows the values of p for trivalent rare-earth ($4f$) ions, deduced from room-temperature measurements, and for comparison the Hund's-rule values p(calc.). With the exception of Sm and Eu, the agreement between the two is very good even though the measurements were not made on free ions but on solid hydrated sulfates. As will be seen in Sec. 4.1, the reason for the good agreement is that rare-earth ions are little affected by their environment.

2. The discrepancy for Eu^{3+} arises because the Hund's-rule multiplet has $J = 0$ (the f shell of Eu^{3+} is one electron short of being half-filled). However the next level, $J = 1$, is separated in energy only by $\Delta E_J = 330$ K, which is comparable to room temperature. It turns out that the overall multiplet width is $21\Delta E_J$ and to obtain the susceptibility accurately, the Van Vleck part of Eq. (26) must be summed over all the multiplets. The result, which obviously depends on T, agrees with the measured value of p. The discrepancy in the case of Sm^{3+} has a similar origin: Even though the ground multiplet has $J = 5/2$, higher multiplets must be taken into account. These two cases illustrate the behavior of $\chi(T)$ when T is comparable with ΔE_J.

3. Finally when T is large compared to the overall width of the ground term multiplets, the expression of $\chi(T)$ become simple again. The Van Vleck terms cancel out in Eq. (26) since the Boltzmann factors effectively can be taken equal to unity, and L and S are decoupled and free to assume random orientations with respect to one other. The susceptibility is then the sum of independent orbital and spin contributions,

$$\chi = \frac{N\beta^2}{3kT}[L(L+1) + 4S(S+1)]. \tag{28}$$

2.6 Saturation

When the magnetic field is so large and the temperature so small that the ground-state Zeeman splitting is comparable to the temperature ($g_J\beta H \gtrsim kT$), the low-field expansion is not useful and the free energy must be calculated exactly. Replacing g_J by g in order to lighten the notation, Eq. (25) becomes

$$\exp\left(-\frac{F}{kT}\right) = \sum_{J_z=-J}^{+J} \exp\left(\frac{gJ_z\beta H}{kT}\right) \tag{29}$$

and the magnetization follows as

$$M(H,T) = NgJ\beta B_J(gJ\beta H/kT), \tag{30}$$

where in terms of $x = gJ\beta H/kT$, the function

$$B_J(x) = \frac{2J+1}{2J}\coth\frac{2J+1}{2J}x - \frac{1}{2J}\coth\frac{x}{2J} \tag{31}$$

is the Brillouin function, which approaches unity as $x \to \infty$. Thus, the magnetization saturates when the Zeeman energy is large compared to kT.

The classical limit of the Brillouin function is the Langevin function $L(x) = \coth x - 1/x$, which is obtained by letting the value of J approach infinity while $gJ\beta$ is kept constant and equal to the value of the classical moment μ. For large J, $B_J(x)$ approaches $L(x)$.

Figure 2 shows measurements of the magnetization in the saturation region, $x \gg 1$, for three ions having J values of $\frac{7}{2}$, $\frac{5}{2}$, and $\frac{3}{2}$ respectively. Gd^{3+} and Fe^{3+} have L = 0 in the ground state, and the moment is that of the spin alone, with $g = 2$. The ion Cr^{3+} has the configuration d^3 and as seen in Fig. 1, the free ion has $L = 3$, $S = \frac{3}{2}$, and $J = \frac{3}{2}$, resulting in a g value of $\frac{2}{5}$. However, the orbital moment is quenched in the solid (Sec. 4.1), and the magnetization is due entirely to the spin. The theoretical curve for Cr^{3+} in Fig. 2 is calculated with $g = 2$. Had $g = \frac{2}{5}$ been used instead, the curve would have strongly disagreed with the experimental points, thus providing confirmation of the quenching of the orbital moment.

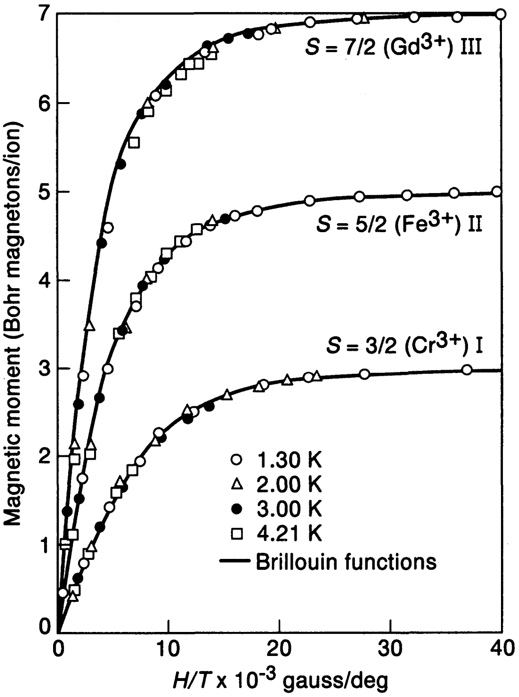

FIG. 2. Plot of magnetic moment vs H/T for (I) potassium chromium alum, (II) iron ammonium alum, and (III) gadolinium sulfate hexahydrate, taken at temperatures T = 1.3, 2.0, 3.0, and 4.21 K. The abscissa is proportional to the argument x of the Brillouin function in Eq. (31). Near-complete saturation is achieved at T = 1.3 K and H = 5 T (after Henry, 1952).

3. PARAMAGNETISM IN SOLIDS

The type of solid that forms when atoms come together depends on the valence electrons. Elements with open s or p shells form either metals, semiconductors (covalent solids), or molecular solids. In the latter two cases, strong bonds form between neighboring atoms, the electron spins pair off, the orbital moments are quenched as described below, and the solid is diamagnetic. Among paramagnetic solids are metals and salts of metallic ions having partially filled shells. The conduction electrons in metals and in doped semiconductors show a weak paramagnetism (Pauli paramagnetism) that is due predominantly to the spin. In addition, they have an orbital diamagnetism with susceptibility χ_L named after Landau (see DIAMAGNETISM) that in the free-electron model only is equal to minus one-third of the Pauli susceptibility. In real metals, χ_L depends on the band structure and the total susceptibility, including the filled-core diamagnetism and the Van Vleck paramagnetism of any partially filled bands, can be either positive or negative. Pauli paramagnetism is discussed in Sec. 5.

Strong, atomiclike paramagnetism occurs in the salts of the elements that have partially filled d shells (of the $3d$, $4d$, and $5d$ series) or f shells (the $4f$ rare earths and the $5f$ actinides). Most intensively studied have been the iron group ($3d$ series) and the $4f$ group, and these are the subject of this section. At high temperatures, the susceptibility obeys a Curie–Weiss law

$$\chi = N\,C/(T - \theta), \tag{32}$$

where the Curie constant C [see Eq. (27)] depends on the value of the effective Bohr magneton of the ion in the solid environment. In the rare-earth ions, according to Table 1, C is given by the full atomic moment, but Table 2 shows that in the ions of the iron group, C is given essentially by the spin-only moment, $2\beta S$: The orbital momentum is quenched (Sec. 4.1). The constant θ accounts for the exchange interactions between moments. In the mean-field approximation, these are represented by a molecular field proportional to the magnetization, $H_{\text{mol}} = \lambda M$, and the value that results for θ is $\theta = \lambda C$.

4. IONIC SOLIDS

The study of paramagnetic ions in solids is of interest because it reveals the changes that they undergo in a crystalline environment. These changes in turn provide information about the electronic state of the whole solid. Aside from its own interest, such a study provides opportunities for designing materials with properties suitable for applications, such as maser or laser materials. The susceptibility is a macroscopic, global quantity, which cannot by itself give much information about these effects. In the decades following World War II, the paramagnetism of solids was extensively studied by electron spin resonance (see ELECTRON PARAMAGNETIC RESONANCE), which measures directly the Zeeman splitting of the paramagnetic ground state. If the ions were free, this would of course be given by the Landé g factor, but in a solid, even the smallest interaction of the ion with the environment is often sufficient to change its Zeeman splittings radically.

The theoretical treatment of these interactions is known as "crystal-field" or "ligand-field" theory, and it is the subject of several excellent books. Discussions of the "spin Hamiltonian" and of the effective spin concept may be found in these. Only a brief account that emphasizes the physics is given here.

The ionic species under investigation is usually at the center of a cage of "ligands," which are negative ions such as F^- or O^{2-} ions belonging to a molecule such as H_2O. The ligands are often at the corners of an octahedron or a cube, and hence the symmetry of the central ion is cubic. Usually a small trigonal or tetragonal distortion is also present. Symmetry is very important in determining the g value in a spin-resonance [electron paramagnetic resonance (EPR)] experiment. The central ion together with the ligands forms a "complex" or complex ion that is a molecular entity that maintains its identity in a water solution. The effect of the charged ligands on the paramagnetic ion is represented by a local electric field (the crystal field) that has the site symmetry of the ion.

The notion of an electric field should not be taken too literally for it serves mostly as a convenient way to parametrize the interaction of the ion with the environment, including for instance the effect of the covalency with the ligands. The crystal-field interaction is written $\mathcal{H}_{\text{cf}}$, and it is added to the Hamiltonian [Eq. (14)]. The manner in and degree to which the states of the free ion are modified depend on the magnitude of $\mathcal{H}_{\text{cf}}$ relative to $\mathcal{H}_2$ and $\mathcal{H}_{\text{so}}$, and three cases can be distinguished: $\mathcal{H}_{\text{so}} > \mathcal{H}_{\text{cf}}$; $\mathcal{H}_2 > \mathcal{H}_{\text{cf}} > \mathcal{H}_{\text{so}}$; and $\mathcal{H}_{\text{cf}} > \mathcal{H}_2$.

Table 2. Effective magneton numbers for iron-group ions [from Kittel (1986), p. 406].

Ion	Configuration	Basic level	$p(\text{calc.}) = g[J(J+1)]^{1/2}$	$p(\text{calc.}) = 2[S(S+1)]^{1/2}$	$p(\text{exp})$[a]

---

[a] Representative values.

1. $\mathcal{H}_{so} > \mathcal{H}_{cf}$ is the weak-field case, which occurs when the ligands have a minimal effect. In the rare-earth ions, the 4*f* shells lie inside the filled 5*s* and 5*p* shells, and as a result the inner 4*f* electrons are kept away from the ligands. As seen in Table 3, $\mathcal{H}_{cf}$ is small, of the order of 100 cm^{-1}, and its effect is limited to splitting the degenerate states of each multiplet and mixing their wave functions according to the local symmetry.
2. $\mathcal{H}_2 > \mathcal{H}_{cf} > \mathcal{H}_{so}$ is the intermediate crystal-field case, which occurs in many salts of the 3*d* group. The spatial extent of the 3*d* orbitals is comparable to that of the 4*f* in the rare earths, but there are no outer 5*s* or 5*p* shells to screen them from the ligands. The ground state is still given by Hund's rule, but the orbital levels are split by the crystal field and the orbital moment is partly or totally quenched. The term *J* is not a quantum number.
3. $\mathcal{H}_{cf} > \mathcal{H}_2$ is the strong crystal-field case, which occurs in some salts of the transition groups. The perturbation by the environment is so strong that the atomic one-electron orbitals (*nl*) have their $(2l + 1)$-fold degeneracy lifted, and the many-electron states must be expressed in terms of these split states. Hund's rule does not necessarily hold, and in fact, in octahedral symmetry the configurations d^4–d^7 do not obey it. Such ions are said to be in the low-spin state, $S = 1$ for d^4, $S = \frac{1}{2}$ for d^5, etc. When the ligands are so close that their wave functions overlap substantially those of the paramagnetic ion, covalent bonding takes place and the magnetic electrons become delocalized into molecular orbitals that are shared with the ligands. The orbital moments and the spin–orbit coupling are then affected through "orbital reduction" factors as the *d* orbitals now constitute only part of the wave function. Covalency strongly enhances the crystal-field splittings, which are as high as 30 000 cm^{-1} in some cyanides.

4.1 Quenching of the Orbital Moment

The $(2L + 1)$-fold degeneracy of the orbital states $|LL_z\rangle$ of a free ion reflects the freedom of the orbital momentum to assume any orientation (classically speaking) in its spherically symmetric environment. In a crystal the internal electric field has lower symmetry and is not radial. The orbit of an electron moving classically in such a field will deviate from being planar and precess in space in some complicated way. The angular momentum will fluctuate in time and either will average to zero or, if the symmetry is high, will have a nonzero average value only for certain orbits. This picture corresponds quantum mechanically to a mixing of the states having different values of L_z. The mixing of states strongly affects the expectation values of the Zeeman energies, and hence of the spectroscopic splitting factor. If the orbital degeneracy is completely lifted, the wave function must be real and the expectation value of the orbital momentum, which is a purely imaginary operator, must vanish. The orbital momentum is then completely quenched. The foregoing discussion has completely ignored the spin–orbit coupling, which must now be taken into account.

The spin–orbit coupling can be viewed as an internal magnetic field generated by the spin moment and acting on the orbital motion. Through the interaction $\zeta \mathbf{s} \cdot \mathbf{l}$, this field is coupled to the orbit of the electron *around* the nucleus, and in this way it opposes the quenching of $\mathbf{l}$. Whether quenching occurs or not depends therefore on the relative magnitudes of $\mathcal{H}_{cf}$ and $\mathcal{H}_{so}$, which are measured by the ratio of the crystal-field splitting Δ of the ground multiplet to the spin–orbit parameter ζ_{4f} or ζ_{3d}.

In the rare-earth ions, Table 3 shows that $\Delta \ll \zeta_{4f}$. The orbital moment is not quenched, but the crystal field mixes the $|JJ_z\rangle$ states of the ground multiplet and splits the multiplet energy. The angular momentum *J* remains as an approximate quantum number for clas-

Table 3. Ranges of the energies that determine the nature of the ground electronic state of a paramagnetic rare-earth (4*f*) ion, or an iron-group (3*d*) ion in a solid environment. E_c is the ground-term splitting, ζ_{nl} is the spin–orbit parameter, and Δ is the ground-state crystal-field splitting.

	E_c (cm^{-1})	ζ_{nl} (cm^{-1})	Δ (cm^{-1})
4*f* ions	$(5–30) \times 10^3$	600–3000	~100
3*d* ions	$(10–40) \times 10^3$	60–800	$(10–30) \times 10^3$

sifying the levels, and the ratio of magnetic to mechanical moment, g', is still given by the Landé g_J factor. However, the spectroscopic splitting factor is no longer equal to g_J but depends on the admixture coefficients of the $|JJ_z\rangle$ states in the crystal-field states. At temperatures T smaller than Δ, the susceptibility deviates from the Curie value both because of the splitting of the states and because of the difference of g from g_J. For T large compared to the overall Δ, the susceptibility should return to the free-ion value with $p = g_J\sqrt{J(J+1)}$ as the effect of the splittings averages out. This is borne out by the experimental results in Table 1, which show that the room-temperature susceptibility of rare-earth ions is not affected by their environment.

The ions of the iron group are usually at the opposite extreme, $\Delta \gg \zeta_{3d}$. The orbital momentum is then quenched and neither J nor g_J retains any validity. There is only a slight deviation of the g factor from $g_s = 2$ that is due to an admixture of orbital moment by the spin–orbit interaction. Table 2 shows that with the exception of Co^{2+}, the measured values of p are close to the spin-only value.

Although affecting the Curie susceptibility only slightly through the deviation of g from 2, the orbital moment contributes now a Van Vleck susceptibility χ_{VV}, which arises from the splitting of the d states by the crystal field and the fact that the orbital moment has matrix elements between the occupied and unoccupied crystal-field states. Being proportional to the product of the number of occupied and number of unoccupied states, χ_{VV} tends to be largest for half-occupied shells. In ionic salts, χ_{VV} is expected to be only a very small fraction of the Curie susceptibility, but in the transition metals the d electrons become delocalized into moderately broad energy bands and the spin susceptibility χ_s is reduced by a factor of order 10^2 compared to the Curie susceptibility (see Sec. 5). The term χ_{VV} becomes then comparable with χ_s. Indirect experimental evidence and an estimate of χ_{VV} came first in Knight-shift and susceptibility measurements in the intermetallics V_3Ga and V_3Si. More direct evidence was obtained later by a measurement of the g' factor in the transition metals themselves (see Sec. 4.4).

4.2 Kramers's Theorem

There is a limit to the removal of degeneracies by a crystalline field. A free ion has degeneracy $2J + 1$, which is even if the number of electrons is odd and, vice-versa, odd if the number of electrons is even. The ion may be a complex ion. Kramers's theorem states that in the presence of an arbitrary electric field and in zero magnetic field, all states of a system having an *odd* number of electrons must still have even degeneracy. The theorem is a consequence of the time-reversal invariance of the Hamiltonian including the spin–orbit interaction. The theorem is proved by showing that when the number of electrons is odd, the operation of time reversal applied to an eigenstate produces another eigenstate, which is orthogonal to the first and hence must be independent of it. The number of states that are degenerate with each other must therefore be even.

Ions with an *even* number of electrons, by contrast, may have their *spin* degeneracy lifted by an electric field of low symmetry. This occurs for instance in the eight-electron Ni^{2+} ion, which has an orbitally nondegenerate ground state with a spin of 1. The threefold spin degeneracy is completely lifted by a rhombic crystalline field acting in conjunction with the spin-orbit coupling (Griffiths and Owen, 1952).

In solids, the ground states of $3d$ and $4f$ ions with an odd number of electrons are usually Kramers doublets.

4.3 Jahn–Teller Effect

In the previous parts of this section, it has been tacitly assumed that paramagnetic ions situated at sites of high symmetry may have a ground state that is orbitally degenerate. By contrast, if the site is without any symmetry, then barring accidental degeneracy, all the states must be orbitally nondegenerate. Jahn and Teller (1937) asked the question, is the stability of a high-symmetry environment compatible with an orbitally degenerate electronic ground state? The Jahn–Teller (J–T) theorem states that excepting the case when the paramagnetic ion is part of a linear molecule (which does not concern us here), stability and orbital degeneracy are not compatible. When the spin is included, the theorem holds for the degeneracy including spin, except for the Kramers degeneracy, which cannot be removed by purely electrical forces. We shall not consider the spin any further here except to say that sometimes the spin–orbit coupling may stabilize the symmetric configuration. A simple system where the J–T theorem applies is illustrated in the following example, taken from their paper.

A planar molecule consists of a *diamagnetic* ion A located at point P and surrounded by four identical ligands B_1, B_2, B_3, B_4 situated symmetrically at a distance a [configuration C_0 in Fig. 3(a)]. This configuration is stable. Ion A is now replaced by ion M, which in the symmetric configuration has an orbitally degenerate ground state: For instance, M has one p electron outside of closed shells, and the orbitals p_x and p_y with wave functions proportional to x and y, respectively, are degenerate as a result of the fourfold local symmetry. The J–T theorem asserts that the configuration C_0 is now unstable with respect to the distortions C_1 and C_2 of Fig. 3(b). The physical reason for the instability is simply that the two degenerate states point in mutually orthogonal directions and a distortion of the symmetric configuration such as C_1 or C_2 will lower the energy of one of the states while raising that of the other, as shown in Fig. 3(c). An elementary calculation that assigns one electron charge, $-e$, to the ligands shows that if ions B_1 and B_3 are moved outward by a distance d while B_2 and B_4 are moved inward by the same distance (configuration C_1), the additional potential seen by an electron situated at the point (x,y,z) with respect to P is, in first order in d.

$$\Delta V(x,y) = -\tfrac{9}{2}(e^2/a^4)(x^2 - y^2)d. \tag{33}$$

Averaging Eq. (33) over the wave functions of p_x and p_y shows that the energy of p_x is lowered by

$$\Delta E(p_x) = -Vd \tag{34}$$

where the quantity V is positive, while the energy of p_y is raised by the same amount. The important fact is that Eq. (34) is linear in the nuclear displacement d. A nuclear configuration cannot be stable if the electronic energy of a neighboring configuration depends linearly on the nuclear displacement since the elastic energy $U = \frac{1}{2}Kd^2$, which provides the restoring force for displacements away from a position of stable equilibrium, is quadratic in the displacement. Minimizing the sum of the energy shift [Eq. (34)] and U, and setting $K = M\omega^2$ where M is the nuclear mass and ω the vibration frequency, the equilibrium value of d is found to be $d_{\text{eq}} = V/M\omega^2$, and the net lowering of the energy, or stabilization energy, is obtained as the negative of

$$E_{\text{J-T}} = V^2/2M\omega^2. \tag{35}$$

Note that the J–T theorem does not say how the system (the molecule) will respond to the instability, but only that the symmetric configuration is unstable. The simplest answer that comes to mind is that the nuclear configuration will distort in the manner suggested above until d assumes the value d_{eq} and the energy is lowered to its minimum, $-E_{\text{J-T}}$. Such a response of the system is called the "static J–T effect" as it assumes implicitly that the nuclei have infinite mass: Once at their position of minimum energy, they stay there forever. The consequence of such a response in an ionic solid would be the removal of all orbital degeneracies, and the

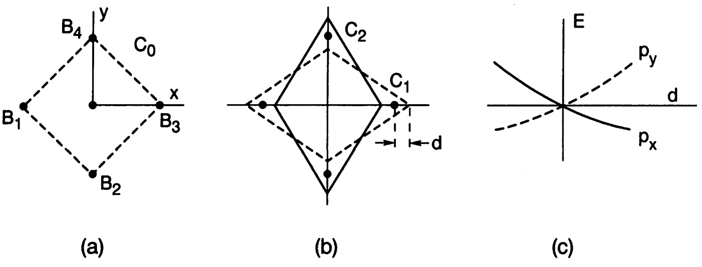

FIG. 3. The Jahn–Teller effect of a *p*-state ion in a symmetric planar molecule: (a) In the undistorted configuration C_0, the ion has fourfold symmetry and the states p_x and p_y are degenerate. The configuration C_0 is unstable against distortion. (b) Two equivalent distortions, C_1 and C_2. The symmetry of the central ion is lowered and the degeneracy is removed. (c) For small distortions, the splitting of the energies is linear in the amplitude *d* of the distortion.

lowering of the site symmetry should be observable as an anisotropic line (or g value) in an EPR experiment. In fact, the first observation of the J–T effect in a solid, made by EPR at room temperature (Bleaney and Ingram, 1950), showed a g value that was isotropic and different from $g_s = 2$.

The experiment was done on the d^9, Cu^{2+} ion at the center of an octahedral complex where, in the absence of any distortion, it would have had the twofold orbitally degenerate Γ_3 level as its ground state. A distorted octahedron, elongated along one of the [100] cubic axes, should have shown a resonance characteristic of tetragonal symmetry with $g_{\parallel} \neq g_{\perp}$. The observed isotropic g value was inconsistent with this, but it was also inconsistent with an undistorted configuration that, because of the twofold degeneracy, should have shown two resonance lines, split by the spin–orbit interaction, and having cubic but not spherical symmetry with $g_{111} \neq g_{100}$. The observed spectrum was explained by Abragam and Pryce (1950) as a manifestation of the "dynamic J–T effect," this terminology having been introduced later. The labeling of the effect as "dynamic" here means that because of their finite mass, the nuclei are able to move over an energy barrier from one distorted configuration to another under the action of the thermal vibrations of the surrounding lattice. At room temperature, these thermal excitations are sufficient to cause the activated transitions to occur at a rate that is large compared to the resonance frequency, and the three resonance lines that would have resulted from tetragonal distortions along any one of the three equivalent [100] cubic axes are motionally narrowed to a single isotropic line. Two years later (Bleaney and Bowers, 1952), the same system at 20 K showed in fact the three anisotropic lines of the "static J–T effect," indicating that at 20 K the transition rate between configurations was smaller than the EPR frequency. The same kind of distortion may thus appear as dynamic or static depending on the time resolution of the measuring apparatus as compared with the transition rate of the distortion between the different configurations.

The condition for the static J–T effect to occur is that the stabilization energy be large compared to the zero-point energy of the nuclei, $E_{J-T} \gg \hbar\omega$. This is referred to as the "strong J–T" condition. When this is not the case and $E_{J-T} \leq \hbar\omega$ ("weak J–T effect"), it is necessary to include the kinetic energy of the nuclear vibrations from the start in solving the problem, i.e., to consider the coupled electronic-vibrational system as a single dynamical system. The Hamiltonian of this system is called the vibronic Hamiltonian, and its states the vibronic states. The full dynamical nature of the J–T effect becomes apparent in the properties of these vibronic states.

It is clear that the vibronic Hamiltonian, inclusive of the J–T coupling, is invariant under the symmetry operations of the undistorted complex since these operations merely replace one distorted configuration by another. This can be seen in Fig. 3(b), where a rotation of a distorted configuration, accompanied by a rotation of the two electronic states, leaves things unchanged. It follows from this invariance that the J–T coupling *cannot lift* a degeneracy that is due to high symmetry, but only *replace* a purely electronic degeneracy by a vibronic degeneracy of the same character, i.e., the vibronic and the original electronic states must transform in the same way under the symmetry operations of the undistorted system. Physically, the electronic states and the nuclear vibrations have become strongly correlated.

Having the same twofold Γ_3 degeneracy as the unperturbed electronic states, the vibronic states should show an EPR spectrum having the same features as those of the electronic doublet described above. Such a spectrum was observed at very low temperatures, independently by Coffman (1965) and by Höchli and Estle (1967), on systems similar to those investigated by Bleaney and Ingram but having a weaker J–T coupling, $E_{J-T} \leq \hbar\omega$. Two anisotropic lines with $g_{111} \neq g_{100}$, characteristic of a Γ_3 level, were observed, but the anisotropy was smaller than that predicted by the known value of the spin–orbit constant. This difference was experimental proof of the presence of a vibronic doublet because such orbital reduction factors are predicted as a consequence of the smaller than unity overlap between the vibrational states associated with different electronic states. From the degree of the reduction, an estimate of the Jahn–Teller coupling could be obtained.

In principle, the static susceptibility should be affected too since the orbital reduction factors cause a change in the g values.

The experimental manifestations of the

dynamic J–T effect are diverse and fascinating. The interested reader (see Further Reading) may consult an excellent account by Sturge that includes physical discussions of the theory and the experimental results. More formal theoretical treatments can be found in the treatise by Abragam and Bleaney and in the review article of a key contributor to the theory, F. Ham. This section owes much to these sources.

4.4 *g* and *g′*

The magnetomechanical ratio in the z direction of a paramagnetic ion in a solid is defined as the ratio of the expectation values:

$$g' = -\frac{\langle \mu_z \rangle/\beta}{\langle J_z \rangle/\hbar}, \tag{36}$$

where μ_z and J_z are the z components of the magnetic moment and angular momentum, respectively. The negative sign reflects the sign of the electron charge so that g' as defined by Eq. (36) is positive. The spectroscopic splitting factor is a measure of the Zeeman splitting in a spin-resonance experiment, and for an effective spin of $\frac{1}{2}$ is defined by

$$g\beta H = \hbar\omega, \tag{37}$$

where ω is positive. For a free spin, $g = g_s = 2.0023$. The sign of g, which can be positive or negative, reflects the sense of precession of the moment around **H** in the solid (Blume *et al.*, 1969).

Early measurements of g and g' in the ferromagnetic 3*d* metals showed that they are not the same. Although both were found to have values close to $g_s = 2$, thus reflecting strong orbital quenching, they differed from 2 in opposite directions with $g > 2$ and $g' < 2$ (Kittel, 1949). The measured g values were close to those deduced from magnetic susceptibility measurements on the salts of the metals.

The first measurement of g' in a paramagnetic salt was made by Sucksmith (1930) on Dy_2O_3. Within experimental error, the result was $g' = g_j = \frac{4}{3}$, implying negligible orbital quenching in agreement with our remarks in Sec. 4.1.

The fact that $g \neq g'$ shows that the torque equation

$$\frac{d\langle \mathbf{J} \rangle}{dt} = \langle \boldsymbol{\mu} \rangle \times \boldsymbol{H} \tag{38}$$

does not hold in solids because it would imply $g = g'$. Thus from Eq. (38), $d\langle \mathbf{J} \rangle/dt$ is proportional to $\omega\langle \mathbf{J} \rangle$ and hence to $g\langle \mathbf{J} \rangle$, while $\langle \boldsymbol{\mu} \rangle$, from Eq. (36) is proportional to $g'\langle \mathbf{J} \rangle$.

The reason Eq. (38) does not hold is that through the interaction with the crystalline field, an exchange of angular momentum between the lattice and the moment is taking place as the latter precesses around the magnetic field (in the case of strong orbital quenching, this exchange is mediated by the spin–orbit interaction). Hence, part of the torque $\langle \boldsymbol{\mu} \rangle \times \mathbf{H}$ that is transferred by the microwave field to the angular momentum of the electron escapes into the lattice (or alternatively an additional torque is exerted by the lattice), and Eq. (38) does not hold. The situation is very similar (Kittel, 1949) to that of an electron in a lattice that is acted on by an external electric field: In free space, an electron of mass m acted on by a force **F** has an acceleration $\langle \dot{\mathbf{v}} \rangle = \mathbf{F}/m$, while in a crystal lattice, as a result of momentum transfer between the electron and the lattice, the acceleration is given by $\langle \dot{\mathbf{v}} \rangle = \mathbf{F}/m^*$, where m^* is the effective mass, here assumed isotropic. In this analogy, the g factor corresponds to m^* and g' corresponds to m.

From Eqs. (36) and (37), g' and g can be expressed as

$$g' = \frac{\langle L_z \rangle + 2\langle S_z \rangle}{\langle L_z \rangle + \langle S_z \rangle}, \tag{39}$$

$$g = \frac{\langle L_z \rangle + 2\langle S_z \rangle}{1/2}, \tag{39'}$$

where $\langle L_z \rangle$ and $\langle S_z \rangle$ are in units of $\hbar$.

In the case of 3*d* ions, strong orbital quenching gives $\langle S_z \rangle = \frac{1}{2}$ and $\langle L_z \rangle \ll \langle S_z \rangle$. Both g and g' are then close to 2, and Eqs. (39) and (39′) show that they satisfy the relation

$$g' = g/(g-1). \tag{40}$$

This is the Kittel–Van Vleck relation, and it is in fair agreement with experiment. Equation (40) has been generalized by Blume *et al.*

(1969) to cases where the g factor can be large and of either sign as for instance in the cases of some rare-earth ions and of the current carriers in semiconductors with very small band gaps.

As mentioned in Sec. 4.1, the 3*d* metals are expected to have a Van Vleck orbital susceptibility χ_{VV} (for which $g' = 1$) that is of the same order of magnitude as the spin susceptibility χ_s for which $g' = 2$. The actual value of g' can be measured in a gyromagnetic experiment and the relative magnitudes of χ_{VV} and χ_s can thereby be inferred. Such experiments, which are very delicate in paramagnetic metals as a result of the smallness of the χ's, were performed by Hughenin *et al.* (1971) on several transition metals. In V and Cr, the measured g' is close to 1.2, indicating the dominance of the Van Vleck term in these metals, while in Pd and Pt, which are at the end of the 4*d* and 5*d* series, the values of g' are about 1.7. The spin susceptibility is strongly exchange-enhanced in Pd and Pt and χ_{VV} is smaller than in V or Cr because the *d* shells are nearly full. As a result, the spin susceptibility is dominant.

5. CONDUCTION-ELECTRON PARAMAGNETISM

In metallic crystals, the valence states of neighboring atoms overlap strongly and the wave functions become delocalized. Ignoring at first the difficult problem of exchange and correlation, the delocalized, or conduction, electrons are assumed to move independently in an average potential that has the periodicity of the lattice. The valence states are broadened into energy bands of "Bloch states" $\Psi_{\mathbf{k}}$, which are modulated plane waves that depend on the wave vector $\mathbf{k}$, and the conduction electrons occupy these states subject to the Pauli principle that allows a maximum of two electrons of opposite spins to occupy each Bloch state. At $T = 0$, these are filled up to a maximum energy E_{F}, the Fermi energy, which ranges in different metals from about 3 to 15 eV, a value considerably larger than the room-temperature energy of $kT = 0.025$ eV. (No confusion between Boltzmann's constant k and $\mathbf{k}$ should arise.)

5.1 Pauli Susceptibility

One of the early successes of the theory of metals was the explanation by Pauli (1927) of their temperature-independent paramagnetism. The Langevin theory predicts a susceptibility $\mu^2/3kT$ per atom, which at the typical atomic densities of metals results in a volume susceptibility at room temperature of order 10^{-3}–10^{-4}. Instead, the observed susceptibilities were temperature independent and of order 10^{-6}. The explanation, well known now, is that the Pauli principle prevents the electrons that are well below the Fermi surface from reorienting their spin. Only those electrons having energies within a range kT of the Fermi surface are free to do so, contributing each a susceptibility $\mu^2/3kT$. For N conduction electrons per unit volume, the paramagnetic susceptibility becomes

$$\chi_{\mathrm{P}}^{(0)} \sim N\frac{kT}{E_{\mathrm{F}}}\frac{\mu^2}{3kT} \sim N\frac{\mu^2}{3E_{\mathrm{F}}}. \tag{41}$$

This is independent of T and smaller than the Curie value by a factor 10^2, as experimentally observed. For a free-electron gas, the actual calculated value is $\chi_{\mathrm{P}}^{(0)} = 3N\beta^2/2E_{\mathrm{F}}$, and for a general band structure having a density of states of one spin direction $n(E)$ per unit volume and unit energy range, the calculated value at zero temperature is

$$\chi_{\mathrm{P}}^{(0)} = \tfrac{1}{2}g^2\beta^2 n(E_{\mathrm{F}}), \tag{42}$$

where $g = 2$ for a free spin and $n(E)$ is evaluated at the Fermi energy. The orbital moment contributes to the Pauli susceptibility only through the spin–orbit coupling $\mathcal{H}_{\mathrm{so}}$. With the exception of points in $\mathbf{k}$ space at which Bloch states may be degenerate, the expectation value of $\mathcal{H}_{\mathrm{so}}$ over a Bloch state vanishes, and only admixtures of states from other bands by $\mathcal{H}_{\mathrm{so}}$ may give an orbital contribution to the g factor. These are usually small and shift the g value by a quantity Δg that ranges from 10^{-3} in Na to 0.2 in the heavy metals (Yafet, 1963). The reason for the smallness is that the interband energies at constant $\mathbf{k}$ are usually large compared to $\mathcal{H}_{\mathrm{so}}$. The g values at the Fermi surface, $g_{\mathbf{k}}$, depend on $\mathbf{k}$, but in a spin-resonance experiment the EPR line is narrowed by motional and exchange averaging to a width that is below the inhomogeneous width associated with the distribution of g values.

When one goes beyond the independent-electron approximation and includes the Coulomb interactions, the susceptibility can be calculated only approximately. Just as exchange interactions in free atoms are responsible for Hund's rule of maximum spin, here exchange interactions (somewhat tempered by correlations) between the conduction electrons tend to maximize the total number of electron pairs with parallel spins when a magnetic field is present. As a result, the susceptibility is enhanced over the noninteracting value $\chi_P^{(0)}$, and in the simplest approximation, the interacting susceptibility χ_P is given by

$$\chi_P = \chi_P^{(0)}/(1 - \nu). \tag{43}$$

The constant ν is the product of an effective exchange energy per electron and the density of states at the Fermi level normalized to one electron. If ν reaches the value 1, the system becomes ferromagnetically unstable. Paramagnetic metals have $\nu < 1$.

Since $\chi_P^{(0)}$ can be obtained from the calculated band structure, it is of interest to measure χ_P directly in order to compare the actual enhancement factor with the theoretical one.

5.2 Measurement of χ_P

The contribution of χ_P to the total χ was isolated by Schumacher and Slichter (1956) through the use of magnetic resonance. The spin paramagnetism χ_P is related to the area under the resonance absorption signal plotted as a function of the frequency. Precise measurements of the absolute value of such areas are very difficult to make. The problem was circumvented by observing the resonances of both electrons and nuclei on the same sample, changing only the magnetic field and leaving the frequency and all other parameters unchanged. The ratio of the areas under the two absorption curves, which involves only a relative measurement that can be done accurately, gives the ratio between the electron and the nuclear susceptibilities, and since the latter is simply the nuclear Curie susceptibility, χ_P may be deduced.

5.3 Localized Moments and Kondo Effect

When dissolved in nonmagnetic metals (Cu, Zn, Au), many elements of the 3*d* transition series show a Curie susceptibility, which indicates that they have a free localized moment. This is not totally unexpected as Hund's rule indicates that if the *d* electrons remain on the atom (as they must in order to keep it neutral) then they might well possess a moment. Friedel (1958) and Anderson (1961) developed the idea of the virtual bound state according to which the *d* electrons can transfer back and forth between the localized state and the conduction states of the host metal. This transfer broadens the localized level, and the higher the rate at which it occurs (which depends on the density of states), the larger the broadening. If the level becomes too broad, the two spin directions become equally populated in order to minimize the total band energy and the impurity atom becomes nonmagnetic. If the level remains fairly narrow, then Hund's rule wins, the energy of the unoccupied spin state rises above the Fermi level, and the impurity atom acquires a local moment.

The moment is coupled by exchange to the conduction electrons, and the exchange integral can be shown to be negative, which favors an antiparallel arrangement of the local spin with respect to the spins of the conduction electrons. Anomalous low-temperature behavior in the resistivity of normal metals with small amounts of magnetic impurities, and its interpretation by Kondo, led to the discovery that this exchange coupling causes the formation of a collective (with the conduction electrons) bound state that is a spin singlet. This Kondo state, as it is known, is at an energy below the Fermi level so that at zero temperature it is fully occupied. Being a singlet, it possesses no magnetic moment, and thus the local moment is compensated collectively by the spin moments of the conduction electrons. The binding energy depends exponentially on the reciprocal of the exchange integral and may thus vary over a broad range. The magnetic susceptibility of the impurity ion, which is Curie-type, $\chi = C/T$ at high temperature, saturates to a constant value $\chi = C/T_K$ as T approaches zero. The term T_K is a measure of the singlet binding energy.

5.4 Nonlocal Susceptibility and RKKY Interaction

It might be expected that if it were possible to apply a local magnetic field extending only within the space occupied by one atom in a metal, the polarization of the conduction electrons would extend up to some distance away because of the delocalized nature of their orbitals. Such a magnetic field is effectively realized by the exchange coupling between a local moment and the conduction electrons. The response of the electron gas to such a field is conveniently analyzed in terms of the wave-vector–dependent susceptibility: The local field is decomposed into Fourier components $H_{\mathbf{q}} \exp(i\mathbf{q}\cdot\mathbf{r})$. Each $H_{\mathbf{q}}$ induces a magnetic-moment density of the same wave vector, proportional to $M_{\mathbf{q}}^{(0)} = \chi_q^{(0)}$ where for convenience the noninteracting susceptibility is used. The dependence of $\chi_q^{(0)}$ on $\mathbf{q}$ is primarily determined by the shape of the Fermi surface. At wave vectors $\mathbf{q} = \mathbf{q}_c$ that span *locally parallel* areas of the Fermi surface (FS), $\chi_{q_c}^{(0)}$ has singularities that depend in detail on the local shape of the FS (Roth, 1966).

These singularities determine the dependence of the magnetization $\mathbf{M}(\mathbf{r})$ at large distances r. It is found that

1. $\mathbf{M}(\mathbf{r})$ is oscillatory in space, with a wave vector related to the spanning vector appropriate to the direction of $\mathbf{r}$; and
2. the amplitude of the oscillations decreases with distance as $1/r^3$ provided the FS has no unusual features at the spanning points.

For a gas of free electrons, the FS is a sphere and the oscillations are isotropic with a wave vector that is twice the Fermi wave vector, $2k_F$ (Ruderman and Kittel, 1954).

The long-range polarization $\mathbf{M}(\mathbf{r})$ causes an exchange interaction to occur between any two localized spin moments, such as those of the nuclear spins of the constituent atoms, or those of any localized electronic moments. This interaction is named the Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction. It is responsible for the magnetic helical orderings of the core $4f$ moments in the heavy rare-earth metals (see Further Reading).

5.5 Spin-Density Waves

The interacting wave-vector–dependent susceptibilities have an enhancement factor similar to that of the Pauli susceptibility in Eq. (43), i.e.,

$$\chi_q = \chi_{\mathbf{q}}^{(0)}/(1 - \Omega v_c \chi_{\mathbf{q}}^{(0)}). \tag{44}$$

If it should happen that the denominator vanishes at some $\mathbf{q}_n$, then χ_{q_n} diverges, which means that the electron gas acquires a spontaneous long-range magnetization having spatial dependence $\exp(i\mathbf{q}_n\cdot\mathbf{r})$ as the spins order themselves in an antiferromagnetic helix. Such a configuration occurs as the ground state in metallic Cr below the Néel temperature $T_N = 311$ K (see Further Reading).

5.6 Large *g* Factors in Semiconductors

In the semiconductor InSb, the energy gap between conduction and valence band occurs at the center of the zone, $\mathbf{k} = 0$, and the magnitude of the gap is small compared to the spin–orbit splitting of the valence band. The magnitude of the g factor of the electrons at the bottom of the conduction band was predicted (Roth *et al.*, 1959) to be very large, $g \approx -50$, even though the wave function at this value of $\mathbf{k}$ is practically of pure s atomic character. Such large g factors were shown by Herring (1963) to arise from interatomic orbital currents circulating over large numbers of atomic sites by virtue of the smallness of the effective mass. Even larger g factors have been observed in the semimetal Bi.

6. APPLICATIONS

6.1 Magnetic Cooling

An early application of paramagnetism was the attainment of very low temperatures by the method of adiabatic demagnetization, proposed independently by Debye (1926) and Giauque (1927). This method makes use of the fact that a paramagnetic salt at a low temperature T has only two kinds of degrees of freedom, namely those of the vibrational motion of the nuclei that constitute the lattice, and those of the orientational dependence of the electronic magnetic moments of the ions (the nuclear moments are left out here). In the absence of a magnetic field, the entropy of the disordered, noninteracting moments is very large as each moment contributes its full orientational entropy $k \ln(2J + 1)$. A magnetic field H such that $g\beta H/kT \gg 1$ lowers this entropy dramatically as the moments become oriented. By contrast, the entropy of the lattice is very small at small T, only of order $k(T/\Theta)^3$ per degree of freedom, where the Debye temperature Θ is of order 400 K. The principle of the method is as follows. Starting from an initial $T_i \sim 1$ K that is reached by pumping on liquid He, the salt is magnetized isothermally so that its temperature remains at T_i. The initial field H_i is of order 1–5 T. The thermal contact with the outside is then broken, and the magnetic field is adiabatically and reversibly reduced to a very low value, $H_f \sim 10^{-3}H_i$.

From Eq. (29), the free energy and hence the entropy of the magnetic moment (or "spin") system depends only on the ratio $g\beta H/k_BT$. Hence, at constant entropy, the final temperature of the spin system is $T_f^{(s)} = (H_f/H_i)T_i^{(s)}$. The final temperature of the salt is attained after the lattice comes into thermal equilibrium with the spins by transfer of entropy between them. But since the entropy of the lattice is so much smaller than that of the spins, this transfer is negligible and the final temperature is simply $T_f \approx (H_f/H_i)T_i$. The limit of attainable values of T_f is determined by the temperature T_c at which the weak interactions (dipolar and exchange) between the spins lead to the formation of a cooperative magnetic state. Hence the choice of a suitable salt is guided by a compromise between minimizing these interactions and maintaining a sufficient density of magnetic ions. This is done by choosing suitable hydrated salts, and temperatures of order 10^{-3} K are thus reached. Lower temperatures, of order 10^{-6} K, are obtained by demagnetizing the nuclei of Cu.

6.2 The Maser

The maser (acronym for Microwave Amplification by Stimulated Emission of Radiation) is basically a microwave amplifier with a very low noise figure. It can be implemented by different physical systems, among them a paramagnetic salt having three low-lying spin levels A, B, C in order of increasing energy (Bloembergen, 1956). With the frequency differences denoted by ω_{AB}, ω_{BC}, and ω_{AC}, a microwave field of frequency ω_{AC} (the "pump" frequency) is used to induce transitions A → C, thereby equalizing the populations of these two levels. The signal that one wishes to amplify has frequency ω_{BC}. Application of this signal to the device induces a net rate of transitions C → B as long as the population of level C is kept higher than that of level B by the pump. The emitted radiation is in phase with and proportional to the amplitude of the applied signal, and hence the device acts as an amplifier. If the material is chosen such that the relaxation rates between the levels are favorable, the device can also operate as an oscillator. The noise figure is low because the maser must of necessity operate at a low temperature. The maser is thus particularly useful for amplifying weak signals that come from outer space and have themselves a low noise figure.

6.3 Tunable Spin-Flip Raman Laser

An infrared laser in the frequency range just below the energy gap ($E_G = 0.23$ eV) that separates the conduction and valence bands in the semiconductor InSb has been realized by inducing electronic Raman transitions in the conduction band (Patel and Shaw, 1971). A large magnetic field is used to quantize the valence- and conduction-band states into sharp Landau levels, and transitions between the two spin states of the lowest Landau level in the conduction band are induced by scattering incident light at a frequency ω_0 slightly below the gap energy.

The scattering cross section for spin reversal is large for two reasons:

1. The spin–orbit coupling is large compared to the band gap, which results in the Raman matrix element for spin reversal being of the same order as or larger than the matrix element for orbital transitions, which is proportional to the magnetic field (Yafet, 1966); and
2. the photon energy $h\omega_0$ is chosen to be nearly in resonance with the gap energy, which enhances the cross section further.

The laser operates at the frequency of the scattered light, $\omega_1 = \omega_0 - |g|\beta H/\hbar$, and since $|g|$ is of the order of 50, the frequency ω_1 can be tuned in a limited range by varying H. This flexibility allows the laser to be used as an analytical tool.

7. SUMMARY

A material is paramagnetic if it contains magnetic moments that are free to orient in an external magnetic field. Electron paramagnetism has been an invaluable probe, mainly through the use of paramagnetic resonance, for exploring the magnetic and electronic structure of solids. By this method, detailed studies of the low-lying states of paramagnetic ions in solids and of the relaxation processes of the magnetic energy have been made; subtle phenomena such as the Jahn–Teller effect have been elucidated.

The thermodynamic properties of spin systems are special in that the total number of states, and hence the entropy, are finite. In addition, the entropy can easily be manipulated by an external magnetic field. This flexibility has been used to reach very low temperatures, and also to achieve very high temperatures (or population inversion) by selective absorption of radiation. Spin systems are even used as model systems in the teaching of thermodynamics.

8. ACKNOWLEDGMENTS

The author is indebted to Prof. Sir Roger Elliott for making available his unpublished lecture notes on magnetism, and to Prof. Michael Sturge for a critical reading of the manuscript.

GLOSSARY

Boltzmann Factor: The population factor of a state in an ensemble that represents thermal equilibrium.

Complex: A compound ion that consists of a central metal ion surrounded by a cage of ligands and is sufficiently stable to retain its identity in a water solution.

Crystal Field: Electric field set up by the ligands that reflects the symmetry of the complex.

Debye Temperature: The temperature above which all acoustic modes of the lattice vibrations are appreciably excited and below which modes begin to freeze out.

Effective Mass: The apparent inertial mass, m^*, of conduction electrons in metals and semiconductors. Under the effect of an external force F, the acceleration of a wave packet in a spherical band is $\dot{v} = F/m^*$.

Effective Spin: If a paramagnetic ion in a solid has a level with degeneracy $2S' + 1$, the effective spin of that level is S'. The effective spin is defined in a more general way in the spin-Hamiltonian formalism.

Energy Band: A set of itinerant one-electron states in metals or semiconductors whose energies vary continuously within an energy range as the wave vector of the states ranges over the reduced Brillouin zone.

EPR: Electron paramagnetic resonance.

Fermi Surface: The surface of constant energy in $\mathbf{k}$ space that corresponds to the Fermi energy.

***g* Factor:** The proportionality coefficient that measures the splitting of a degenerate level by a magnetic field. In free atoms, g is equal to the Landé g factor.

Knight Shift: The shift of the nuclear resonance frequency in a metal, produced by the polarization of the conduction electrons in the applied magnetic field.

Ligand: A molecule or ion attached to the central ion of a complex (or complex ion).

Line of Force: A line formed by connecting neighboring points in space that are situated along the direction of the local magnetic field with respect to one another.

Magnetic Susceptibility: A measure of the response of a substance to an applied magnetic field. More precisely, the derivative of the magnetization with respect to the applied field.

Magnetization: The magnetic moment per unit volume of a piece of matter.

Paramagnet: A substance that contains elementary magnetic moments that tend to orient themselves along an applied field but that do not exhibit a macroscopic moment or any kind of magnetic ordering in the absence of a field.

Polarization of Light: The specification of the direction of the electric field of a light wave. In plane-polarized light, this direction stays the same at all points of space, at all times, while in circularly polarized light the direction of the field at each point in space rotates uniformly with time.

Van Vleck Susceptibility: The paramagnetic susceptibility that arises from off-diagonal matrix elements of the orbital magnetic moment.

Vibronic State: In a system that undergoes the Jahn–Teller effect, a state in which the electronic state of the paramagnetic ion and the state of the surrounding nuclei are strongly coupled. The total wave function is no longer a simple product of an electronic function and a function of the nuclear displacements, but a sum of such products.

Zeeman Energy: The energy of a spontaneous magnetic moment in a magnetic field.

Zeeman Splitting: The energy splitting of a multiplet level or of any degeneracy connected with the existence of a spontaneous moment by an external magnetic field.

19.1
Introduction

19.1.1
Brief History

The first particle accelerator consisted of two parallel plates with voltage applied, which was used by J. J. Thomson in 1897 to accelerate and detect the passage of charged particles (Thomson, 1897). Thomson ingeniously applied a magnetic field that allowed him to determine the charge-to-mass ratio of the mysterious ''cathode rays,'' which when combined with Millikan's measurement of the fundamental charge gave the first measurement of the electron mass. In 1929, John Cockcroft and Ernest Walton managed to accelerate protons to 800 keV, providing enough energy to produce the first artificial disintegration of the nucleus. The more sophisticated accelerators that followed (cyclotrons, linacs, and synchrotrons) were used to discover and measure the properties of a hoard of particles while pushing the frontier of physics to higher and higher energies. During this exciting period, M. Stanley Livingston pointed out that the technology to accelerate particles to higher and higher energies was developing exponentially in time, producing a factor of 10 increase in the highest particle energy achieved, every 7 years or so (Livingston, 1969).

19.1.2
The Birth of Particle Colliders

The prophesy of exponential growth by Livingston (Figure 19.1) was realized with the invention of colliding beam machines, which have the advantage of producing a center-of-mass energy equal to the sum of the energies of the colliding particles, in contrast to a single beam colliding with a stationary target, which produces a center-of-mass energy proportional to the square root of the beam energy. For example, it would take a 36-TeV electron hitting a stationary electron to have the same center-of-mass energy as 3-GeV electrons in a collider. The first colliding beam machines were driven by the physics of quantum electrodynamics (QED), as it was speculated that a breakdown of QED may be observable in electron–electron scattering. The first particle collider was the Princeton–Stanford accelerator at Stanford, CA (Figure 19.2). The project was colead by Gerard K. O'Niell of Princeton and Wolfgang Panofsky of Stanford. The energy was 550 MeV per beam and first physics results were recorded in 1963. Another electron–electron collider, VEP-1 in Novosibirsk, Siberia, followed quickly

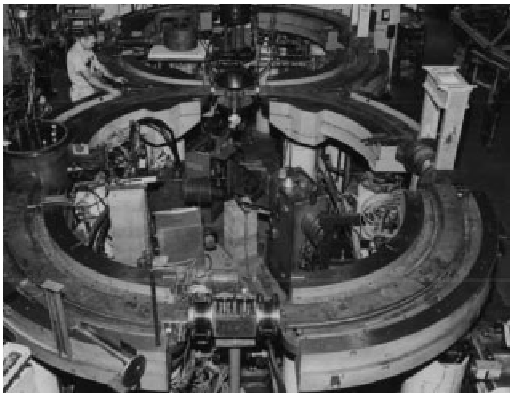

Fig. 19.2 The first particle collider, the Princeton–Stanford accelerator, was a double ring of 550-MeV electrons (Panoksky, 1997).

in 1966 with an energy of 700 MeV per beam. The beam instabilities discovered at these first colliders were overcome in future designs, allowing an increase in luminosity of nearly 2 orders of magnitude (Panoksky, 1997). The development of colliders through the solution of these beam instability problems became an international effort with huge contributions made by the groups led by B. Richter (SLAC), G. I. Budker (Novosibirsk), and F. Amman (Frascati) (Richter, 1976).

It was quickly realized that new dynamics could be explored with an electron–positron (e^+e^-) collider. Demonstration of the technique was made in Frascati, Italy, with the construction of the ADA e^+e^- collider (Bernadini, 2004). This machine was soon followed by other larger e^+e^- machines in Cambridge (MA, USA), Orsay (France), Novosibirsk (Siberia), and DESY (Germany).

19.1.3
Ingredients of Colliders

All particle colliders need an injection system, a ring (or two) of magnets to store the particles, a mechanism for accelerating the particles and keeping them in stable orbit, and a system to focus the particles at one or more collision points. In modern colliders, the storage ring is a synchrotron. The figure of merit for colliders is the luminosity (L), or number of times per square centimeter per second that the colliding particles meet. All physics rates are proportional to L, which may be written as

$$L = f\frac{n_1 n_2}{4\pi\sigma_x\sigma_y} \tag{1}$$

where f is the collision frequency of bunches containing n_1 and n_2 particles, and σ_x and σ_y are the transverse widths of the Gaussian beams. Thus, to be useful, a particle collider needs a large number of well-focused particles colliding at high frequency. The transverse size of the beams can be written in terms of a transverse emittance (ϵ) and an amplitude function (β) (Yao *et al.*, 2006). A particle collider is designed to collide large numbers of particles with low ϵ at places with low β. For electrons, the emittance is an equilibrium condition of quantum fluctuations in radiation with synchrotron radiation damping. For protons, the emittance is dominated by forces exerted during acceleration and storage.

Synchrotron radiation is emitted by relativistic particles traveling in a circular orbit. The power emitted may be written as

$$P = \frac{2ke^2\gamma^4 c}{3r^2} \tag{2}$$

where k is the electric force constant, e is the electric charge ($ke^2 = 1.44\,\mathrm{eV}\cdot\mathrm{nm}$), γ is the Lorentz-gamma factor, c is the speed of light, and r is the radius of the orbit. For electrons, the energy loss per turn around the ring (W) is

$$W = 8.85 \times 10^{-5}\,\frac{E^4/(\mathrm{GeV}^4)}{r/(10^3\,\mathrm{m})}\,\mathrm{MeV} \tag{3}$$

The radiation spectrum is broad but falls rapidly above a critical energy ($3\hbar c\gamma^3/2r$), which is typically in the hard X-ray region. Synchrotron radiation is the reason that high-energy e^+e^- colliders have a large radius. For protons, with their much larger mass, the energy loss per turn is

$$W = 7.8 \times 10^{-3}\,\frac{E^4/(\mathrm{TeV}^4)}{r/(10^3\,\mathrm{m})}\,\mathrm{keV} \tag{4}$$

Synchrotron radiation will be important for the first time in a proton collider at the CERN Large Hadron Collider (LHC).

Table 19.1 summarizes the many colliders that have been built in the last 40 years. The particle colliders fall into two general classes: e^+e^- and hadron machines, which are either proton–proton (pp) or proton–antiproton ($\bar{p}p$). There is but one exception, Hadron-Electron Ring Accelerator (HERA), which is an electron–proton (ep) machine. The energy of hadron colliders is limited by high-field magnet technology, rather than synchroton radiation,

Tab. 19.1 Summary of high-luminosity particle colliders.

and they tend to be viewed as our "discovery" machines. This has been proved true in the discovery of the W and Z^0 bosons at the CERN Super Proton Synchrotron (SPS) collider and the top quark at the Fermilab Tevatron collider. The reason for this is partly the composite nature of the proton, resulting in a wide variation in center-of-mass energy of the colliding quarks. Thus, a hadron collider cannot be tuned to a specific energy. The e^+e^-, on the other hand, tend to be machines that map out, in great detail, the decays of particles of known mass. This has been true for the strange, charm, and b-quarks as well as the Z^0 boson.

19.1.4
Famous Colliders

A large number of interesting physics results are from the many particle colliders (Table 19.1) as each order of magnitude increase in sensitivity (luminosity), coupled with more sophisticated detectors, reveals even rarer decay modes of known particles. These important results include the observation of high transverse-momentum hadrons in pp collisions (CERN Intersecting Storage Rings (ISR)), detailed studies of strange, charm and b quarks, as well as the tau lepton (e^+e^- colliders), measurements of the proton structure function at high momentum transfer (HERA), and heavy-ion collisions (Relativistic Heavy-Ion Collider (RHIC)). A few discoveries at particle colliders, however, stand out for their particularly important impact on the advancement of the field of high-energy physics and our understanding of the standard model of particle physics. These discoveries are listed in Table 19.2.

Tab. 19.2 Summary of famous discoveries at particle colliders.

Collider	Beams	Discovery	Year
SPEAR	e^+e^-	Charm	1974
PETRA	e^+e^-	Gluon	1979
CERN SPS	$\bar{p}p$	W,Z^0	1983
LEP	e^+e^-	Three neutrinos	1989
Tevatron	$\bar{p}p$	Top	1995

Tab. 19.3 Basic parameters of the LHC.

Circumference	26,659 m
Dipole field	8.33 T
Energy per beam	7 TeV
Number of dipoles	1232
Total number of magnets	9994
Operating temperature	1.9 K
Power consumption	120 MW
Revolution frequency	11.2455 kHz
Revolution period	88.9 μs
Radio frequency (RF)	400.8 MHz
RF electric field	5.5 MV/m

19.1.4.1 Stanford Positron Electron Accelerating Ring

The first particle collider to produce exciting physics results was the Stanford Positron Electron Accelerating Ring (SPEAR), a project led by Richter (1971). The SPEAR design originally called for two asymmmetric rings, but evolved throughout the 1960s becoming ultimately a single ring of magnets about 80 m in diameter, which circulated electrons and positrons at energies up to 4 GeV. The first collisions were recorded in 1972. The codiscovery of charm at SPEAR in 1974, a period still referred to as the *November Revolution*, dramatically changed the field of high-energy physics, providing new insight into the dynamics of both the electroweak and strong interactions. The Schrödinger equation was applied to the

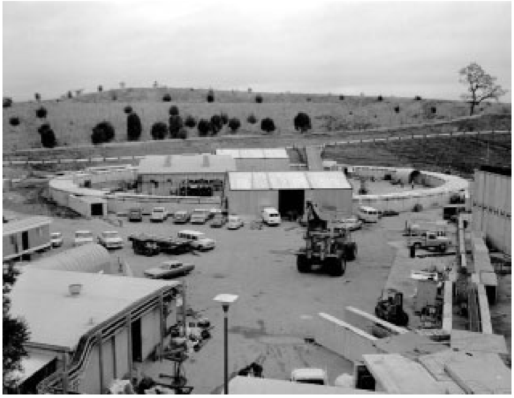

Fig. 19.4 Construction of the SPEAR machine nearing completion in 1971 (Stanford Linear Accelerator Center, 2002).

measured spectra of charmonium providing evidence beyond any reasonable doubt for the existence of quarks in the context of quantum chromodynamics (QCD). Figure 19.3 shows an event recorded at a center-of-mass energy of 3.7 GeV. In addition to charm, a third lepton family (tau) was discovered at SPEAR in 1975.

The SPEAR machine (Figures 19.4–19.5) was located at the end of the 3-km long Stanford Linear Accelerator Center (SLAC) linac, which was used to inject single 5-cm long bunches of positrons first and then electrons. The filling process took 15–30 min. The electrons and positrons collided at midpoint of two straight sections on opposite sides of the machine where quadrupole magnets were used to focus the beams to a transverse size of 1 mm × 100 μm. The data-taking periods lasted about 2 hours in a 5×10^{-9} torr vacuum before the positrons and electrons needed refilling. The synchrotron losses were about 300 kW at the maximum beam energies of 4 GeV (Richter, 1976). The muon components of Mark-I detector used to make the initial physics discoveries at SPEAR are shown in Figure 19.6.

19.1.4.2 **PETRA**

The Positron–Electron Tandem Ring Accelerator (PETRA) at DESY, along with Positron–Electron Project (PEP) at Stanford, was built with strong motivation to search for the top quark, but sadly, the top mass was far beyond the energy reach of these machines. The PETRA machine is basically a higher energy version of SPEAR. In 1979, the experiments at PETRA

19.1.4.3 **CERN Proton–Antiproton Collider**

In the late 1970s, an international race was on to observe the weak interaction gauge particles, the W and Z^0 bosons, proposed to exist as free particles at energies of about 100 GeV. The fastest route to such energies was conversion of existing proton synchrotrons into proton–antiproton colliders. The key technical hurdle was that of producing and cooling (reducing the momentum spread) a sufficient number of antiprotons to obtain useful luminosity for the collisions (Rubbia, 1985). This problem was solved by Simon Van der Meer, who applied stochastic cooling to the antiprotons (Van Der Meer, 1985). A proton–antiproton collision showing the decay of a Z^0 boson into e^+e^- is seen in Figure 19.8.

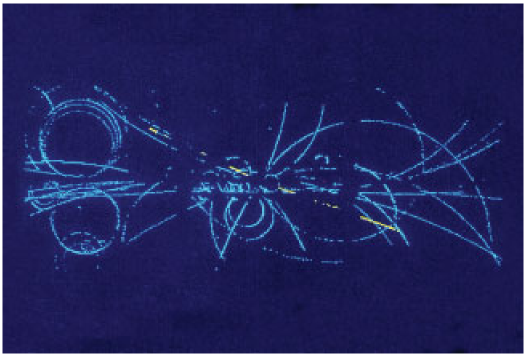

Fig. 19.8 High-energy proton–antiproton collision containing the decay $Z^0 \rightarrow e^+e^-$ (straight tracks) in the UA1 detector at CERN proton–antiproton collider. The events signified the unification of electromagnetic and weak forces.

Fig. 19.9 Schematic of the CERN SPS collider. Beams of protons from the PS were used to make antiprotons, which are accumulated and cooled. The antiprotons are injected into the SPS at an energy of 3.5 GeV and then accelerated to high energy for collisions with protons (Van Der Meer, 1985).

Fig. 19.10 The antiproton accumulator ring (Van Der Meer, 1985).

The successful operation of the CERN SPS as a proton–antiproton collider involved an exercise in accelerator gymnastics (Figure 19.9). Intense beams of protons from the CERN Proton Synchrotron (PS) were sent into a target where antiprotons were occasionally produced. The antiprotons were directed into an antiproton accumulator (Figure 19.10) where they were stochastically cooled. The principle of stochastic cooling involves measurement of the deviation of particles from the nominal orbit and sending a signal to a correction magnet. The correction signal is able to arrive before the particles because the direct path across the ring is shorter than the particle path along the arc (Figure 19.11). A scope trace demonstrating the fast cooling of 6×10^6 antiprotons is shown in Figure 19.12. The cooled antiprotons were injected, together with counter-rotating protons, into the SPS where they were accelerated to 315 GeV and collided.

Besides the anticipated discovery of the W and Z^0 bosons at the CERN SPS,

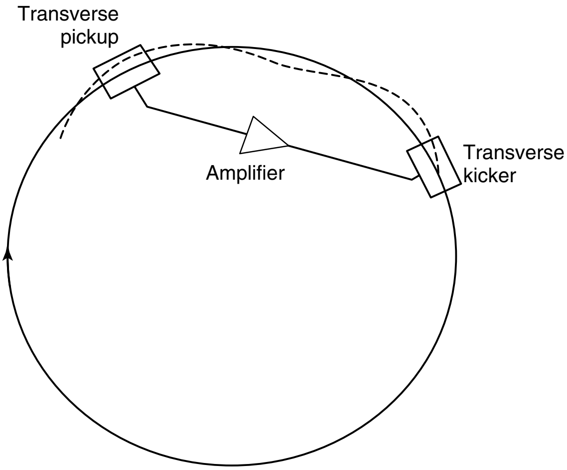

Fig. 19.11 Schematic of the cooling of the horizontal betatron oscillation of a single particle (Van Der Meer, 1985).

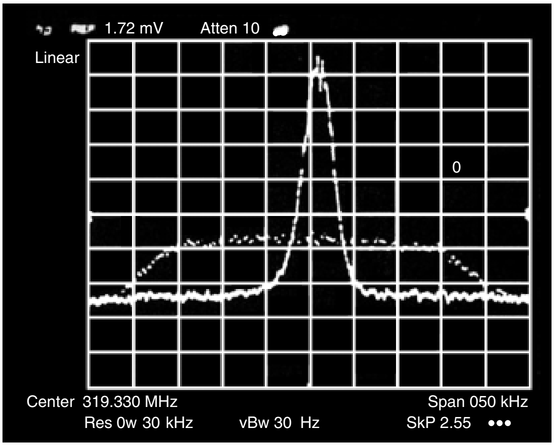

Fig. 19.12 A pulse of 6×10^6 antiprotons is cooled in 2 seconds (Van Der Meer, 1985).

another discovery dramatically changed the planning for future colliders. This was the clear observation of hadron jets from quark scattering at high energies (Figures –19.13, 19.14). Jets had been first observed in e^+e^- collisions (Hanson *et al.*, 1975) and then in low-energy hadron collisions (Bromberg *et al.*, 1980), but the results from the CERN SPS changed the international thrust for the next big accelerator almost overnight from an e^+e^- linear accelerator (linac) to a pp machine with the realization that ‘‘clean’’ physics was possible with a hadron collider (Rohlf, 2005). Sadly, the high-luminosity ISABELLE machine project at Brookhaven was canceled (eventually to become the heavy-ion RHIC machine project) to make room for the Superconducting Super Collider (SSC) in Texas, which eventually was canceled too. In the meanwhile, the rival Large Hadron Collider (LHC) machine at CERN became fully approved and actually built. The entire future of experimental high-energy physics depends on the physics learned (or not) at this machine.

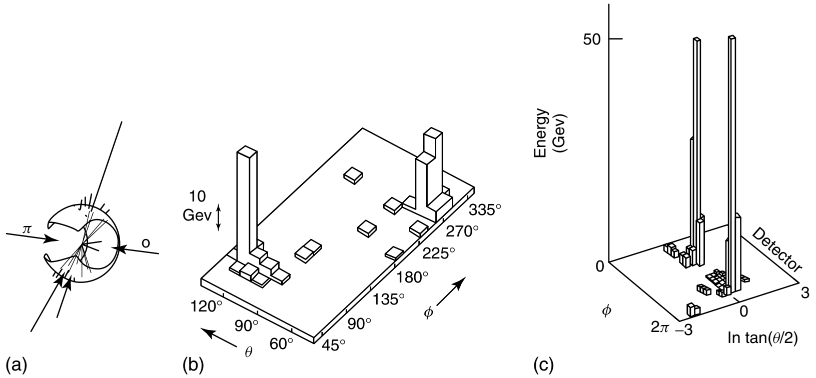

Fig. 19.13 Jet events from quark scattering observed at the CERN SPS collider in the UA2 detector (a and b) and the UA1 detector (c).

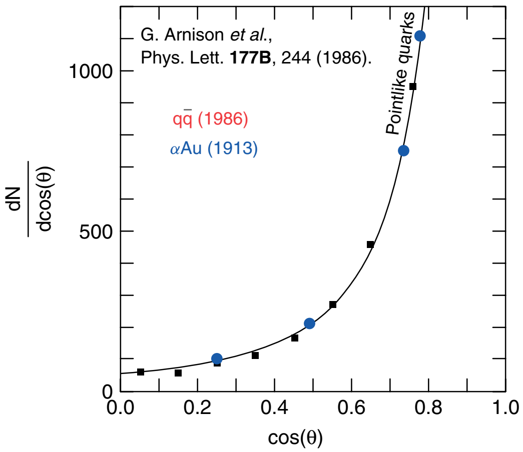

Fig. 19.14 The clean observation of jets at the CERN SPS collider allowed a Rutherford-type scattering experiment to be carried out to prove that the quarks were pointlike down particles to 10^{-18} m, interacting by the exchange of massless spin-1 gluons via a $1/r^2$ force (Arnison *et al.*, 1986).

19.1.4.4 **Fermilab Tevatron Collider**

The Fermilab Tevatron collider *http://www-bdnew.fnal.gov/tevatron/* is conceptually the same as the CERN proton–antiproton collider, except that the more powerful superconducting synchrotron magnets allow beam energies of up to 1 TeV, about three times more than previously available at the SPS collider. The Tevatron accelerator layout is shown in Figure 19.15. Owing to the improvements in the operation of the Tevatron over many years, the luminosity has exceeded that achieved at the CERN ISR (Table 19.1), long considered the benchmark for hadron colliders. The integrated luminosity delivered by the Tevatron collider is shown in Figure 19.16.

A key ingredient for the Fermilab detectors was the development of silicon vertex detectors. These detectors allow the identification of long-lived b quarks, which are the decay products of top quarks. An event with top and antitop quarks from the Collider Detector Facility (CDF) detector is shown in Figure 19.17.

19.1.4.5 Large Electron–Positron Project

The Large Electron–Positron (LEP) project was designed to study the properties of the Z^0 boson as well as to be able to reach the W^+W^- threshold (Figure 19.18). The LEP accelerator was commissioned in 1989 and ran successfully until the end of 2000 (Assmann, 2001). The LEP collider was distinguished by its unprecedented size, made necessary by the phenomena of synchrotron radiation, whereby particles emit electromagnetic radiation as the fourth power of energy and the inverse square of the radius. The LEP machine was optimized for an energy of 85 GeV per beam, resulting in a circumference of 27 km after balancing the costs of construction and operation. The large radius limits the radiated power from a single electron to the μW level so that large numbers of electrons and positrons can be kept in stable orbits.

At LEP, the collision energy was measured with extraordinary accuracy, about 2 parts per 10^5. This allowed the machine to be sensitive to external forces that could change the diameter of the machine very slightly. An orbit change of 1 mm corresponds to an energy change of about 10 MeV. The machine was thus sensitive to the water level in Lake Geneva and the tides caused by the moon, which produce small distortions in the earth's crust. In addition, trains from Geneva to Paris caused induced currents on the LEP beam pipe that caused observable changes in the magnetic fields of the LEP magnets (Figure 19.19).

Figure 19.20 shows the decay of a Z^0 into quark and antiquark. Detailed measurements of the Z^0 decays proved that three and only three light neutrinos exist in nature. The precise measurement of the Z^0 mass is shown in Figure 19.21.

19.1.5
The Energy Frontier: CERN Large Hadron Collider

The CERN LHC is designed to uncover the secrets of electroweak symmetry breaking, providing a natural progression to access the physics beyond the Tevatron and LEP. The LHC occupies the same tunnel originally built for LEP. It was obvious even before LEP was completed that the radius of the tunnel was approximately 1 TeV per tesla (Amaldi, 1981), implying that if one used the same tunnel to build a proton collider, which is energy limited by magnet technology, 10 TeV per beam could be feasible with 10 T magnets. Figure 19.22 shows the location of the old LEP experiments and the new LHC experiments and services.

19.1.5.1 LHC Basic Parameters

Since the LHC physics demands the highest possible proton energy, the bending magnets are at the limit of present technology. The existing superconducting proton accelerators (Tevatron, HERA, and RHIC) all have fields around 5 T or below using Nb–Ti Rutherford cables cooled to 4.2 K. To make use of the proven cable technology and get increased field strength requires cooling below 2 K with superfluid helium. Unfortunately, the lower temperature reduces the heat capacity of the cables by an order of magnitude such that a magnet quench can be triggered by a substantially lower energy deposit. The tight mechanical control that must be maintained on the movement of the superconducting strands, plus the limited space inside the tunnel together with cost considerations, has lead to a "two-in-one" design with one cold mass containing the apertures and coils for both proton beams. The field design is 8.33 T at a current of

11.8 kA. The two-in-one dipole is shown in Figure 19.23. The integrated dipole magnets and helium cryostats are referred to as *cryodipoles*. Each cryodipole has a mass of 34 tons. The details of a cryodipole are shown in Figure 19.24.

The basic parameters of the machine are given in Table 19.1 (*http://ab-div.web.cern.ch/ab-div/Publications/LHC-DesignReport.html*, 2004). The superconducting main bending dipole magnets fill about two-thirds of the 27-km circumference. The remaining tunnel length is necessary for quadrupole focusing magnets and straight sections to accommodate four interaction regions plus beam injection points, radio frequency (RF) acceleration, the beam dump, and two beam-cleaning sections. The first of 1232 8.33-T dipole bending magnets was installed in 2005. The LHC group at CERN maintains an excellent website (*http://lhc.web.cern.ch/lhc/*) containing a wealth of technical information. Also much technical information is available from the

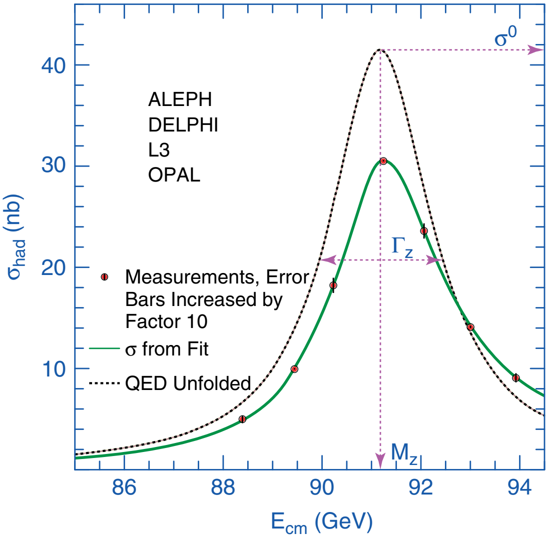

Fig. 19.21 Precision measurement of the Z^0 mass and width provides a powerful constraint to the standard model of particle physics (*http://delphiwww.cern.ch/*).

proceedings of an accelerator workshop held each winter in Chamonix, France (*http://ab-div.web.cern.ch/ab-div/conferences/Chamonix/*).

The amount of energy stored in the circulating LHC beams is unprecedented, having serious consequences for the operation of the accelerator (Schmidt, 2003). A simple calculation shows that the energy per beam is

$$\begin{aligned} E_s &= E_p n_b N_b \\ &= (7\times 10^{12}\,\text{eV})(1.6\times 10^{-19}\,\text{J/eV}) \\ &\qquad (2808)(1.1\times 10^{11}) \\ &= 350\,\text{MJ}. \end{aligned} \tag{5}$$

The LHC beams have the kinetic energy of an aircraft carrier at 10 knots or enough to melt a couple of tons of copper. Figure 19.25 shows the stored energy of previous particle accelerators versus beam momentum together with that of the LHC. The energy stored in the LHC beams is more than 2 orders of magnitude greater compared to any previous accelerator.

19.1.6
Beam Dump

The LHC has interaction region 6 dedicated to dumping the beams. The beam dump is needed for fast extraction of the proton beams into an external absorber. For the assumed 20-year lifetime of the LHC, a total of 2×10^4 beam dumps are foreseen at full energy and intensity. A loss-free extraction requires a gap of about 3 μs in the circulating proton beams to accommodate the rise time of the beam dump kicker magnets. Each proton beam has 15 kicker magnets (MKD), which deflect the beams horizontally into the high-field gaps of 15 septa magnets (MSD), which provide a vertical deflection raising the beams above the entrance to the arc. The beams then travel 750 m through special vacuum chambers passing through 10 dilution kicker magnets (MKB) before finally striking the beam dump graphite core (TDE). Special magnets (TCDS and TCDQ) are inserted to protect the LHC machine from an unplanned beam dump that might occur with the kicker magnets

The unprecedented stored energy of the LHC beams is shown compared with that of the Intersecting Storage Rings (ISR) as the first pp collider at CERN, Super Proton Synchrotron (SPS) at CERN operating in fixed target and proton–antiproton collider modes, Hadron-Electron Ring Accelerator (HERA) ep collider at DESY, the proton–antiproton collider at Fermilab (Tevatron), the Relativistic Heavy-Ion Collider (RHIC) at Brookhaven with protons, and the Large Electron–Positron (LEP) collider at CERN.

ramping out of synchronization with the planned abort gap.

Each beam ends up in a carbon graphite core that is chosen for its high melting temperature and thermal shock resistance. The carbon graphite core is a cylinder 0.7-m diameter and 7.7-m length and is fitted into a water-cooled stainless steel jacket. The core is surrounded by 900 tons of radiation shielding blocks made from recycled ISR magnets filled with concrete. The dilution magnets (Figure 19.26), four horizontal and six vertical, providing kicks of $1.6\,\mathrm{T \cdot m}$ and $1.1\,\mathrm{T \cdot m}$, respectively, are used to sweep the beam into a letter “e” pattern during the dumping process in order to spread out the energy deposition. The dilution magnets are sinusoidally powered by a pulse generator (14.2-kHz horizontal and 12.7-kHz vertical) via a low-impedance transmission line. The resulting pattern at the graphite core is shown in Figure 19.27. The motion of the impact point on the beam dump is at least $10\,\mathrm{mm\mu s^{-1}}$, resulting in a trace that is approximately 1 m in length for the 89-μs orbit period.

19.1.7
LHC Layout

The LHC is divided into octants as indicated in Figure 19.28. Each octant has at its center a 528-m long straight section (LSS). At four of these sections, the beam lines cross and the experiments are located. The general purpose ATLAS experiment is housed at LSS1 or “point 1” adjacent to the CERN main entrance. The neighboring sections, LSS8 and LSS2, house ALICE, a retrofit of the former L3 experiment at LEP to specialize in heavy-ion collisions, and LHCb, a spectrometer specialized for b-quark physics, respectively. The beams are also injected from the SPS into the LHC rings at points 2 and 8 with a vertical momentum kick from below the LHC plane. The other general purpose detector, CMS, is located at LSS5. For ATLAS, the proton beams cross in the vertical plane,

while for CMS they cross in the horizontal plane. Beam collimators are located at LLS3 and LSS7, the beam dump at LSS6, and the RF acceleration of each beam at LSS4. Each LSS is sandwiched between dispersion sections (DSL and DSR).

An arc of the LHC is optimized for maximum integrated field strength to result in the highest possible proton energy. Each arc contains 23 106.9-m cells, which are divided into half cells that each contain a quadrupole embedded in a short straight section (SSS) 5.335-m cold mass in a 6.63-m cryostat plus 3 14.3-m dipole bending magnets. The LHC cell is shown in Figure 19.29.

19.1.8
Cryogenics

Part of the uniqueness of the LHC among superconducting synchrotrons is its operating temperature of 1.9 K in order to maximize the field strength that can be obtained with NbTi coils. This is accomplished by immersing the coils in a pressurized (1.3 bar) bath of superfluid helium. In addition, the effective thermal conductivity of helium is at a maximum at 1.9 K providing a margin of stability over operation at the conventional 4.5 K. The expected temperature profiles of the LHC magnets are shown in Figure 19.30.

The cryogenic system is designed to cool the entire LHC cold mass of 3.7×10^7 kg in 15 days and to rapidly warm up and cool strings of magnets in order to replace a defective unit.

The LHC refrigeration entropic capacity is 144 kW at 4.5 K, making it the world's largest helium system. The design has eight refrigeration stations (one every 3.3 km) including recycled use of the four LEP refrigeration units and their associated infrastructure. The cryogenic system is designed for continuous operation for nine months followed by a three-month shutdown for maintenance.

19.1.8.1 Injection Scheme

The protons for each LHC beam are accelerated by a linac to a kinetic energy of 50 MeV, a booster to 1.4 GeV, the PS to 25 GeV, the SPS to 450 GeV, and finally the LHC to 7 TeV (Figure 19.31). The

important geometric factors in the injection scheme are that the PS circumference is 1/11 of that of the SPS, which in turn is 7/27 that of the LHC. These factors have important implications for the time structure of the beams.

The baseline design calls for operation of the machine at approximately 40 MHz. This is based on “harmonic 84,” in which the PS is divided into 84 time bins or *buckets*. The geometric factors for the PS and SPS lead to a division of the LHC into

$$(84)\,(11)\left(\frac{27}{7}\right) = 3564 \tag{6}$$

time buckets of size

$$\frac{88924\,\text{ns}}{3564} = 24.95\,\text{ns} \tag{7}$$

resulting in a beam crossing frequency of 40.079 MHz.

There are many factors that limit filling of the LHC buckets with protons. The

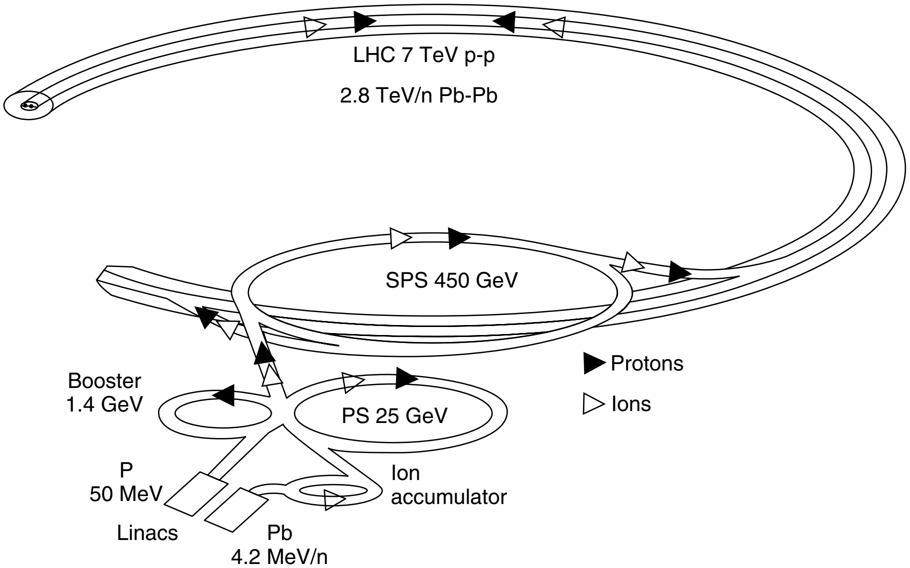

Fig. 19.31 The LHC injection scheme involves a proton linac, a booster ring, the proton synchrotron (PS), and the super proton synchrotron (SPS) accelerators. A second linac is used to accelerate heavy ions where they are collected in an ion accumulator.

main hardware limits come from the SPS injection kicker rise time of 225 nanoseconds, the LHC injection kicker rise time of 975 nanoseconds, and the 3 microseconds needed for the LHC beam dump kicker. The resulting proton bunch disposition is shown in Figure 19.32. The time needed for SPS injection means that only 72 proton bunches of 25-nanosecond spacing (out of 84 possible) are loaded into the PS. The time needed for LHC injection means that only 10 PS fills are loaded into the SPS (of 11 possible). Four SPS fills are needed to load the LHC, but the last SPS injection has only 9 PS fills because of the time needed for the LHC beam dump kicker, necessary to empty the protons from the LHC. The net result is that of the 3564 LHC time buckets only 2808 contain protons, according to the formula

$$\begin{aligned}3564 = \big\{&[[(72\mathrm{b} + 8\mathrm{e}) \times 3] + 30\mathrm{e}] \times 2\\ &+ [[(72\mathrm{b} + 8\mathrm{e}) \times 4] + 31\mathrm{e}]\big\} \times 3\\ &+ \big\{[[(72\mathrm{b} + 8\mathrm{e}) \times 3] + 30\mathrm{e}] \times 3\\ &+ 81\mathrm{e}\} \qquad (8)\end{aligned}$$

where b stands for buckets with protons and e stands for empty buckets. The 8e is due to injection into the SPS, the 8e + 30e and 8e + 31e are due to injection into the LHC, and the 8e + 30e + 81e is due to the LHC beam dump. The resulting bunch structure is extremely fortuitous for the experimenters, because a priori knowledge of when the beams can and cannot collide provides a powerful technique to synchronize the electronics. The large gap of 3.0 microseconds, referred to as the *abort gap*, may be used for fast reset of the electronics and certain calibration triggers.

The first time bucket after the abort gap is referred to as *bunch count zero* (*BC0*).

To synchronize the transfer, the LHC sends two master clock signals via fiber optics to the SPS: (i) a fiducial frequency, which is the LHC revolution frequency divided by 7 (equal to the SPS frequency divided by 27) and (ii) the 400.8-MHz RF that is phase adjustable. The operation of the SPS is locked to these clock signals and the relative phase of the RF is adjusted to place the injected protons at the center of the LHC bucket.

19.1.9
Radio Frequency Acceleration

Since protons cannot be accelerated with magnetic fields, this leaves the electric field as the only technique for particle acceleration. At the beginning of the acceleration stage, this is accomplished with a constant (DC) high voltage. In the PS, SPS, and LHC, the electric field causing the acceleration is sinusoidal (AC) at an RF. RFs are chosen because the electric field can be fed into a cavity whose dimensions are chosen to support a resonant standing wave. The presence of a strong resonance means that the protons are pushed only by the RF electric field and not by any potential noise. The RF cavity contains a gap where voltage is applied such that every time a proton crosses the gap it is accelerated by a small fixed amount. The desired acceleration occurs quickly since the orbit frequency is large. Voltage is fed into the cavity in a suitable fashion.

The RF acceleration in the LHC takes the proton beams from injection energy of 450 GeV to the collision energy of 7 TeV and is also needed to keep the tight bunch structure of the protons. The RF acceleration occurs in the LSS of octant 4 (Figure 19.28). Unlike LEP, which as an electron accelerator was burdened with synchrotron radiation, the main consideration of RF design (Boussard and Linnecar, 1999) for the LHC is determined by the need for precise voltage control in the presence of a high current of protons (0.5 A) and not by the total power delivered to the beam. Use of conventional copper cavities would lead to unacceptable bunch lengths.

The LHC RF must be a multiple of the SPS RF (200.4 MHz) in order to allow rapid transfer of multiple bunches. The bunch length in the SPS at 450 GeV is 1.6 nanoseconds. This means that an RF system operating at 400.8 MHz (2.5-nanosecond period) can be used to capture the protons at injection into the LHC, as well as accelerate them and maintain their energy for storage during collisions. A maximum acceleration voltage of 16 MV is chosen to be compatible with the desired maximum bunch length and emittance at 7 TeV to meet design luminosity. An LHC superconducting RF module is shown in Figure 19.33.

To accommodate the high beam current and the 3-microsecond abort gap, 30-cm-wide aperture superconducting RF cavities are chosen. The RF cavities are based on the successful design used at LEP, copper cavities with a niobium film on the RF surface. (The LEP cavities operated at 352 MHz.) To make room for the RF system for two separate beams, special superconducting dipoles are used to separate the beams by 42 cm at point 4. With the RF systems for the two beams longitudinally staggered, the adjacent beam can pass outside the RF cavity of the beam being accelerated; however, it still passes through the RF cryostat as shown in Figure 19.34. This special section of the beam pipe is designed so as not to interfere with the replacement of a faulty RF cavity.

Fig. 19.32 Proton bunch structure in the LHC (P. Collier (*http://lhc.web.cern.ch/lhc/*)).

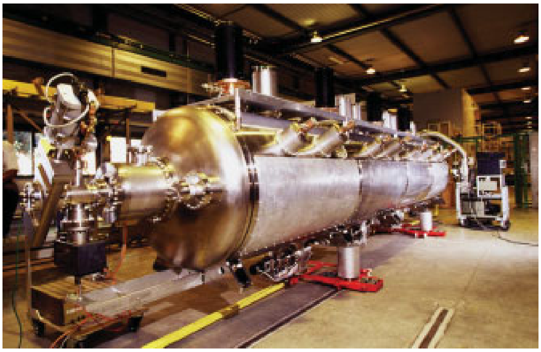

Fig. 19.33 Superconducting RF module.

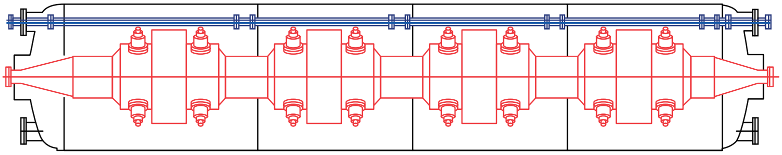

Fig. 19.34 In order to provide space for the RF cavities, the beams are separated from their nominal 194–420 mm in point 4. The beam adjacent to the one being accelerated, however, still must pass through the superconducting RF cryostat. A second beam pipe is installed in the RF cryostat outside of the acceleration cavities as shown.

This is accomplished with eight superconducting RF cavities per proton beam, two groups of four in a single cryostat, giving a total acceleration voltage of 16 MV. Each RF cell provides 2 MV, with a corresponding electric field of 5.5 MeV m^{-1}.

Klystrons are specialized vacuum tubes that have been in existence since 1937. Their function in the LHC is to amplify microwave signals that are sent to the RF cavities through which the proton beams pass. The RF power (4800 kW maximum) is provided by 16 300-kW klystrons, one per cavity, operating at 10 times the crossing frequency, or 400.8 MHz. The klystrons were developed specially for the LHC, although much of the auxiliary equipment is recycled from LEP. The klystrons are installed at a distance of 10 m in a ''klystron gallery'' adjacent to the LHC tunnel.

19.1.10
Beam Vacuum

A high-quality vacuum for the proton beams is needed in the LHC, otherwise the protons will be rapidly depleted through interactions with the gas molecules (beam–gas interactions). This poses a challenge in a superconducting environment where heat must be minimized and large numbers of gas molecules condense on the vacuum chamber. The beam vacuum must be able to handle the dynamic effects of synchrotron radiation (200 mW m^{-1} per beam), image currents (200 mW m^{-1} per beam), energy loss from nuclear interactions (20 mW m^{-1} per beam), plus the energy dissipated from the formation of electron clouds.

The beam vacuum system includes the following parts: the experimental regions, the adjacent long straight sections, and the arcs. The LHC vacuum contains components at both room temperatures in the region of the experiments and at cryogenic temperatures inside the magnets. The beam vacuum is divided into sectors defined by the distance between cryomagnets, except in the arcs, which are single sectors of length 2900 m. Additional vacuum systems are needed to insulate the helium distribution line and the cryomagnets.

The quality of vacuum in an accelerator is measured by the single-beam lifetime, the time taken for the number of particles in stable orbit to be reduced by a factor of $(1 - (1/e))$, *approximately* 0.63, due to beam–gas interactions. The design figure of merit for the LHC vacuum lifetime is 100 h so as not to inhibit the luminosity lifetime of 15 hours, which ideally would be dominated by proton–proton collisions. The 100-hour beam lifetime corresponds to an equivalent hydrogen (H_2) gas density of 10^{15} m^{-3}. In the immediate vicinity of the experiments, this vacuum will be 100 times better at 10^{13} m^{-3} equivalent hydrogen density.

Figure 19.35 shows the vacuum pressure versus temperature for several common molecules (Redhead, Hobson, and Kornelsen, 1993). Superimposed on this graph is the vacuum pressure needed to achieve the LHC design vacuum lifetime of 100 hours. For CO this vacuum pressure corresponds to 10^{-9} torr. An overview of the LHC vacuum system and problems to be faced for maintenance and commissioning of the accelerator are given in (Refs. Baglin [2004–2006]).

The LHC beam vacuum system is equipped with a ''beam screen,'' perforated low magnetic permeability stainless steel, which lines 44 km of magnet walls (Cruikshank, 1997) (see Figure 19.36). The beam screen operates between 5 and 20 K and serves the purpose of reducing the heat load on the superconducting magnet

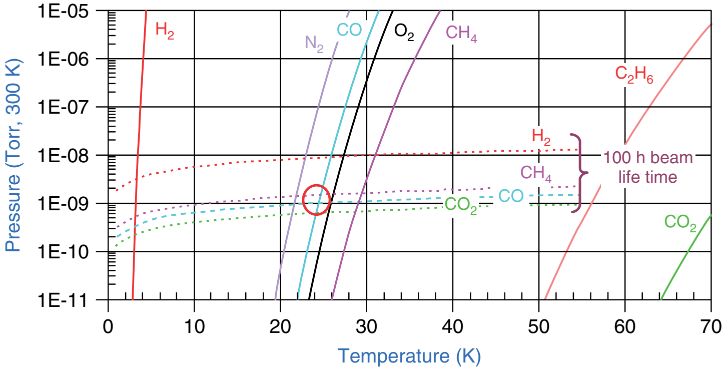

Fig. 19.35 Vacuum pressure of common gases (Redhead, Hobson, and Kornelsen, 1993) with the LHC beam lifetime superimposed (Baglin, 2004).

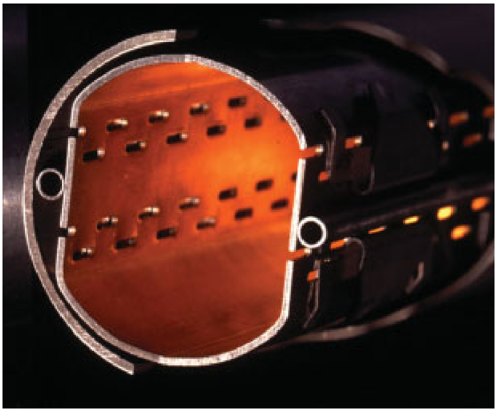

Fig. 19.36 The beam screen is a copper-clad stainless steel liner for the vacuum system. The cross-sectional area is about 44 mm × 34 mm. The beam screen reduces the heat load on the helium, which cools the LHC magnets.

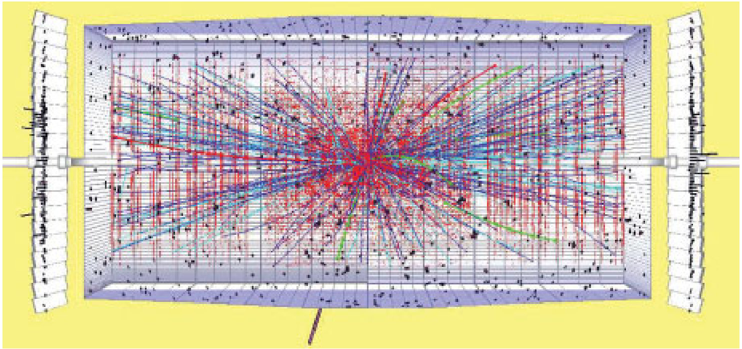

Fig. 19.37 Simulated LHC pp collisions for one beam crossing (25 nanosecond) in the Compact Muon Solenoid detector at design luminosity.

helium bath. The beam screen is lined with 50 μm of high purity copper in order to provide a low-resistance path for the image current of the beam and to resist induced forces from eddy currents during a magnet quench. The beam screen contains holes through which gas molecules may be pumped. The pattern and size of the holes is arranged to minimize impedance and keep RF losses below 1 mW m^{-1}.

The LHC is the largest scientific instrument ever built. The detectors are even more sophisticated than thought possible when the large hadron collider was in the infancy of its planning stage two decades ago. Figure 19.37 shows simulated pp collisions from a single 25-nanosecond beam crossing in the Compact Muon Solenoid detector at design luminosity (compare with Figure 19.3). Individual pp collision occur at 1 GHz.

19.1.11
Super LHC

An upgrade to the LHC is foreseen, which will raise the luminosity by an order of magnitude to $10^{35} cm^{-2} s^{-1}$. This project is known as the Super Large Hadron Collider (SLHC). The increased luminosity would come from increased currents (×5) and squeezing of the beams (smaller β by ×2) at interaction points 1 and 5 (ATLAS and CMS). The increase in luminosity and associated radiation levels near the interaction regions will require extensive upgrades to the detectors (Rohlf, 2003).

19.1.12
The Next Frontier

19.1.12.1 International Linear Collider

The International Linear Collider (ILC) is a proposed 35-km, 500-GeV total energy e^+e^- collider intended to complement the LHC (*http://www.linearcollider.org/cms/*). The design goals call for an integrated luminosity of 50 fb^{-1} during the first four years and an ability to scan in center-of-mass energy from 200 to 500 GeV. An upgrade to 1 TeV is foreseen as a second stage. The ILC design uses 1.3-GHz superconducting RF cavities providing an accelerating gradient of 31.5 MeV m^{-1}. The machine would deliver a 1-microsecond pulse at the rate of 5 Hz.

19.1.12.2 Compact Linear Collider

The Compact Linear Collider (CLIC) is an e^+e^- collider designed for a nominal center-of-mass energy of 3 TeV (*http://clic-study.web.cern.ch/clic%2Dstudy/*). The CLIC design differs from the ILC in that it uses a very high accelerating gradient of 150 MeV m^{-1}. Such a gradient would be achieved using room-temperature traveling wave structures operating at 30 GHz. The CLIC acceleration is a two-beam concept, with the RF power generated by a high-current electron beam (the drive beam) parallel to the main beam. A lower cost option would use an RF of 12 GHz generating 100 MeV m^{-1}. The proposed CLIC layout is shown in Figure 19.38.

19.1.12.3 Very Large Hadron Collider

While a TeV linear collider may well be able to exploit the initial discoveries made at the LHC, it seems that the next big step in energy will require a bigger hadron collider, referred to as the *Very Large Hadron Collider* (VLHC). Such a machine is foreseen to collide protons at a center-of-mass energy of 100 TeV or more (Foster, 2000). While the details are much less defined than the ILC or CLIC, one basic design option for the VLHC is a scaling of the LHC with high-field cold-bore magnets, while other options use larger tunnels with smaller field magnets.

23.1
Introduction

Particles can be emitted in a variety of physical processes. They differ by their energy, the way they interact with other particles, and their mass. In the majority of cases, they are detectable by their electromagnetic interactions, directly if they are charged, and by their decay products if they are uncharged (the latter case applies to the conversion of photons into an electron or electron–positron pair). In a few cases, detectors are directly sensitive to the energy deposited in a medium – for example, the bubble chamber and the superconductive bolometer.

Charged particles are detected when crossing solid, liquid, or gaseous media by the ionization they produce or by the production of photons as in scintillation, Cherenkov light, and transition radiation. This can be exploited in electronic detectors to obtain information on the particle's energy, velocity, and charge. Normally, in the field of high-energy physics, a combination of detectors must be used to identify particles, since each detector can only measure a single parameter.

The types of detectors that the physicist has at his disposal are ionization chambers, wire chambers (in proportional and nonproportional mode), drift chambers, multistep avalanche chambers, micropattern gaseous detectors, scintillation counters, liquid detectors, solid-state detectors, Cherenkov counters, and transition–radiation detectors. While most detectors deliver a signal for a specific particle interaction, it is sometimes necessary to have a full image of particle trajectories in various media. For this, tracking devices play a major role in today's nuclear and subnuclear physics and have been the backbone of large detectors in the past. The development of particle detectors started with the earliest cloud chambers and progressed to nuclear photographic emulsions and then bubble chambers, spark chambers, and streamer chambers, and finally reached the combinations of time projection chambers and silicon trackers used at present.

Most applications of tracking detectors are in magnetic spectrometers. Tracking systems are placed, for example, either in front of/behind or inside dipole magnets, e.g., BRAHMS (Adamczyk *et al.*, 2003), PHOBOS (Back *et al.*, 2003), LHCb (Augusto Alves *et al.*, 2008), or inside large solenoidal fields, e.g., STAR (Ackermann *et al.*, 2003), ATLAS (inner barrel) (Aad *et al.*, 2008), CMS (Chatrchyan *et al.*, 2008), ALICE (Aamodt *et al.*, 2008). Following the trajectories of charged particles in three

ISBN: 978-3-527-40691-3

dimensions inside a known magnetic field determines the momentum of the particle.

With the continuously increasing complexity of particle collisions being examined at present, particle tracking becomes an essential part of the field of particle and nuclear physics, with applications in astrophysics, nuclear imaging in the medical profession, biological analysis, and even archeology.

23.2
Particle Detectors

Particle detectors (with the exception of photographic imaging detectors) deliver an electrical signal after they interact with charged particles. Stable neutral particles such as photons and neutrons are only detectable via an intermediate conversion step, in which their kinetic energy is used to produce secondary charged particles in a nuclear (neutron–proton recoil) or electromagnetic (photon–electron/positron conversion) interaction. These detectors are used to count the number of particles emitted by unstable nuclei or produced in nuclear collisions, to measure their energies or trajectories, and to evaluate their masses. The type of detector depends on the intrinsic properties of the particles to be detected, but generally, it is the electromagnetic interaction of the particle with its surroundings that is observed; typically, the interaction involves the production of electron–ion pairs in a medium. The result may be current pulses in wire chambers, electron-hole production in solid-state devices, photons in a scintillating material, Cherenkov light, or transition radiation.

The electric fields in gaseous detectors are controlled by electrode configurations and are not always of uniform intensity. The nature of the gas filling is strongly dependent on the applications foreseen for a detector. Furthermore, the nature of the interaction or the radiation to be detected may be a factor leading to the choice of some components. For instance, in order to detect slow neutrons with high efficiency, BF_3 or ^{3}He is used. For soft X-rays, xenon or krypton fillings are favorable. For charged particles, the criterion is sometimes the maximum permissible gain in order to simplify electronics. Because of its very low cost, argon is often used as the major component. The additional gases (methane, alcohol, CO_2, etc.) have various functions: quenching of the metastable states of the noble gases that are responsible for UV photon emission, reduction of the resolution time by increasing the drift velocity, enhancement of the visible photon emission when the optical detection of the avalanches is required, reducing the ageing rate due to polymerization of the vapors, and more. The average energy loss of a charged particle in a gas varies between 20 and 35 eV per liberated ion. In large systems, the gas filling is flushed continuously.

Photosensitive gases, used as an additive in a main gas carrier, have extended the field of applications for gaseous detectors. Triethylamine (TEA), for example, has an ionization potential of 6.5 eV. It has a peak quantum efficiency for UV photons larger than the best photocathodes used in photomultipliers, and it permits the detection and imaging of photons emitted by Cherenkov radiation or by scintillators like BF_3, with spatial accuracies close to 1 mm.

23.2.1
Gaseous Detectors in Proportional Mode

When a charged particle crosses a gaseous medium, it can collide with the atoms of that gas, and if it can transfer more than the electron-binding energy, electrons can be liberated from the medium. These can either stay free or be rapidly recaptured by parent ions or atoms with (unwanted) electron affinity, such as oxygen.

The introduction of an electric field in the detection region leads to many other effects that need to be taken into account in the design of detectors or the selection of detector types. These are determined by the nature of the gas and the field intensity. The presence of a field leads to two possibilities:

1. If the field is strong enough, electrons will be sufficiently accelerated between collisions to knock another electron out of the next atom they hit, ultimately causing an electron avalanche.
2. If the field is not sufficiently strong, electrons freed from the material will only collide with atoms and drift along field lines until they reach the field anode, where they are captured.

The average velocity of these drifting electrons is determined by the properties of the gas and the strength of the electric field; Figure 23.1 shows electron drift velocity versus electric field for four different gases (Sauli, 1977). This finite velocity results in a time delay between emission and detection of a given electron, which is used to determine the point at which the electron was liberated (see Section 23.2.1.3).

For further discussion, see Palladino and Sadoulet (1975) and Sauli (1977).

23.2.1.1 **The Ionization Chamber**

In an ionization chamber, a weak homogeneous electric field is used to collect the electrons at the anode, without their undergoing charge multiplication (Figure 23.2). The amount of charge collected gives a measure of the average radiation intensity and the energy loss (dE/dx) that the particles have suffered in traversing the gas gap of the chamber. This instrument is widely used in dosimetry and calorimetry (where a liquid, such as liquid argon (LAr), liquid xenon (LXe), or tetramethyl pentane (TMP) Ankoviak *et al.*, 1989, is often used instead of a gas). As a result of not relying on gas gain, it has a very stable and uniform response and can measure average fluxes with an accuracy of 10^{-4}.

Ionization chambers can detect a single particle if that particle has enough energy and gas volume to liberate many electrons. Depending on the quality of the amplifier used, the noise equivalent can be between 100 and 1000 electrons, so that at least this many must be produced for a detectable signal to be generated by the chamber.

Generally, ionization chambers have little or no spatial granularity (except in calorimetry) and are rarely used in tracking. They often serve as charge-integrating rate meters, such as accelerator beam monitors.

23.2.1.2 **The Proportional Wire Chamber**

The simplest proportional chambers (Figure 23.3) consist of a thin wire held taut between two points, along the axis of a hollow cylinder. The wire acts as the anode, and the cylinder, which is the cathode, is filled with gas that can be maintained at a pressure between 100 Pa and 10 MPa, although it is generally kept at atmospheric pressure for mechanical reasons. The parameters of size and wire potential are chosen to give the correct signal gain (and hence electron multiplication factor) close to the wire. The detector is strictly operated in a regime where the response of the detection cell is proportional to the primary charge produced within the sensitive volume.

The simple cylindrical wire counter is still used for limited applications where the detection of soft X-rays (in the range of 1–50 keV) is required. It delivers pulses

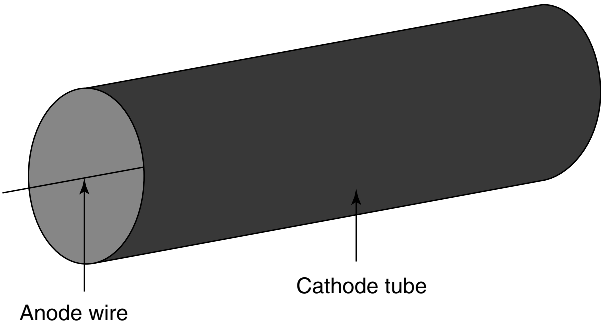

Fig. 23.3 The proportional wire tube.

with an energy resolution of 13% (full width at half maximum, FWHM) at 6 keV, varying like $E^{-1/2}$. This is much poorer than what can now be achieved with solid-state detectors (cf. Section 23.2.4), but the device is less expensive.

More elaborate detectors – for example, the multiwire proportional chamber (MWPC) (Charpak *et al.*, 1979) – have been developed from these simple chambers and are in use at CERN and other research facilities because of their versatility, good resolution, and large surface coverage (Figure 23.4). With the possibility of very accurate localization of ionizing events, they allow precise imaging for high-energy collisions.

In multiwire chambers, there are two electric field regions: one far from the wire, where the field is uniform, and the other close to the wire, where the field is radial. In the latter region, electrons experience inelastic collisions leading to an avalanche effect, which gives the detector its signal gain; that is, one electron outside this region leads to many electrons hitting the wire.

Typically, with mean free paths for the electrons of about 1 μm and proportional gains of $\leq 10^5$, the multiplication process occurs over a distance of about 15 μm. The electrons from the avalanche are rapidly collected by the wire, whereas the positive ions must drift across the full potential gap of the chamber before hitting the

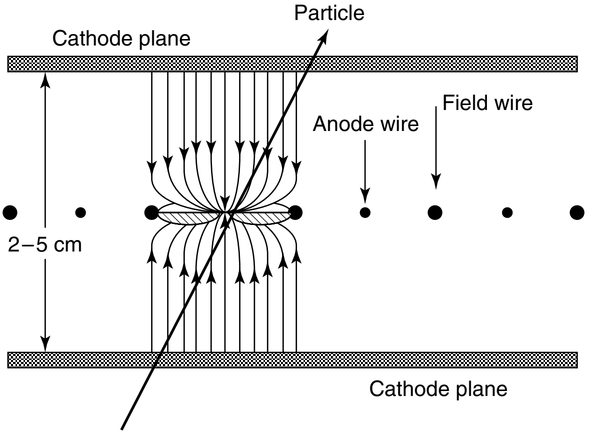

Fig. 23.4 The multiwire proportional chamber (MWPC).

cathode. The electrons generated in the avalanche result in a sharp current pulse followed by a steady decay because of the induced current from the receding positive ions. It is important to notice that the collection time of electrons induces a very small pulse on the wire since the induced charge is proportional to the potential drop experienced by the moving charge and, for electrons, it is only a minute fraction of the total applied potential difference. In contrast, the heavy positive ions have to cross the entire anode–cathode distance, and it is their motion that induces most of the observed pulse. The motion is fast close to the wire, because of the intense electric field, and slow after a distance of a few tens or hundreds of microns.

The resolution time of a proportional counter, that is, the accuracy with which one can ascertain the initial time of the ionization process, is equal to the fluctuations in the time required for an electron liberated in the gas to reach the multiplication region. It may be of the order of 0.5 microseconds for a counter of 10-mm diameter. This resolution time is much larger than that reached by scintillation counters.

In planar geometries, sense (anode) and field (shaping) wires are interspaced at regular distances (in the order of millimeters) between an upper and lower cathode plane (Figure 23.4). This arrangement builds individual and isolated detection segments with a sense wire at the center. The cell size, also known as the *wire pitch*, determines the potential accuracy of the detector. In such planar geometries, an ionizing event can be measured with an accuracy of 10^{-2} times the wire spacing. This is done by using the values of the current pulses measured from neighboring field wires to construct a Gaussian envelope, the peak of which lies at the position of the ionizing event. To obtain information *along* the wire in the same chamber, two methods are most commonly employed in MWPCs:

1. *Cathode segmentation*: if the cathode surface of the detector is divided into strips or pads along the wire, the charges induced on individual cathode segments can be measured as functions of distance from the electron-wire impact. The mutual sharing results in a Gaussian-shaped distribution whose peak position describes the impact point with very high precision (order of tens of microns). This method, however, requires adequate granularity and yields a large number of electronic channels. This property is essential for the imaging of soft radiations, such as X-rays or neutrons, when the two coordinates have to be determined from a single totally absorbing interaction.
2. *Charge division*: if a resistive alloy (several kiloohms per meter) is used for the sense wire, signals detected at *both* ends of the wire will suffer different attenuation depending on the distance traveled. The charge asymmetry can then be used to determine the avalanche impact point on the wire. The precision of this method crucially depends on the gain (signal/noise ratio (S/N)) and is typically 1% of the total wire length.

MWPCs have shaped more than three decades of particle tracking. No other detector has ever acquired the same versatility, experience, and confidence in operational safety, even at present system standards. In maintaining the basic operating principles they have gradually paved the way to more elaborate and sophisticated devices that will be discussed in the following sections.

For further discussion, see Charpak *et al.* (1979) and Walenta (1983).

23.2.1.3 The Drift Chamber

The drift chamber is an extension of the proportional wire chamber in which the position of the ionizing event normal to the plane is found by examining the drift time of the electrons. This is done by using an external triggering device to start a clock and exploiting the fact that the electrons have constant drift velocity until they enter the nonuniform field region close to the sense wires. The signal, which is proportional to the ionization of the track segment as projected on the receiving sense wire cell, stops the clock.

Most drift chambers operate with the drift (E) field oriented transverse or parallel to the direction of a magnetic bending field (B). Therefore, nonparallel E and B fields strongly influence the velocity and direction of drifting electrons, usually leading to loss of efficiency and resolution (Schmidt, 1980; Atac *et al.*, 1986). The time resolution of such a chamber also depends on how much the electrons diffuse away from the ionization cluster while they undergo drifting, which in turn depends on the magnetic field and combined electric and magnetic effects. However, choosing suitable gases (fast or slow) in combination with high drift fields can restore chamber performance.

Planar Drift Chambers A typical drift-chamber cell is shown in Figure 23.5. Using inexpensive electronics, which permits reaching an accuracy of the order of 1 nanosecond in the measurement of the drift time (corresponding to an order of 100 μm for the position of the initial electron), it is easy to reach the same spatial resolution as that the wire planes achieve in the proportional chamber. The drift distance can also be large (of the order of 10 cm), which reduces the need for large numbers of sense wires, helping to cut the cost of such detectors.

Large planar chambers have dimensions of 163 cm × 556 cm (width × length) (Adeva *et al.*, 1990), and large areas of up to 600 m^2 (Aarnio *et al.*, 1991) have been instrumented. The spatial resolution attainable with large area chambers is

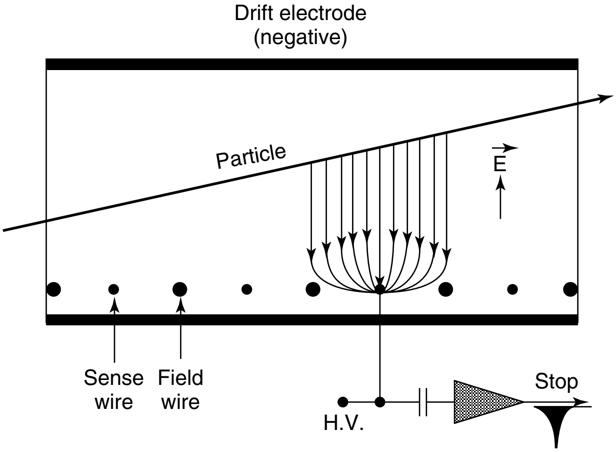

Fig. 23.5 The drift chamber.

mostly limited by mechanical tolerances in positioning wires (100–300 μm) and by the sagging of wires under their own weight.

For further discussion see Breskin *et al.* (1975) and Sauli (1977).

Cylindrical Drift Chambers Solenoidal magnetic fields around the beam pipe are usually used in colliding-beam experiments, which necessitate cylindrically symmetric layers of drift cells. The wires generating the E-field run parallel to the B-field or have a small stereo angle with respect to the B-field axis; field wires that are parallel to each other surround a single sense wire. Cylindrical drift chambers were and still are widely used in colliding-beam experiments like BABAR (Sciolla, 1998) and BELLE (Uno, 1996).

23.2.1.4 The Parallel-Electrode (Plate) Chamber

Parallel-electrode or plate chambers produce uniform electric fields in which electron multiplication can take place nonetheless, but it is more difficult to achieve high gains with this type of detector without the strong radial fields created by wires. The gain of such a detector is proportional to an exponential function of the distance from the ionization point to the anode. The result is that this type of detector has been preferred for particles that do not require high gains (i.e., strongly ionizing particles). However, for average gas gains of 5×10^4 over a 1-mm gap, an efficiency of 90% for minimum-ionizing particles (MIPs) can be maintained. Moreover, these chambers have a fast response and an excellent time resolution of a few nanoseconds, since all electrons from an avalanche will arrive at the anode at the same time, eliminating the time-dispersion characteristics of the wire chamber, in which the charge multiplication is confined to a small region near the wire (Figure 23.6). As a result of this, the parallel-plate detector can sustain very high rates of charged particles (up to $10^7\,\text{cm}^{-2}\,\text{s}^{-1}$) and, because of its highly polished conducting surface, will provide radiation resistance 100 times larger than conventional wire chambers. This, combined with geometrical flexibility and low-production costs, makes the device

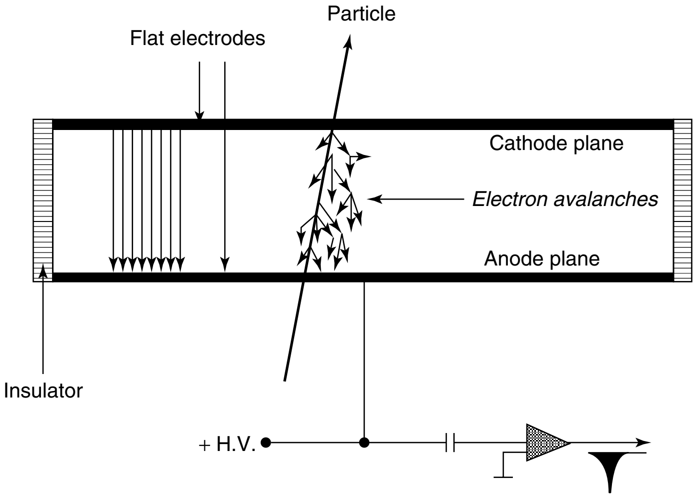

Fig. 23.6 The parallel-plate chamber.

suitable for operation at high luminosity and large backgrounds, such as the forward regions of detectors at hadron colliders.

23.2.1.5 The Multistep Chamber

Parallel-plate counters have experienced a renewal of interest for two reasons: the introduction of multistep structures (Figure 23.7), and the fact that this structure is most favorable for the imaging of avalanches from light emitted by some vapor additives in the counter gas.

The multistep chamber allows the use of more than one stage of gas amplification: a wire grid is used as the anode for the first stage of amplification, where the electrons from the avalanche are extracted and transferred to a second parallel-plate structure where they start a second round of avalanches. This technique can achieve gains of 10^6 or even 10^7, with fewer secondary effects such as sparking at the anode, which produces undesirable ultraviolet radiation or positive ions. This high level of gain easily allows the detection of a single electron, making this type of detector ideal for measuring weakly ionizing particles and imaging vacuum ultraviolet photons emitted by Cherenkov radiators.

For further discussion, see Breskin *et al.* (1980), Bouclier *et al.* (1983), and Charpak and Sauli (1984).

23.2.1.6 The Time Expansion Chamber

The internal structure of the time expansion chamber (TEC) is very similar to that of the MWPC, but the principle of operation is slightly different (Figure 23.8). The electrons drift much more slowly in the drifting region than in the multiplication region. Usually, these two regions are separated by another wire grid held at ground. Using this technique, it is possible to improve the resolution dramatically, since there is a much longer time interval between successive ionized clusters. The mean drift-time interval from subsequent single-ionization clusters of a relativistic particle in the TEC can be made large compared to the width of the anode signal to allow the recording of the clusters separately. In other detectors, these usually appear as one long ionized track and cannot be resolved because they arrive too quickly. Tracks that are parallel to the wire plane are resolved by reducing the wire spacing. The result is that one can distinguish individual ionized clusters as opposed to track segments made up of many clusters. Basic ionization phenomena and drift properties can be measured at the single-electron level.

The problems associated with this type of chamber arise from the relatively long drift time of some of the clusters, which will tend to fade out through diffusion and electron capture by electronegative impurities at the parts per million levels, for example, oxygen. However, in TEC chambers, a "cool" gas is used giving a low drift velocity ($v_d \sim E/p$) and resulting in low diffusion of $a/x^{1/2} \sim 100\,\mu\text{m cm}^{-1/2}$. The effect of diffusion can be further reduced if, instead of measuring the arrival of the first electron (leading-edge discrimination), the centroid of the nearly Gaussian electron cloud of n electrons can be measured. In that case, one ideally obtains $\sigma = \sigma_0/n^{1/2}$,

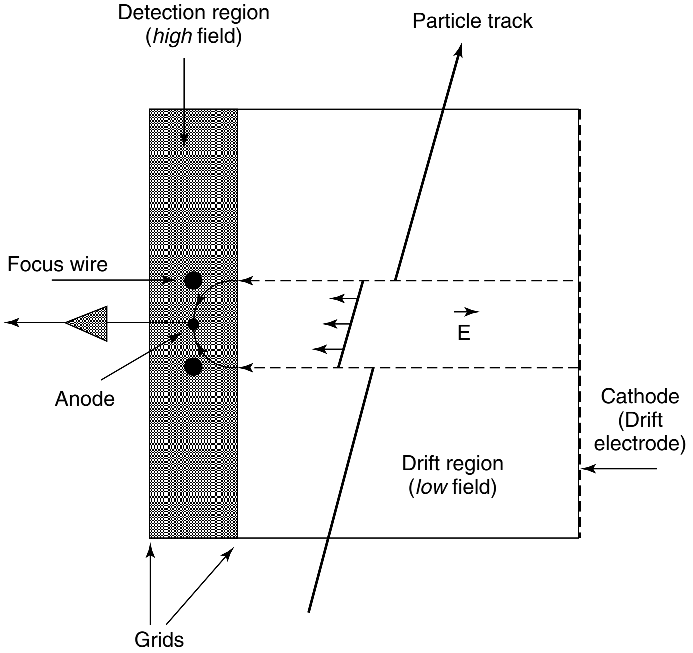

Fig. 23.8 The time-expansion chamber.

where σ_0 is the single-electron diffusion. The transition from the low-field to the high-field region is also a point of concern. The resulting deformation of the arriving electron cloud by the converging field lines in the amplification region can normally be sharpened by altering the choice of gas, chamber geometry, and applied voltages so as to define a narrow amplification region.

For further discussion, see Walenta (1979) and Anderhub *et al.* (1985).

23.2.2

Proportional Detectors for High-Rate Applications

For proportional gas detectors to cope with very high particle rates (i.e., $>10\,\mathrm{MHz\,cm^{-2}}$), the detector cell area must be sufficiently small to avoid signal pileup (Walenta, 1983). This effect is further enhanced by the long drift times of electrons and the very low mobility of positive ions generated in the charge avalanche. Unfortunately, in attempting to achieve very short drift times, the drift volume of gaseous chambers cannot be made arbitrarily thin, because the ionization of gas atoms by charged particles proceeds via a nonuniform clustering process. This limits the efficiency and operation of any gas-filled detector. On the other hand, positive ions copiously produced at the anode migrate to the cathodes at a speed more than a thousand times slower than electrons. Their presence in the drift space reduces the effective fields. The effect of this is twofold: a change of drift velocity for electrons and a reduction of the amplification field near the anode.

The best way to overcome these drawbacks is to reduce the detector cell size to submillimeter dimensions. Fast gases with electron drift velocities of more than $100\,\mathrm{\mu m\,ns^{-1}}$ can help for certain (nonmagnetic) applications as well. However, these gases operated in a magnetic field face the problem of large drift angles for electrons subject to the Lorentz force (Atac *et al.*, 1986; Schmidt, 1980).

23.2.2.1 Micropattern Gaseous Detectors

Modern photolithographic technology has enabled a series of novel micropattern gaseous detector concepts, revolutionizing cell size limits. By using a smaller feature size compared to classical gas counters, these detectors offer an intrinsic high rate capability (fine pitch and fast collection of positive ions) and an excellent spatial resolution ($\sim 30\,\mathrm{\mu m}$) (Titov, 2007).

For further discussion, see Sauli and Sharma (1999).

The Microstrip Gas Chamber (MSGC) Microstrip chambers are, as the name implies, made of very thin, narrow, conducting strips that lie on a thin and flat glass or ceramic substrate similar to printed circuit boards (PCBs). For more ‘‘flexible’’ applications, plastic foils made of Kapton or Tedlar with similar strip designs have been shown to work satisfactorily in nonplanar, say cylindrical, detector geometries (Bouclier *et al.*, 1992b). These strips, whose pitch is $\leq 200\mathrm{\mu m}$, replace the anode and cathode wires in the traditional MWPC, which normally uses much larger wire separation. Similar to the induction drift chamber, the drift region of this detector lies between these strips and the cathode plane (2–5 mm above) as shown in Figure 23.9. The strips are formed by electron-beam or photolithography, which can give a spatial accuracy of $0.1\,\mathrm{\mu m}$ for the position of the strips. Despite a modest potential difference of 200–500 V between the anode and cathode strips, a very high anode field of $100\,\mathrm{kV\,cm^{-1}}$ is produced (Florent *et al.*,

Fig. 23.9 The microstrip gas chamber.

1993). Apart from the close separation of electrodes, this must be attributed to the edges of the strips and the high dielectric constant of the insulating substrate. Thus, almost the entire gain is established between the anode and cathode strips with almost no effect from the upper cathode plane. The result is a very homogeneous proportional gain ($\leq 10^4$) giving rise to an excellent energy resolution (12% FWHM for 6-keV photons), and a high rate capability ($\geq 10^7$ events/(cm^2 s^{-1})) due to the short drift path of the positive ions.

The small detection cell lends itself to another important feature of this chamber: spatial resolution. In the classical readout mode, only the anode strips are read out, resulting in a modest space resolution comparable to the cell size divided by $\sqrt{12}$, that is, $\approx 60\,\mu$m at 200-μm cell size. A more elaborate method makes use of the induced signal on the field or cathode strips next to the signal-producing anode strip (cf. Section 23.2.1.2). Using carefully calibrated analog electronics, the relative charge sharing between the two cathode strips allows a weighted interpolation inside the cell width with a precision of better than 30 μm. It should be noted that the resolution of this detector is spoiled by angular tracks, where the charge is deposited over several detection cells (Angelini *et al.*, 1992).

To exploit the full measuring potential of microstrip gas chambers (MSGCs), the back electrode of the substrate (see Figure 23.9) can also be segmented into strips or pads of any suitable shape, which, in analogy to silicon double-sided detectors (refer to Section 23.2.4.1), can be used for the readout of the second hit coordinate. The capacitive coupling of the anode signal into the back plane is achieved by placing the back electrodes into close proximity (separated only by an insulating SiO_2 film of ~1 μm) to the front (anode–cathode) plane (Angelini *et al.*, 1993b). In these so-called double-sided MSGCs, the back-plane potential not only ensures an optimum field configuration for avoiding charge buildup (as for single-sided MSGCs) but also plays an essential role in the gain mechanism because of its closeness to the anode.

Gases with high cluster statistics and drift velocity must be chosen for operation in high-rate environments. Two gases that simultaneously satisfy these constraints are dimethyl ether (DME)-CO_2 (60 : 40) and Xe-DME-CO_2 (30 : 30 : 40). Efficiencies are maintained at nearly 100%, even for high discriminator thresholds ($\geq 5 \times$ noise level). Under operating fields close to $10\,\mathrm{kV\,cm^{-1}}$, these gases reach drift speeds of $70\,\mu\mathrm{m\,ns^{-1}}$.

Early test samples operated at low rates have shown significant drops in gain (>30%) within a few hours (Figure 23.10), most likely due to surface charging as a consequence of the high surface and bulk resistivity of the detector substrate (Bouclier *et al.*, 1992a). The applied potentials on the substrate favor the depletion of charge carriers within the bulk, thus further increasing the resistivity of the material. By choosing substrates of low bulk resistivity (i.e., $10^{10}\ \Omega\,\mathrm{cm}$), this effect can be avoided or substantially reduced.

MSGCs exposed to very high rates of ionizing radiation experience flux-dependent dynamic gain modifications. As in the

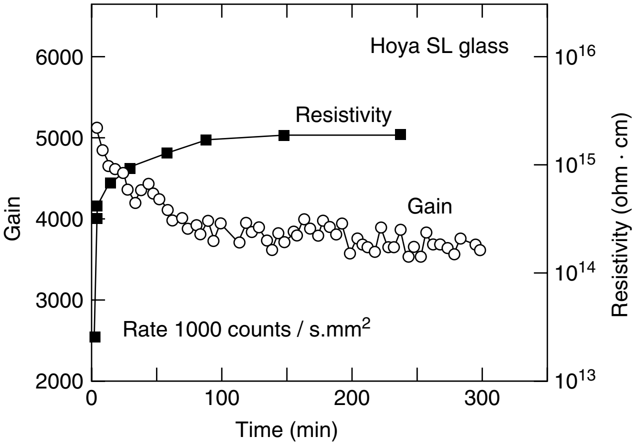

Fig. 23.10 Gain drop in a microstrip gas chamber after turning on the voltage and simultaneous rise in bulk resistivity for a substrate made of Hoya SL glass.

case of spontaneous charge buildup, these can be avoided by a proper choice of a low-resistivity support and suitably chosen bias voltages. Despite gain changes, the detectors can be safely operated at fluxes up to $10^8\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ (Bouclier *et al.*, 1993). More serious is the phenomenon of aging in MSGCs as observed by Bouclier *et al.* (1992a) leading to an unrecoverable loss of performance due to permanent damage of the electrode area. The mechanisms seem to be comparable to those observed in ordinary proportional chambers. Therefore, similar precautions must be taken in the selection of material and counting gases with very low impurity concentrations.

The hadron-electron ring accelerator (HERA)-B experiment has used several hundred MSGC plates as part of the inner tracking system. Despite their impressive performance, the MSGC turned out to be easily damaged by discharges caused by imperfections in the photolithography or induced by heavily ionizing particles destroying the fragile electrode structure (Bagaturia *et al.*, 2002).

For further discussion, see Oed (1988), Angelini *et al.* (1991), Angelini *et al.* (1993a) and Sauli and Sharma (1999).

MICRO-MEsh GASeous structure (Micromegas) The MICRO-MEsh GASeous structure (Micromegas) is miniaturized from a very asymmetric two-stage parallel-plate avalanche chamber (Giomataris *et al.*, 1996). The detector consists of a thin metal grid (micromesh) stretched at a very small distance, 25–150 μm, above a readout electrode (strips/pads of conductor printed on an insulator board), shown in Figure 23.11 (Colas *et al.*, 2004). With a very high field applied across the gap, typically 50–70 $\mathrm{kV\,cm}^{-1}$, electrons released in the upper drift region are collected and multiplied.

Micromegas has many advantages; some of them are a fast signal, no $E \times B$ effect, a high gain, and a good energy resolution. It also has the capability to naturally stop most of the ions produced in the amplification space. Owing to the very large field ratio between the multiplication and the drift regions (as high as 400 or 500) the electric field lines are very much compressed between the two regions (‘‘funnel’’ effect). However, owing to collisions in the gas, electrons do not drift along the field lines. They diffuse, especially in the multiplication space: the transverse extension σ (standard deviation) of the avalanche due to diffusion is of the order of 10–15 μm, depending on the gas mixture, the electric field, and the gap width. A simulation by GARFIELD of the electron diffusion and the multiplication in the drift and the multiplication gaps is shown in Figure 23.12 (Colas *et al.*, 2004). The size of the electron cloud is much larger than that of the funnel end, but owing to their high mass ions are not submitted to diffusion and drift along the field lines. Assuming that they are emitted with the same distribution as the avalanche, most of them are naturally collected by the micromesh and only the fraction of ions created in the small funnel will flow back into the drift volume.

Fast signals (≤ 1 ns) are obtained during the collection of the electron avalanche on the anode microstrip plane. The fast evacuation of positive ions combined with the high granularity of the detector provides a high rate capability. Gas gains of up to 10^5 have been achieved (Giomataris *et al.*, 1996).

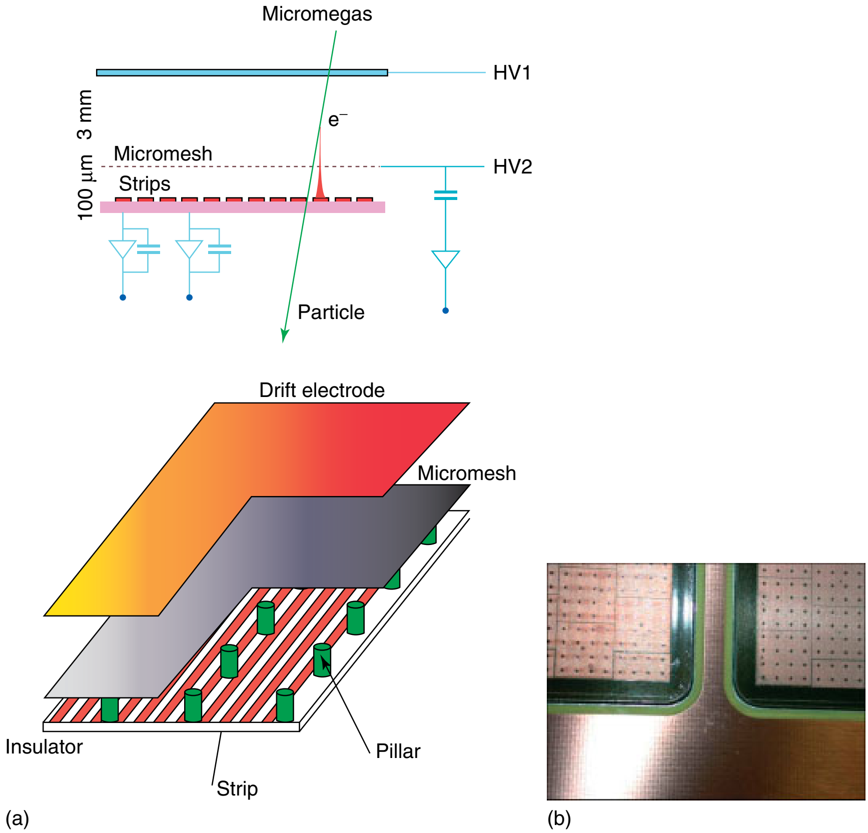

Fig. 23.11 Schematic drawing of the Micromegas detector (a) and photograph of the "Bulk" Micromegas detectors (b) (Giomataris *et al.*, 2006). Pillars of 400-µm diameter every 2 mm are visible (b).

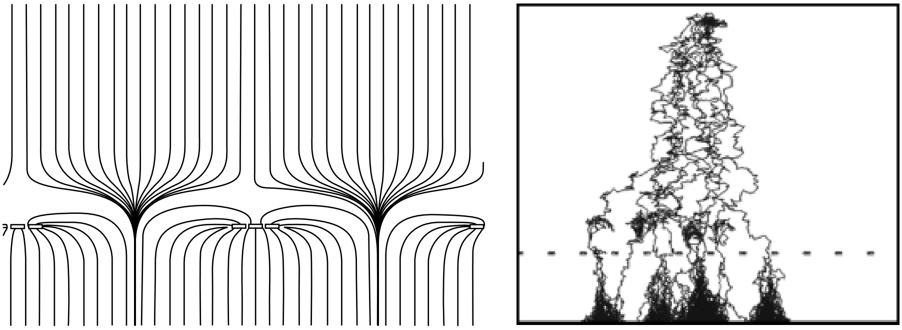
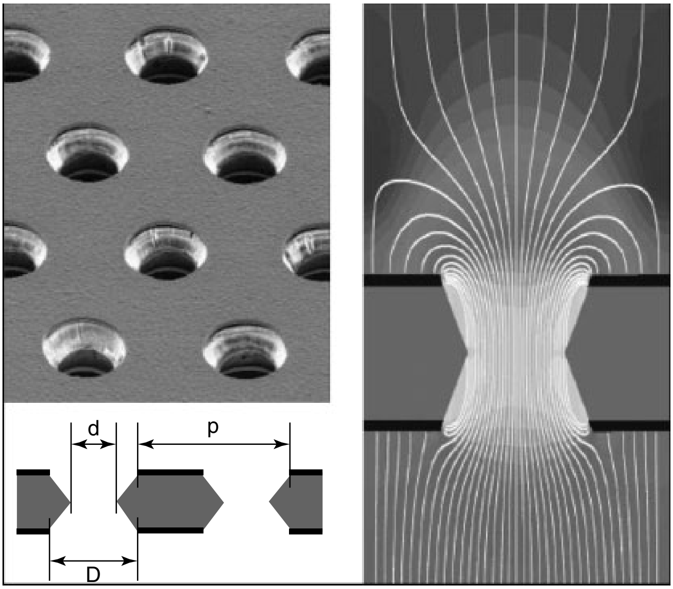
Gas Electron Multiplier (GEM) The gas electron multiplier (GEM), introduced by Sauli in 1996 (Sauli, 1997), consists of a thin, metal-clad polymer foil chemically perforated by a high density of holes, typically 100 mm^{-2} (see Figure 23.13). As shown in panel (b) of the figure, with a suitable choice of voltages, all electrons released by ionization in the overlying gas layer are sucked into the holes, where charge multiplication occurs in the high electric field (50–70 kV cm^{-1}). Most of the electrons generated in the avalanches transfer into the lower region; the GEM foil acts as a charge preamplifier, preserving the original ionization pattern to a large extent. The gain is a property of the GEM structure and is only mildly affected by the external fields, considerably relaxing the mechanical requirements. The GEM manufacturing method, developed at CERN, is a refinement of the double-side printed circuit technology. The metal-clad polymer (Kapton) is engraved on both sides with the desired hole pattern; controlled immersion in a Kapton-specific solvent opens the channels in the insulator.



(a) (b)

Fig. 23.12 Field lines in Micromegas (a) and GARFIELD simulation of electron drift and multiplication (b) (Giomataris *et al.*, 2006).



(a) (b)

Fig. 23.13 (a) Electron microscope photograph of a GEM in standard geometry ($p = 140$-μm pitch, $D = 70$-μm outer diameter and $d = 60$-μm inner hole diameter). (b) The plot of the electric field lines illustrates that electrons are guided into the holes and undergo proportional gas amplification in the locally strong electric field (Kappler *et al.*, 2004).

A unique property of the GEM detector is the complete decoupling of the amplification stage (GEM) and a simple PCB readout electrode, which operates at a gain of 1 and serves only as a charge collector. This offers some freedom in the optimization of the anode readout structure, which can be made of pads or strips of arbitrary pattern.

The maximum gain achievable with the GEM electrode depends on the thickness of the polymeric support, the diameter of the holes, the gas mixture, and the applied voltages. Proportional gains up to 10^4 have been achieved for single GEM devices. Cascading amplifying elements in a double or triple GEM (Figure 23.14a) can produce gains well above 10^5 (Figure 23.14b,) (Benlloch *et al.*, 1998a; 1998b, Büttner *et al.*, 1998).

Single and double GEM detectors with PCB readout have been extensively tested in the laboratory and in particle beams (Bressan *et al.*, 1999). Figure 23.15 shows the large efficiency plateau and the position resolution as a function of voltage obtained with a double GEM device. The signal detected on the strips is entirely due to the electrons, without a slow ion tail, and is typically a few tens of nanoseconds wide for a 1-mm-wide gap.

GEMs can also be easily bent to form cylindrically curved ultralight detectors, as preferred for inner tracker applications (Bencivenni *et al.*, 2007). Controlled etching of GEM foils (decreasing the thickness of the copper layer from 5 to 1 μm) allows to reduce the material budget in triple GEMs to $1.5 \times 10^{-3}\, X_0$, which is about one half of a 300-μm-thick Si-microstrip detector (Bondar *et al.*, 2006).

For further discussion, see Sauli (2004).

23.2.2.2 The Straw-Tube Chamber

As the name implies, straw-tube detectors are long (≥1 m) cylindrical chambers with a central wire for charge collection (Figure 23.3). Closely resembling the classical Geiger–Müller tube in basic geometry, they differ in size and operational mode. The radial size of a few millimeters (diameters mostly between 4 and 6 mm) is chosen to employ the detector in high-rate environments. Correct choice

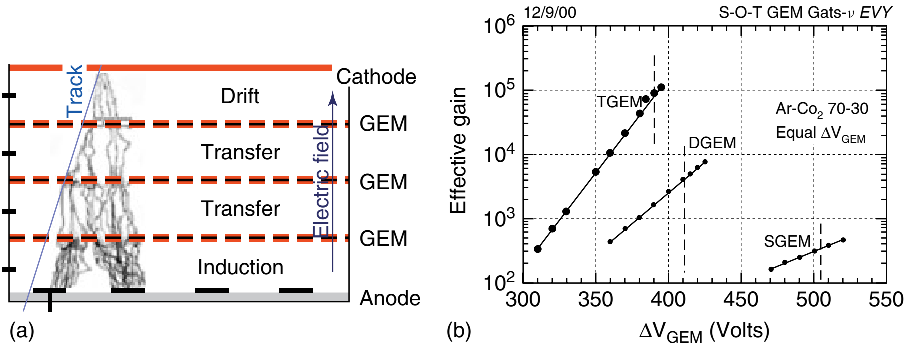


Fig. 23.14 Schematic drawing of the triple-GEM detector (Titov, 2007) (a) and (b) the gain (full curves) and discharge limits on exposure to alpha particles (dashed lines) of multiple GEM detectors (Sauli, 2004).

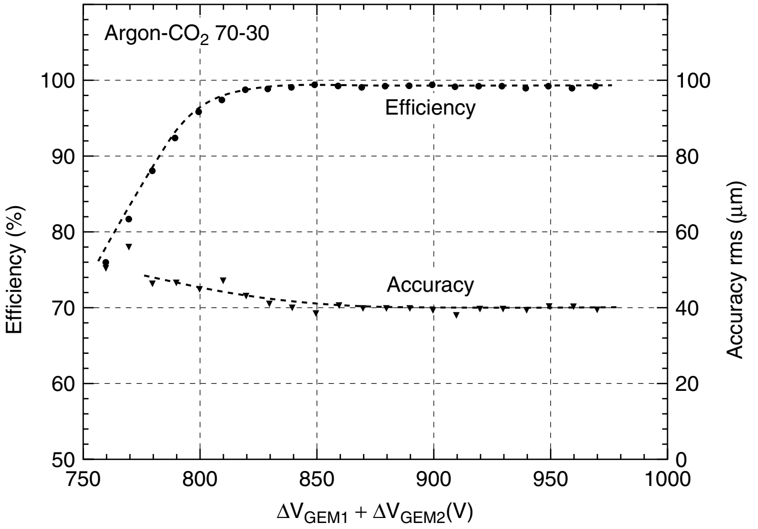

Fig. 23.15 Efficiency and position accuracy for minimum-ionizing particles measured with the double GEM plus printed circuit board detector, as a function of total potential difference applied to the multipliers, $\Delta V_{GEM1} + \Delta V_{GEM2}$.

of gas and electric field makes it work as a proportional counter that is fast, simple, and relatively radiation hard while not sacrificing the good spatial resolution ($\leq$100 μm) derived from electron drift time. Straws can equally well be used to form detector modules or layers in a geometry dictated by other experimental components (Figure 23.16). Typical problems encountered in long (>1 m) straws are the precise positioning of the sense wires and gravitational sag.

Straw-tube chambers have been widely used as vertex detectors (Frautschi *et al.*, 1991) and are being used as tracking detectors at the hadron colliders, Relativistic Heavy-Ion Collider (RHIC) and LHC. In comparison to the previously discussed microcell proportional chambers, straw tubes are still large-surface devices that benefit from high drift velocities and simple construction.

23.2.3
Gaseous Detectors in Nonproportional Mode

If, in a gaseous detector, the electric field is above a certain critical value the ultraviolet photons emitted in an avalanche will have sufficient energy to generate further ionization elsewhere in the chamber. This is determined by the choice of wire diameter and the gas composition in the chamber. If the appropriate gases (i.e., with a reduced concentration of organic quencher) that do not impede the propagation of the photons are used, then secondary avalanches can occur far from the initial one.

23.2.3.1 Limited Streamer Mode

In this mode of operation, avalanches occur at the wires but are not confined and extend *radially* out from them to form

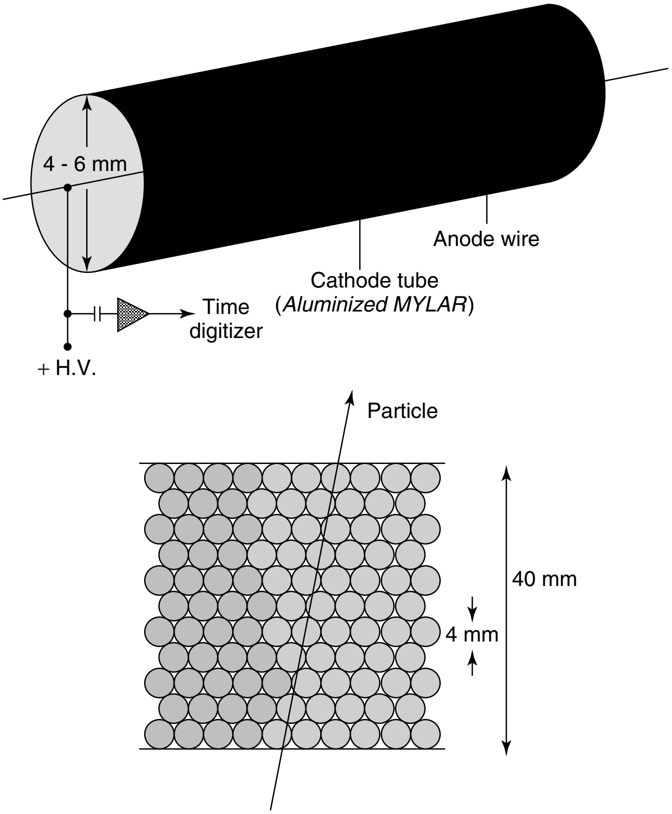

Fig. 23.16 A single straw tube and a straw-tube detector.

"streamers." However, the electric field is not high enough for a complete ionized channel to be formed between anode and cathode, which would lead to an unwanted spark. Depending on the geometry of the chamber, the streamer can finish close to one face or two streamers may be formed on neighboring wires that do not quite meet each other. This method of detection leads to "fast" pulses, which are 100 times larger than in the proportional mode of operation. However, the locally high concentration of positive space charge causes the effective field in the avalanche region of the wire to drop so low that during the migration of the positive ions toward the cathode, charge multiplication cannot occur. These are the typical dead regions formed in limited streamer mode detectors.

See Brehin *et al.* (1975) and Sauli (1977).

23.2.3.2 **The Gaseous Pixel Chamber**

The pixel chamber is based on etched PCBs instead of wires, using a small-scale modular approach, making it useful for moderate rate applications in which detector occupancy would not allow the use of large wire chambers. The accuracy of measurement is determined by the film printing and etching process used on the board; this means that relatively cheap chambers can be constructed with high levels of

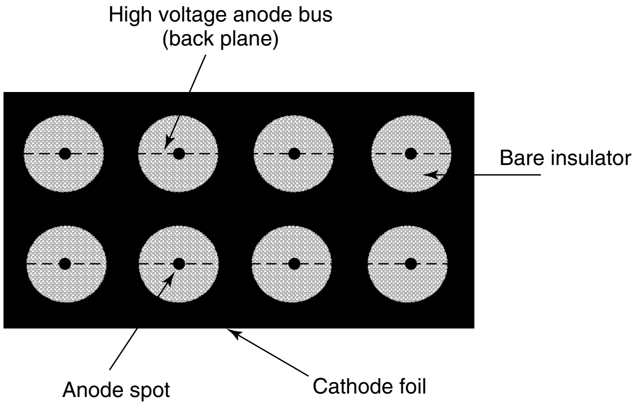

Fig. 23.17 The gaseous pixel detector (top view).

accuracy on a large scale. The chamber is constructed from a thin metal foil, used as a cathode plane, with small holes for the anodes, overlaid on a circuit board as shown in Figure 23.17.

A second foil is employed 8 mm above the anode–cathode plane, on which are mounted cathode strips for field shaping, as shown in Figure 23.18. These strips are linked together in one direction in the detector plane and the anode points are linked in the other direction in order to give a two-dimensional picture of each hit. The third spatial coordinate is obtained from the electron cluster drift time as determined by the choice of chamber gas, as in other types of chambers.

For further discussion, see Antreasyan *et al.* (1990).

23.2.3.3 The Geiger–Müller Counter

When one is using (‘‘counting’’) gases with essentially no photon-absorbing additives, electron avalanches will copiously produce photons that are not suppressed and, consequently, will lead to more charge multiplication along the wire (in contrast to radial streamers). This process will continue until the entire region is saturated with ions, causing the electric field near the wire to drop sufficiently to prevent further avalanches. The result is a charge at the output of the detector of almost constant value for every particle entering the detector. This tends to make counting particles easy, and this type of chamber was used extensively in the past for such measurements. The disadvantage of this counter is the long busy time experienced (1 microsecond approximately), which is why it has been superseded, for the most part, by solid-state devices. The Geiger–Müller counter can also be used in proportional mode. In this mode, the dead time is the same but is limited to a region of about 0.1-mm length instead of extending over the full length of the wire.

For further discussion, see Charpak and Sauli (1971).

23.2.3.4 The Spark Chamber

This chamber is constructed in a parallel-plate configuration, which produces a uniform field throughout the gas volume. A spark is caused as follows: an ionizing particle passes through the chamber and ionizes a track; at some stage during this process, the particle causes a trigger to be

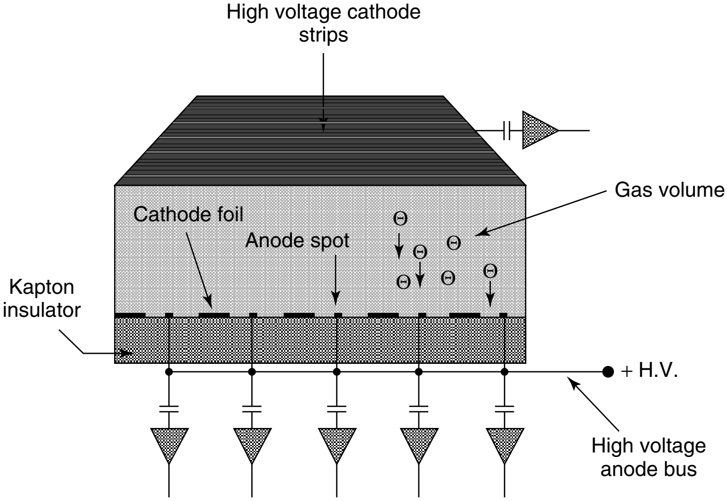

Fig. 23.18 The gaseous pixel chamber.

set that rapidly raises the voltage across the chamber to a breakdown level, suitable for discharges anywhere in the chamber. At this point, a complete ionized channel is formed from anode to cathode leading to a rapid (nanosecond) discharge, or spark. This results in a large number of positive ions in the detector, which are removed by the application of a clearing field while the chamber is waiting to be triggered again. Spark chambers are extremely robust and easy to handle. Because of the high spark energy, simple and low-cost electronics can be used. They are, however, limited for use at very low-rate particle detection.

23.2.3.5 **The Resistive Plate Chamber (RPC)**

The operating principle of the resistive plate chamber (RPC) differs greatly from that of the classical spark chamber although it is one itself. Using flat electrodes with high resistivity allows the operation of this type of spark detector in a continuous, that is, nontriggered, mode. The violent discharge that is produced by an ionizing particle does not propagate nor continue for long because of the instant *local* breakdown of the electric field at the point of impact. The resistivity of the electrode material prevents an immediate charge rebuildup within an area of typically $0.1\,\mathrm{cm}^2$ around the spark center. Furthermore, gases with very high photon-absorption cross section (quenching) must be used to avoid secondary sparks induced by UV photons generated in the first spark.

The immediate advantages of the RPC lie in the ease of construction (costs) and excellent time resolution (<1 nanosecond), pulse rise time (3–4 nanoseconds), and pulse duration (about 10 nanoseconds). The generated pulses are so large that they induce sufficient charge (300–500 mV) on so-called pickup electrodes exterior to the high field electrodes. These pickup electrodes can be arranged in x and y giving the detector spatial granularity and modularity (Figure 23.19). This permits use of low-cost amplifiers for large-scale operation as, for example, outer muon

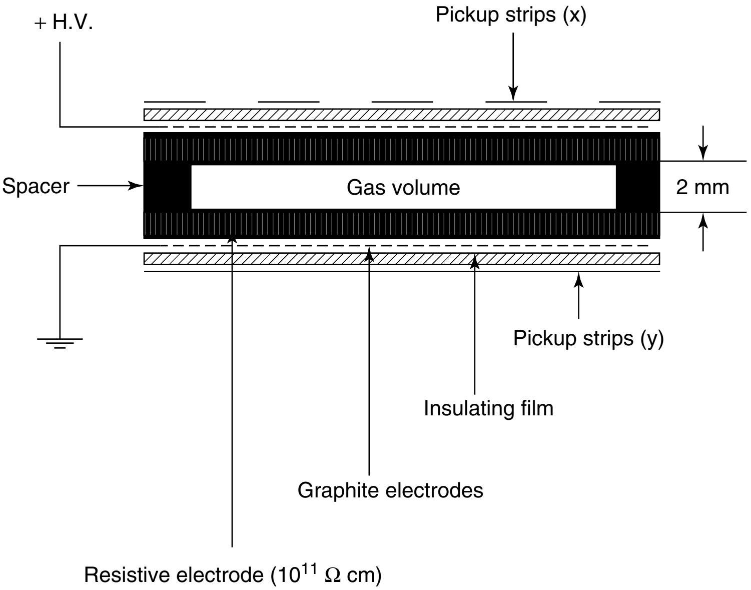

Fig. 23.19 The resistive plate chamber.

detectors in colliding-beam experiments at the LHC (CMS, 1992).

It must be noted, however, that in spite of the fast response of the chamber the rate capability is largely limited by the field restoring time. Resistive plate detectors therefore operate only at rates not exceeding 100 Hz cm^{-2}.

For further discussion, see Cardarelli and Santonico (1981) and Cardarelli *et al.* (1988).

23.2.4
Solid-State Detectors

Solid-state or semiconductor detectors are based on a reverse-biased n–p semiconductor junction in which a carrier-free zone, the depletion zone, is created. In this way, they are used as ionization chambers. Charged particles interacting with the material in this area will liberate electron-hole pairs at the expense of only 3.6 eV (in Si) energy loss per pair, against 30 eV for a gas and 1000 eV for the combination of a scintillator and a photomultiplier. Therefore, compared to gaseous and liquid ionization detectors, larger primary signals and high charge statistics are expected, yielding exceptional performance in energy and position resolution. These detectors have revolutionized fields where the detection of γ-rays played an essential role, like the study of nuclear structure.

Silicon and germanium are the most widely used materials. The latter is mostly used for kiloelectronvolt and megaelectronvolt photon detection, but it has to be operated at the temperature of liquid nitrogen. The energy resolution varies with the energy of the photons. At 6, 60, and 661 keV it reaches 0.15, 3.3, and 4.3 keV (FWHM), respectively. This is 10 times better than what can be obtained with the best scintillator. Silicon can be used at room temperature. It is commonly used in low-energy nuclear physics for the energy loss of particles and their identification (Comiso *et al.*, 1975).

For high-energy physics applications, these detectors can be made very compact, with excellent granularity and precision. They are, therefore, first-choice technologies for today's vertex detection and tracking, predominantly in congested high-rate environments.

23.2.4.1 **The Silicon Sensor**

Silicon has become the most widely used semiconductor material in electronics application today. Its features, quality, and production costs have also made it a nearly ideal candidate for a solid-state detector. The basic detector size is determined by the area available on a 100–150-mm (4–6-in.) diameter wafer. An area less than this is available for the active detector region, which will be subdivided into strips or pads. A convenient choice is dimensions of $\sim 70 \times 56\,\text{mm}^2$ with an active area of $64 \times 51.2\,\text{mm}^2$.

The simplest type of a silicon sensor is shown in Figure 23.20 (Rossi *et al.*, 2006). A large area p^+-implantation is placed in an *n*-bulk. On the backside, an n^+-implantation and an aluminum layer provide an ohmic contact. A positive bias is applied to the backside; the metal electrode on the top is on ground potential. A depletion zone starts to grow from the *pn*-junction into the bulk. This reverse biased *pn*-junction is the basic building block of silicon sensors. It builds up an electric field that collects the signal charge and suppresses the leakage current. An ionizing particle traversing the depletion zone liberates charge, which is collected by the field and can be detected by both electrodes; usually a preamplifier is connected to the electrode on ground potential.

In order to obtain spatial information, one or both electrodes have to be segmented. If the elements of a segmented electrode are approximately rectangular, the detector is called a *pixel detector* (or *pad detector* if the segmentation is coarse): a strip detector consists of largely asymmetric segmented electrodes (e.g., several centimeters long and a few tens of micrometers wide). One of the first examples of pad detectors used for tracking is the UA2 experiment at the CERN SppS Collider (Ansari *et al.*, 1989); H1 at the HERA storage ring at Deutsches Elektronen-Synchrotron (DESY) used large pad detectors in a calorimeter (Fretwurst *et al.*, 1990).

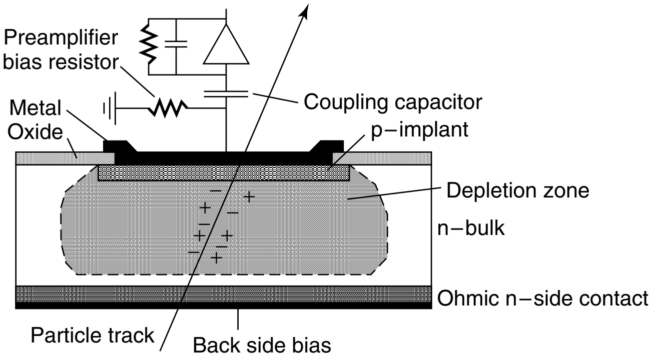

Fig. 23.20 Schematic cross section of a simple silicon pad sensor (Rossi *et al.*, 2006).

23.2.4.2 The Silicon Strip Detector

The most common design is that of a strip detector where thin metal strips are deposited on the p or junction side of the silicon wafer (single-sided readout) (Bencze *et al.*, 1993; Heijne *et al.*, 1980). Ion implantation and photolithographic techniques are used to selectively dope the surfaces of the wafer and to deposit the metallization patterns necessary to extract the signals (Kemmer, 1980). A sketch of a generic single-sided microstrip detector is shown in Figure 23.21. The strips are p^+-implants on n-type silicon, repeated at a pitch p. A voltage is applied between the backside metallization and the strips (Rossi *et al.*, 2006). Perpendicular strips or suitable pad structures on the back plane (n side) of the wafer provide two-dimensional track information (double-sided readout) (Sadrozinski, 1989; O'Shaughnessy *et al.*, 1990; Brenner *et al.*, 1992). Diffusion during charge collection allows interpolation from strip pulse heights. Reading, for example, every strip (20-μm wide) results in a single-track resolution of $\sigma < 3\,\mu\text{m}$, and a double-track resolution of $\sigma < 50\,\mu\text{m}$ (Sadrozinski and Seiden, 1989).

The band-gap energy of silicon is only 1.3 eV. Thus, in a substrate of 300-μm thickness, an MIP generates a signal of ~25 000 electrons, which can easily be interfaced and processed with integrated circuits, sometimes even mounted on the same substrate. Signal collection time is limited by the mobility of the holes, which is roughly one-third of the electron mobility ($0.15\,\text{m}^2\,\text{V}^{-1}\,\text{s}^{-1}$). Most detectors have collected the full charge within tens of nanoseconds. Interstrip capacitance and strip resistance of 6-cm-long strips have little influence on signal quality and signal propagation and are found to be adequate even for operation at the highest particle rates expected at hadron colliders. The effects of radiation on the detector performance (e.g., n- to p-type inversion, bulk damage, and surface charging) impose stringent conditions on the sensor, that is, operating at temperatures in the range of $-5°$ to $-10°$. (Wunstorf *et al.*, 1989; RD-20 1992; Barberis *et al.*, 1993; Aad *et al.*, 2008).

For further discussion, see Lutz (1999).

23.2.4.3 The Silicon Drift Chamber

By making use of the uniform and constant drift velocity of charge in silicon, a simple

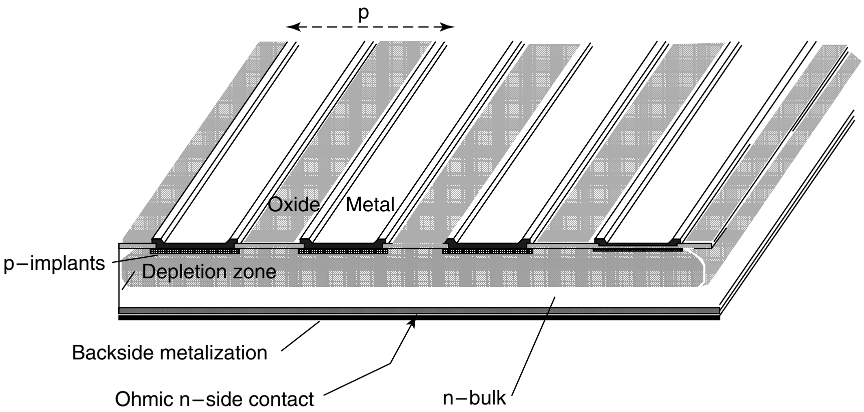

Fig. 23.21 The single-sided silicon strip detector (Rossi *et al.*, 2006).

and low-cost detector can be built from this material providing two-dimensional readout for tracking. This detector employs anode pads for signal readout and junction strips, spaced at 150 μm, for creating a uniform drift field of 150 V cm^{-1} transverse to the bias field (Figure 23.22). The drift velocity within the device is approximately 2 μm ns^{-1}.

One track coordinate is derived from the measurement of the drift time, and the other from anode pad interpolation. Both result in about 20-μm resolution over 4 mm of drift distance. Because of the weak drift field, very pure and uniform doping of the *n*-type Si crystal is needed. Furthermore, this method will result in inferior double-track separation as compared with classical silicon strip detectors with similar strip spacing.

For more information, see Gatti and Rehak (1984, 2005), Gatti *et al.* (1984), Faschingbauer *et al.* (1996), Holl *et al.* (1996), Pandey *et al.* (1999, 2002), Beole *et al.* (2007), and Aamodt *et al.* (2008).

23.2.4.4 **The Silicon Pixel Detector**

Under extreme conditions, such as in high-luminosity hadron colliders, there is such a density of particles that individual tracks cannot be resolved, even using the most granular strip detectors. Particle multiplicities in high-energy jets with opening angles of order 20 mrad are likely to be 30–70 and several thousand charged particles per unit pseudorapidity might be produced in Pb + Pb collisions at the LHC. The pixel detector is a device that precisely detects and recognizes dense tracks in a crowded environment (Campbell *et al.*, 1990; Heijne *et al.*, 1990; Anghinolfi *et al.*, 1992). The sensitive cell size of this detector is reduced to pads or pixels of $100 \times 100\,\mu\text{m}^2$ or less, operated similarly to the silicon strip detector.

Hybrid Pixel Sensor The fabrication of a pixel sensor is very similar to the fabrication of a microstrip sensor, but the implants have a higher segmentation. If the area of the sensing element is below

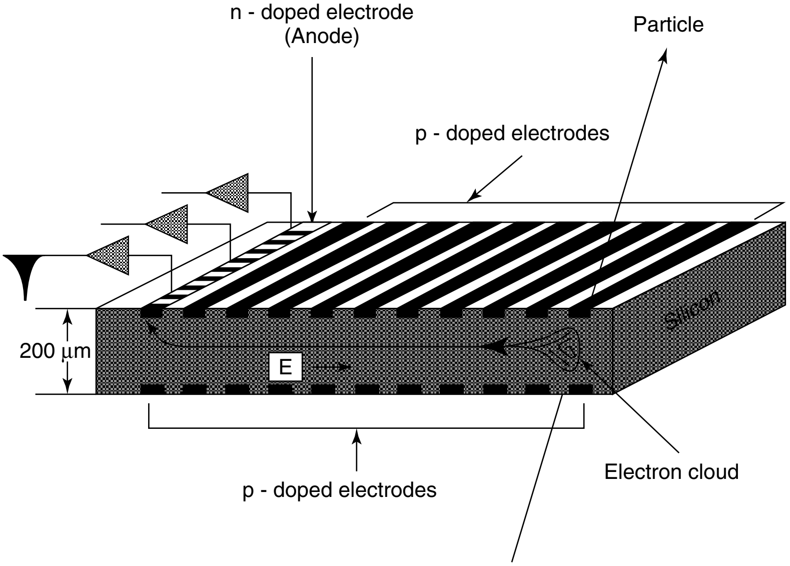

Fig. 23.22 The silicon drift chamber.

1 mm^2 and their number is in the order of 10^3–10^4, the signals cannot be routed to the periphery any longer. This makes a real two-dimensional connectivity to the electronics necessary. The connection between the sensor and the electronics must be vertical and match the sensor dimension and the electronics chip must be very close (10–20 μm) to the sensor (Rossi *et al.*, 2006). Figure 23.23 shows a typical pixel cell, the basic building block of a hybrid pixel detector. The ionizing particle traverses the sensor and generates charges, which will be collected by the electric field and detected on the electrodes. The produced signal is amplified and processed by the electronics chip.

One of the key advantages of hybrid pixel detectors is the low capacitance of the sensing element due to its small dimensions. Each pixel covers a very small area (about 10^{-4} cm^2) over a thin (about 300 μm) layer of silicon, resulting in a very low capacitance (0.2–0.4 pF). Such a low capacitance allows fast signal shaping with very low noise. Noise figures of $200e^-$ for electronics operating at 40 MHz are obtained. The S/N thus exceeds 100 for a fully depleted sensor of 300-μm thickness and an MIP traversing it.

Hybrid pixel sensors are the choice of technology for the vertex and tracking detectors at the LHC. They can be made radiation-hard and provide nonambiguous three-dimensional information with good time resolution and a spatial resolution, which is needed to measure short-lived particles (Aad *et al.*, 2008; Chatrchyan *et al.*, 2008; Aamodt *et al.*, 2008; Augusto Alves *et al.*, 2008).

The Monolithic Active Pixel Sensor (MAPS) The monolithic active pixel sensor is a silicon detector technique that allows to

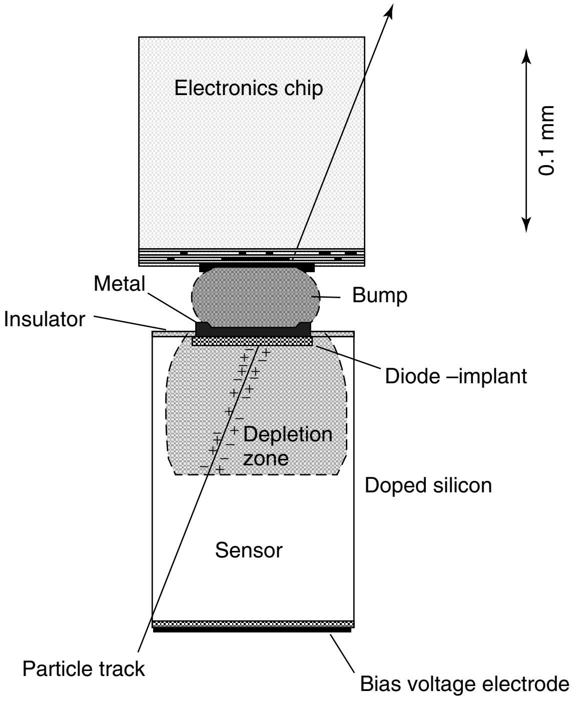

Fig. 23.23 Schematic view of one cell of a hybrid pixel detector (Rossi *et al.*, 2006).

integrate the detector element and the processing electronics on the same substrate (Gornushkin *et al.*, 2002). Commercial CMOS technologies use low-resistivity silicon, which is not suited for charge collection. However, some technologies allow the use of thin (at most 15 μm) epitaxial silicon layers. In a MAPS, a partially depleted thin epitaxial layer of low-resistivity silicon is used as a sensitive detector volume. The charge generated by the impinging MIP, about 80 electron-hole pairs/μm, is collected by an *n*-well/*p*-epi diode, created by *n*-well implantation into the epitaxial layer. The electrons liberated in the epitaxial layer diffuse toward the diode within a typical time of a few tens of nanoseconds. The active volume is underneath the readout electronics, allowing 100% fill factor. Because of the 3 orders of magnitude between the doping levels of the *p*-epitaxial layer and of the p^{++} wells and substrate, potential barriers are created at the region boundaries, which act like mirrors for the excess electrons (Figure 23.24).

This concept has undergone a very rapid development, with much effort concentrated on the MIMOSA (Turchetta *et al.*, 2006) chip, which has completed at least 15 full cycles of chip design since 1999. Noise figures of 10–30 e^- and $S/N > 20$ have been achieved (Dulinski *et al.*, 2003) with spatial position resolutions below 5 μm. The advantage of a fully CMOS monolithic device is its potentially low cost – besides the excellent spatial resolution. The disadvantages are the small signal, the long charge collection time, and the sensitivity to radiation effects, although some progress concerning the radiation hardness of MAPS has been made (Deveaux *et al.*, 2007).

The Depleted Field Effect Transistor (DEPFET) Another approach to build monolithic pixel detectors is to use high-resistivity silicon and to integrate simple electronics circuits (e.g., the first stage of the amplifier of each pixel and some addressing scheme). The signal generation is optimal as large depletion zones and

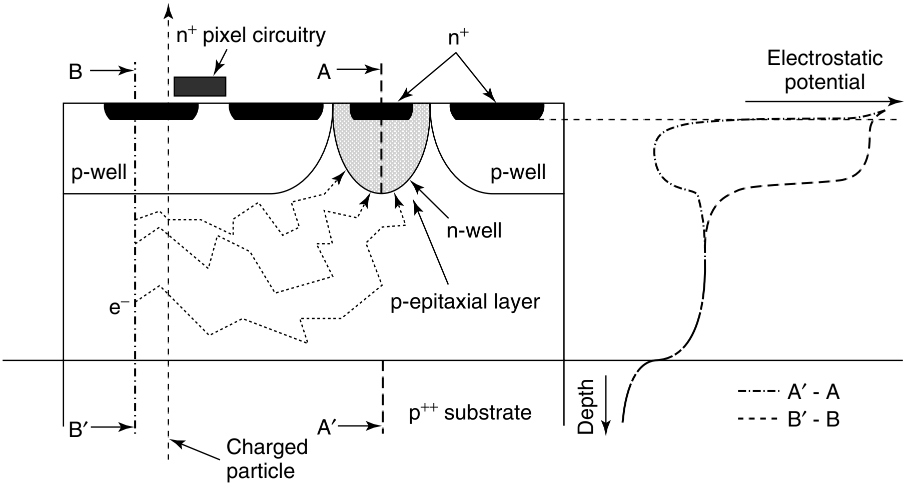

Fig. 23.24 Schematic cross section of a CMOS pixel detector cell (MAPS) (Turchetta *et al.*, 2001).

high electric fields provide fast and efficient charge collection. However, the on-chip signal processing is limited since all design technologies are tailored to low-resistivity silicon. The depleted field effect transistor (DEPFET) structure is one such method to provide both signal detection and amplification (Kemmer and Lutz, 1987; Kemmer *et al.*, 1990; Ulrici *et al.*, 2001). A DEPFET detector and amplification structure is shown in Figure 23.25. A field effect junction is integrated onto a sideward depleted substrate. Sideward depletion provides a parabolic potential (see Figure 23.25b) with a minimum for majority carriers (electrons in the case of n-type silicon) inside the detector volume. This local minimum can be moved toward the top surface right underneath the transistor channel (internal gate) by locally varying the doping concentration (deep n-implant) and by applying appropriate electrical potentials. When a charged particle traverses the detector, it creates electron-hole pairs, the electrons being collected at the internal gate. The transistor channel current, steered by the voltage at the external gate, is now modulated by the collected charge at the internal gate. The collected electrons are eventually removed from the internal gate, for example, by applying a clear pulse to a dedicated contact outside the transistor region. The very low input capacitance ($\approx$ femtofarads) and the *in situ* charge to current conversion result in low-noise figures (a few e^-) (Ulrici *et al.*, 2001). The low-noise feature can be exploited to make very thin sensors ($\approx$50 μm), while still yielding a very good S/N performance and thus allowing a very fast readout.

Silicon-On-Insulator (SOI) A third possibility for a monolithic pixel detector is based on the silicon-on-insulator (SOI) technology. High-resistivity bulk material for charge collection is combined with an electronics layer. By means of a thick buried oxide layer (BOX) in the bulk, the active sensor volume is isolated from layers with CMOS circuitry (see Figure 23.26). Contact through the insulation (BOX) to the sensor substrate is made by vias of p^+-implants, which also form the diodes. The advantages of this pixel detector type are the 100% fill factor, a large signal and a fast charge collection, and the possibility to use NMOS

and PMOS transistors for the readout. A first prototype of a 64 × 64 pixel array with 26-μm pitch has been produced (Arai *et al.*, 2007; Deptuch *et al.*, 2007).

Charge-Coupled Device (CCD) Since the invention of the charge-coupled device (CCD) in 1970 (Boyle and Smith, 1970; Amelio *et al.*, 1970), this technology has had and still has applications in the fields of optical imaging, particle tracking, X-ray detection, analog storage devices, and so on. CCDs are large two-dimensional arrays of highly segmented (very small pixel dimensions below $2 \times 2\,\mu\text{m}^2$) silicon sensors with a very thin active layer (10–20 μm). Their unique advantage for tracking lies in their ability to confine the signal charge within an extremely compact collection volume, and then to transfer the signal packet without loss onto the gate of a very low capacitance on-chip sensing transistor. However, this on-detector multiplexing has its disadvantages: the serial sensing of the signals from a large number of pixels by a single output circuit takes time. CCDs are slow detectors in comparison with "real" two-dimensional detectors where the signals are read out in parallel by a separate output circuit for every detector element, that is, the hybrid pixel detector.

In optical imaging, each pixel is typically supplied with a signal of the order of $10^5 e^-$. MIPs generate a signal in the sensitive layer, which is about a factor 100 smaller, which imposes two major challenges on design and operation of CCDs used for particle tracking detectors. First, there is the requirement of extremely efficient, noiseless transport of the tiny charge packet through possibly thousands of transfers within the imaging and readout regions of the device. The second major challenge is the electronic noise performance of the output circuit and associated signal processing.

Figure 23.27 shows the cross section of a typical device. It consists of a lightly doped epitaxial p layer on a heavily doped substrate, with a $\sim 1\,\mu\text{m}$ n^+ layer on the

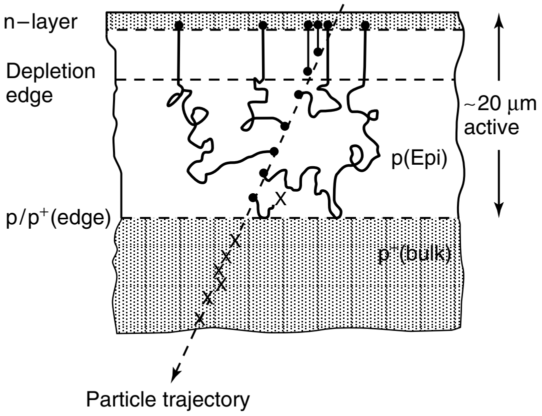

Fig. 23.27 Cross section of a buried-channel CCD structure (Damarell, 1998).

top. The partial depletion of the n^+/p region creates a potential minimum for storage of charge carriers (electrons in this case) just above the depth of the n^+/p edge. Signal electrons generated within the depletion region of thickness of ~5 μm will be transported toward this minimum by drift in the electric field. Minority carriers (electrons) generated in the undepleted p-type substrate will diffuse isotropically. Those that reach the depletion edge will be drawn into the potential energy minimum while those that diffuse to the p/p^+ edge are reflected by a potential barrier due to the thin intrinsic depletion layer and will eventually be collected in the storage region.

Charge is confined in depth by the potential distribution mentioned above. Transversely, charge confinement in the imaging area is achieved by vertical p^+ implants (channel stop regions) and horizontal polysilicon gates, electrically isolated from each other and from the substrate (Figure 23.28). The charge localized in such a way is transferred in parallel down each column toward the output register by manipulating the potentials on the imaging register ($I\Phi$) gates in such a way that the two-dimensional image is preserved. On each I shift, the charge from the bottom row of the image area is transferred into the R register. This row is then read out serially through the output circuit at the end of the R register, after which the next row transfer is made. The horizontal transfer along the R register is achieved by a similar, independent set of readout register ($R\Phi$) gates. The signal charge is then transferred – pixel after pixel – to the output circuit where it modulates the drain current in an FET (Damarell, 1998).

CCDs have been employed as vertex detectors in a fixed target experiment, NA32 (Damerell, 1985), and an e^+e^- collider experiment, the SLD (SLAC Large Detector) experiment (Abe *et al.*, 1997). The use of CCD detectors is ruled out at hadron colliders because the instantaneous rates are excessive and their life expectancy is inadequate owing to their sensitivity to hadronic radiation damage. CCDs are a well-established baseline option for the International Linear Collider (ILC) vertex detector design. However, the readout speed and radiation hardness have to be improved. A major innovation developed for the ILC design is to replace the traditional serial register readout, where the charges from each readout column

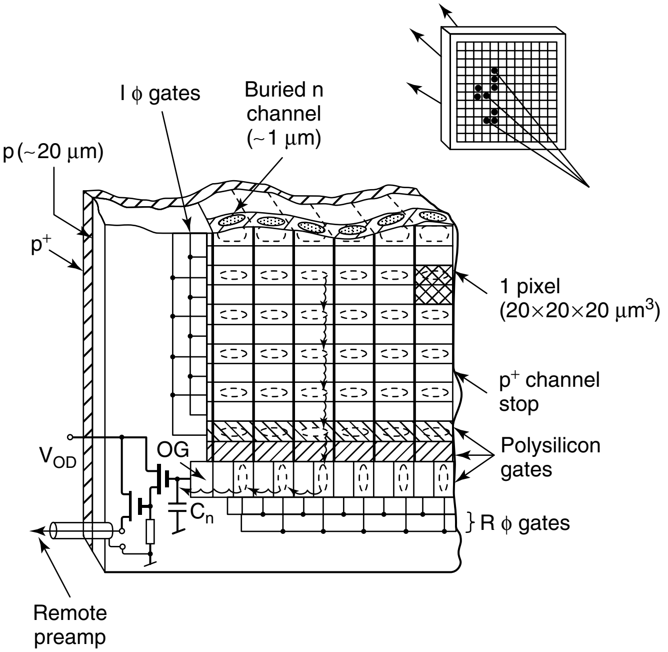

Fig. 23.28 Upper right: Sketch of charge storage in a CCD detector traversed by a number of ionizing particles. Lower left: Corner region of the CCD showing the principal structural features (Damarell, 1998).

are moved toward a readout circuit on the corner, with a column parallel readout, where the readout chip receives analog signals from all columns in parallel (Stefanov, 2005). A recent development of the CCD concept is the *in situ* storage image sensor (ISIS). The design of this detector is tailored to the specific bunch structure of the ILC (1-millisecond-long bunch trains at a rate of 5 Hz) and the beam-related RF pickup (Figure 23.29). The charge is collected at the photogate and transferred to a storage pixel every 50 microseconds during the beam. After 20 samples have been stored, the charge is shifted out for readout like in normal CCD and converted to voltage in the 200-millisecond gap between the bunch trains, completely avoiding the RF pickup. Clock frequency of only 1 MHz, assuming column parallel readout, is required to retrieve all stored charge from the full-scale device (Stefanov, 2006b).

Three-Dimensional Detectors For efficient operation of a conventional (planar) silicon detector, all electrons and holes generated by the incoming radiation have to be collected at the detector electrodes. The detector should be thick enough to generate a sufficient number of electron-hole pairs to get a high S/N and the detector should be fully depleted to collect the generated carriers from the full thickness of the detector. When the detector is exposed to radiation defects are produced in the silicon lattice. Some of these defects are electrically active

and are very efficient carrier recombination centers. The formation of such centers reduces carrier lifetime, and charge collection efficiency deteriorates. Besides, these electrically active centers influence the equilibrium carrier concentration (effective doping) in Si, which results in increasing full depletion voltage and ultimately renders the detectors inoperable. A radical approach to combat radiation damage is to make the electrodes penetrate into the bulk instead of lying on the surface of the sensor. This design has the great advantage of decoupling the drift distance, which governs the radiation hardness properties, from the sensor thickness, which dictates the amount of signal collected. The small electrode separation gives intrinsically fast charge collection, and low depletion voltages, along with the possibility of removing dead regions at the sensor edges.

Three-dimensional detectors (Parker *et al.*, 1997) have electrodes that go all the way through the bulk of the material (Figure 23.30). This allows the electrodes to be positioned much closer together without the need to reduce the thickness of the detector, and thus the active

volume. The close positioning of the electrodes is beneficial for both the full depletion voltage and charge collection efficiency. Indeed, since the depletion voltage depends quadratically on the distance between the electrodes, the effect is dramatic and the full depletion voltage can be decreased to as low as 1–10 V depending on the Si doping (compared to 50–500 V for conventional detectors). The charge collection efficiency improves simply owing to the fact that the generated carriers have to travel a shorter distance to the electrodes, which decreases the carrier collection time (Kenney *et al.*, 1999) and thus less carriers will recombine before reaching the electrodes. Three-dimensional detectors can be fabricated using established techniques that are widely implemented for Si micromachining and porous Si formation: reactive ion etching (RIE) and electrochemical etching (EE) (Pellegrini *et al.*, 2002). Although some parts of the fabrication process are relatively well characterized, the problem of fabrication of the three-dimensional detector poses serious scientific and technological challenges specific to carrier recombination and charge collection.

Recent testbeam results are very encouraging, with efficiencies reaching 98%, and irradiated devices (single-type-column design, only *n*-type columns etched into a *p*-type substrate (Piemonte *et al.*, 2005)) have been characterized with lasers, showing good charge collection efficiency at relatively modest depletion voltages (Eckert *et al.*, 2007).

23.2.4.5 The Gallium–Arsenide (GaAs) Detector

Solid-state detectors are often subject to high radiation fluences because they are located close to the beam-interaction vertex (Groom *et al.*, 1989; Stevenson, 1992). From the physics point of view, they must be placed close to the decay origin of short-lived particles. Therefore, silicon detectors are particularly prone to radiation damage by charged particles and neutrons, resulting, for example, in high-leakage currents from bulk defects in the crystal (Wunstorf *et al.*, 1989).

Gallium–Arsenide (GaAs), as a semiconducting material operated in a similar fashion as silicon, can tolerate higher radiation levels than silicon before undergoing gradual destruction (Smith, 1990). The signal produced by GaAs detectors is, however, inferior to that from silicon by approximately a factor of 2.

23.2.4.6 The Diamond Detector

For reasons of even higher radiation tolerances, diamond crystals have become an attractive alternative to silicon and GaAs devices. For a long time, natural diamond crystals have been found to function as homogeneous conduction counters offering a few unique features for application as tracking detectors. Their major advantages over comparable detection techniques are survivability after radiation exposure to tens of millirads and more than 10^{14} neutrons/cm^2/year, very fast charge collection ($\sim$1 nanosecond) due to roughly equal electron-hole mobility ($0.18/0.12\,\mathrm{m^2\,V^{-1}\,s^{-1}}$), and lower strip capacitance due to different dielectric properties of the crystal. The high resistivity of the crystal lattice ($>10^{12}\,\Omega\,\mathrm{cm}$) as compared with silicon (10^5) reduces leakage currents to negligible levels at high bias voltages allowing saturation velocity of the charge carriers. Unfortunately, high bulk resistivity also leads to polarization effects that, from accumulation of charges, render the detector inoperable when exposed to high rates. A band-gap energy more than 5 times as high as in silicon, requires higher energy losses per ionizing particle in order to yield comparable signals. Thus, pulse heights of diamond detectors, at present, are roughly 3–4 times lower than silicon signals.

To form a full-scale tracking detector, some of the inherent drawbacks in this technology have yet to be solved. Natural diamond, although produced in quantities of several tons (i.e., millions of karats) per year (Kozlov *et al.*, 1975), is still unaffordable, where sensitive detector areas in the order of several square meters are required. Furthermore, even rather pure crystals contain traces of impurities (these create the different colors) such as nitrogen that trap free carriers and thereby reduce the lifetime of drifting electrons and holes. A commercial process called *chemical vapor deposition* (*CVD*) produces low-cost, thin sheets of artificial diamond that is chemically purer than natural crystals. In the beginning, the process suffered from lattice defects that act as trapping centers for drifting charges. The production of high-quality polycrystalline CVD material made it possible to develop a prototype of a pixel detector. A pixel module (46 000 channels) using diamond from a 12-cm wafer with a charge collection distance exceeding 300 μm was bump-bonded to the radiation-hard electronics of ATLAS. The module was tested in a 120-GeV pion test beam at CERN. This module performed quite well with a noise of $136\,e^-$ and an efficiency of >97% (Trischuk, 2008). High-purity single-crystal CVDs have been grown to sizes larger than $1\,\text{cm}^2$. Owing to the lack of grain boundaries, this CVD material has superior electronic characteristics (Barbero *et al.*, 2007).

23.2.5
Visual Tracking Detectors

23.2.5.1 The Cloud Chamber

This is the simplest and most straightforward form of tracking technique, using visual means to observe the tracks of charged particles. The basic construction is simple: a closed chamber containing a supersaturated vapor and a window to view the interior (see Henderson, 1970). When ionized clouds form inside the chamber, small droplets of liquid condense out of the gas at these points and become visible. The chamber can be used only for the study of reactions that are relatively abundant, because a large chamber of, say, $0.5\,\text{m}^3$ volume can be triggered only once every few minutes. This type of detector has been superseded by the more sophisticated and accurate bubble chamber.

23.2.5.2 The Bubble Chamber

Discovered by Glaser in 1956, the bubble chamber has been the major tool in particle physics for almost two decades. It relies on the properties of a superheated liquid for its operation, although it is basically similar to the cloud chamber (see Henderson, 1970). The liquid in question is held well above its boiling point and under pressure to prevent expansion. To bring the chamber into operation, the pressure is released slightly at the point when the trigger is set and the liquid is free to vaporize. Bubbles preferably form along the paths of charged particles in the chamber and can be recorded visually using photographic emulsion or CCD imaging systems. The further growth of bubbles is stopped by recompression. The repetition cycle is typically of the order of seconds. With separated beams of charged particles, this instrument has permitted the gathering of

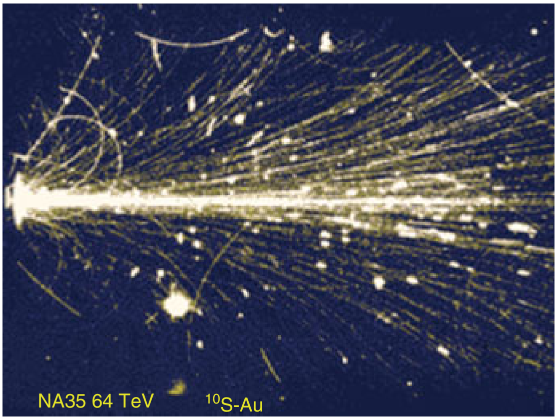

Fig. 23.31 A heavy-ion collision seen by the NA35 streamer chamber (Brinkmann *et al*., 1995).

Tab. 23.1 Summary and special features of the different detector technologies.

Detector technology	**Major application**	**Pros**	**Cons**
Gaseous detectors	Large volume and high-rate tracking, muon triggering	Rugged, cheap, relatively radiation hard, tailored to experimental needs	Sensitive to magnetic field, limited precision
Solid-state detectors	Vertex detection, high-rate tracking	High precision and good energy resolution	Radiation sensitive (Si), expensive
Visual tracking detectors	Vertex measurement (outdated)	High track precision (holographic)	Very slow, dangerous

information on resonant states and new particles, which has been the basis for our present concept of particle structure. The intrinsic accuracy in the measurement of the bubble position is of the order of 100 μm. A great variety of liquids has been used, from liquid hydrogen to xenon.

Extensive data analysis and processing are necessary to obtain three-dimensional track information (a common factor in all types of tracking systems). This kind of chamber is rarely used nowadays, with physicists choosing fast electronic detectors, which are more reliable and easier to control.

23.2.5.3 The Streamer Chamber

A streamer chamber is a large rectangular box with two planar electrodes at its ends and filled with a suitable gas mixture (e.g., Ne/He 80/20). When triggered, a sharp high-voltage pulse (~340 000 V) of short rise time and small duration (~12 nanoseconds) is applied to the electrodes. Every electron released by ionization of a charged particle, which has traversed the gas volume, initiates an avalanche in the intense uniform electric field. Since the electric field is of short duration, the avalanche formation terminates quickly. The excited atoms in the avalanche emit visible light, which forms luminous streamers of about 1-cm length in the direction of the electric field along the trajectory of the charged particle. The streamer chamber events are photographed and processed like bubble chamber data. Nuclear collisions at the SPS have been recorded by such a device (Figure 23.31).

A brief summary of the different detector technologies is given in Table 23.1.

23.3
Tracking Systems

A complete tracking system is composed of various tracking techniques and different types of chambers, combined in such a way as to be complementary in operation. The ultimate aim is to completely pin down a particle in space and time as it passes through the detector. In the following, some of the tracking systems in operation today are described, complete with details of position, momentum, and time resolution, where they are of importance.

23.3.1
The Time Projection Chamber

The time projection chamber (TPC) is a more sophisticated version of the imaging drift chamber. In most applications, the electric and magnetic fields are parallel (Clark *et al.*, 1976). Under the combined action of the fields, it is possible to drift electrons over large distances (up to several meters), while retaining their precise location in space and time (Figure 23.32) (ALEPH, 1990). Thus the detector essentially consists of a large gaseous drift volume with a homogeneous drift field similar to the classical parallel-plate configuration. One end generates the electric field necessary to transport electrons, while the other, at low potential, receives and measures the arriving charge. Similar to a photographic plate, this so-called end cap of the detector records the arrival of information (tracks) in short time slices, so that the full history of an event can be reproduced.

The actual detector elements are proportional chambers shaped into sectors in

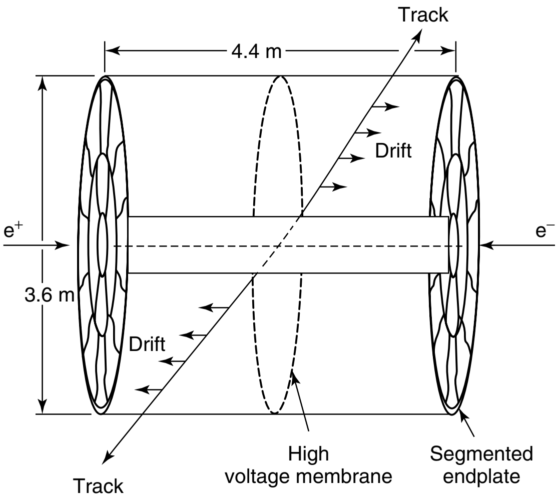

Fig. 23.32 Principle of the time projection chamber (TPC). Long-distance electron drift without lateral diffusion is assured by the parallel arrangement of electric and magnetic field.

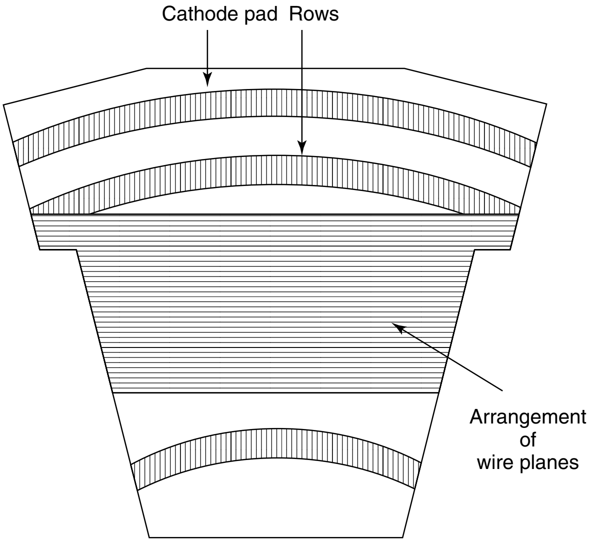

Fig. 23.33 Schematic of an end-cap sector of the ALEPH TPC. Sectors of a TPC are standard multiwire proportional chambers, specially shaped in order to avoid long cracks for particle tracks projected onto the end plates. Cathode pad shape and their circular arrangement are optimized for high spatial and double-track resolution.

order to adapt to the overall geometry of the TPC (Figure 23.33). They have fine-grained cathode segmentation (pad structure) for high-resolution tracking. In analogy to photographic techniques, these sectors can even be equipped with electronic shutters (known as *gates*) to prevent unwanted charge from entering them. Given the size of such a detector (typically 25–88 m^3), an impressive resolution in all three space coordinates can be achieved.

23.3.1.1 The ALEPH TPC

A good example of such a detector is the ALEPH TPC at LEP/CERN. It had a diameter of 3.6 m and a length of 4.4 m. The two end caps were segmented into 18 sectors each, which came in three different shapes, designed to make optimum use of the space and to lose a minimum of data along the sector boundaries (Figure 23.34). This detector had a spatial accuracy in the event projection on the end plates $(x - y) \leq 200\,\mu\text{m}$. This was kept low by having the magnetic and electric fields parallel, so that electrons did not diffuse laterally but were forced to orbit about the center of the ionized cluster. The z-coordinate precision are determined by the longitudinal diffusion of electrons along their drift path and was of the order of 1 mm (Atwood *et al.*, 1991).

The values for the resolution also depend on the angle at which tracks hit the anode wires, since, in the avalanche region, the magnetic field is no longer parallel to the electric field and there is a smearing effect on each track segment along the wire caused by the electromagnetic interaction with the electrons.

This detector concept is especially suited to colliding-beam experiments with sufficiently long (≈10–100 microseconds) time intervals between successive beam interactions. Figure 23.35 illustrates a typical two-jet event from the decay of a Z^0 boson into a quark–antiquark pair as produced at the 100-GeV LEP Electron–Positron Collider (ALEPH, 1991).

23.3.1.2 TPCs for High-Energy Nucleus–Nucleus Collisions

TPCs are the main tracking detectors in collisions of heavy ions at ultrarelativistic

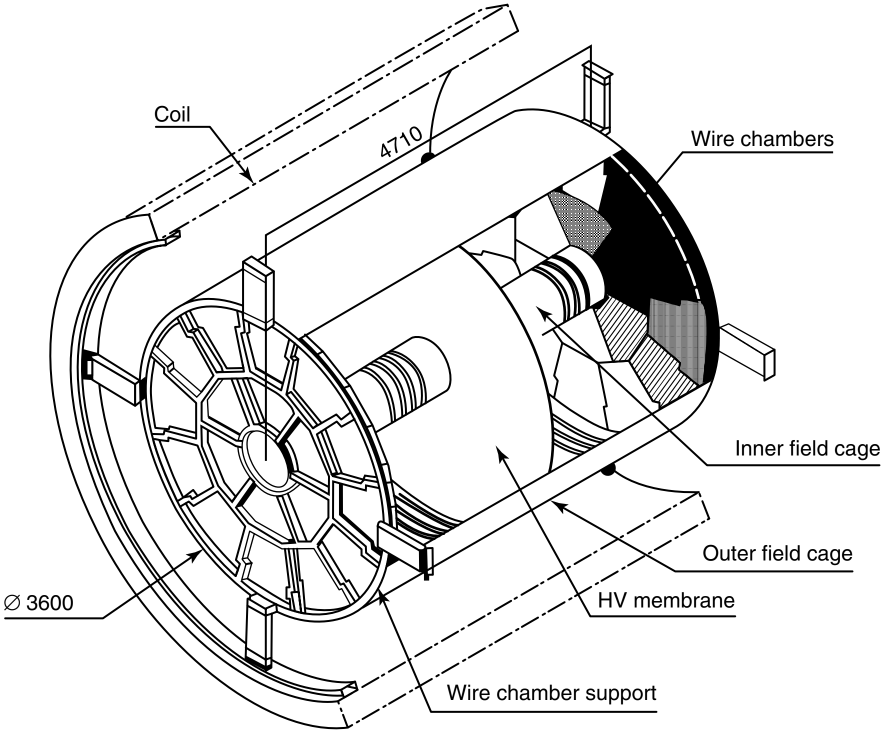

Fig. 23.34 Three-dimensional view of the ALEPH TPC.

energies. They have been used in fixed target experiments at the AGS and the SPS (e.g., NA49 (Afanasiev *et al.*, 1999)). The STAR detector at RHIC at BNL has demonstrated that a large-volume TPC is capable of recording thousands of charged particle tracks per collision at an event rate of up to 1 kHz. Figure 23.36 shows an event display of an Au + Au collision at $\sqrt{s_{NN}} = 200$ GeV (Ackermann *et al.*, 1999).

The ALICE experiment at the LHC is designed to record collisions of Pb nuclei at $\sqrt{s_{NN}} = 5.5$ TeV. Various detectors arranged in cylindrical shells around the interaction point (see Figure 23.37) are designed to determine the identity and precise trajectory of the more than 10 000 charged particles propelled by a lead–lead nuclear collision into the active volume of the apparatus (ALICE, 1995; Braun-Munzinger and Stachel, 2007). The innermost detector is the inner tracking system (ITS), which consists of six layers of silicon detectors surrounding the 1-mm-thick beam pipe that encloses the ultrahigh vacuum of the accelerator. These detectors are capable of high-precision tracking (resolution around 20 μm) in order to determine the decay vertex of short-lived particles carrying strange, charm, or bottom quantum numbers that typically decay within a few millimeters to centimeters of the primary interaction point. ALICE's major tracking device is a TPC with 560 000 readout channels; it provides essentially continuous, three-dimensional tracking of charged particles between radii of 80 and 250 cm from the central interaction point.

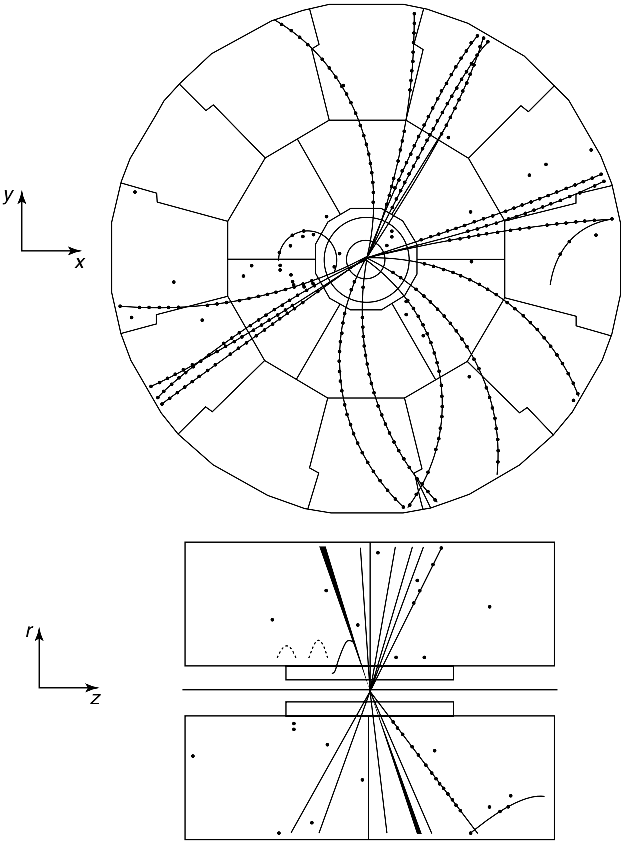

Fig. 23.35 Decay of a Z^0 into hadrons (jets) seen by the ALEPH TPC. Each point on a track corresponds to a pad-row hit (x–y plane).

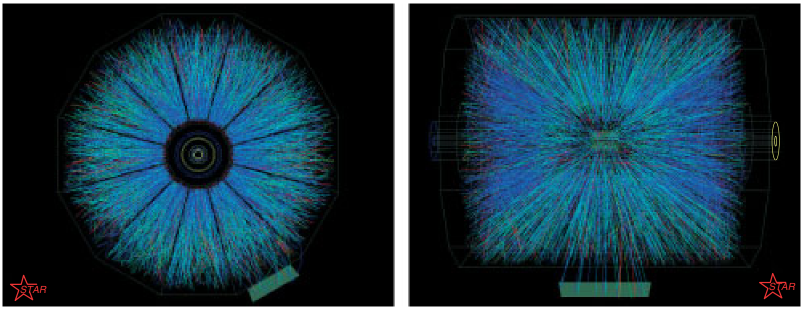

(a) (b)

Fig. 23.36 Event display of charged particle tracks in a Au + Au collision at RHIC energies recorded by the STAR TPC. (a) Front view and (b) side view. Images reproduced with permission from BNL.

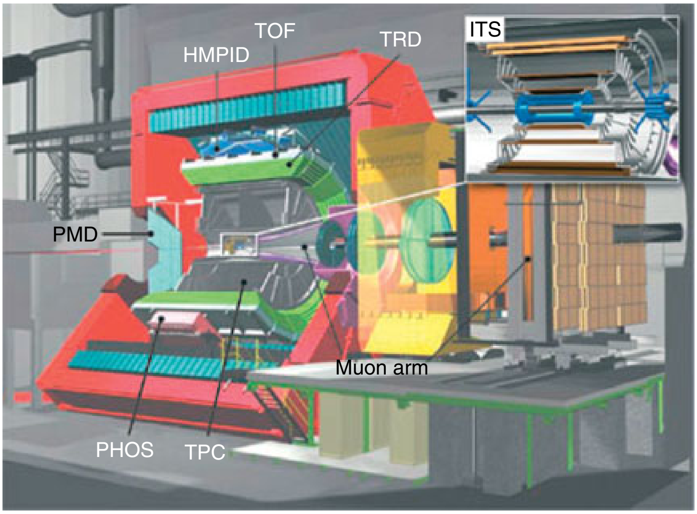

Fig. 23.37 The ALICE detector at the LHC (Braun-Munzinger and Stachel, 2007).

Outside the TPC there are two large particle identification detectors: the transition radiation detector (TRD) and the time-of-flight (TOF). The central barrel of ALICE is completed by dedicated detectors to measure photons (PHOS and EMCal). Separated from the main detector in the forward direction of one of the accelerator beams, and behind a conical absorber that projects into the central barrel, is a muon detector with its own large dipole magnet.

The TPC as the main tracking detector of the ALICE central barrel has to provide – together with the other central barrel detectors – charged-particle momentum measurements with good two-track separation, particle identification, and vertex determination.

At the Pb + Pb design luminosity of the LHC an interaction rate of 8 kHz is expected, of which about 10% are to be considered as central collisions. In the TPC design phase, that is, before RHIC data allowed a better extrapolation to LHC energy, an extreme multiplicity of $dN_{ch}/d\eta = 8000$ was assumed, which would have resulted in 20 000 charged primary and secondary tracks in the acceptance. These extreme multiplicities result in maximum occupancies (defined as the ratio of the number of readout pads and time bins above threshold to all pads and time bins) of about 40% at the innermost radius and 15% at the outermost radius.

It is expected that the TPC can be operated at central collision rates of up to 200 Hz. Simulations have shown that at this rate the space charge due to the ion feedback during gate-open time starts to be comparable to the space charge due to the ionization in the TPC drift volume itself. The true space-charge limit, however, might eventually depend on the background conditions due to the beam quality.

The TPC is cylindrical in shape; the active volume has an inner radius of about 85 cm, an outer radius of about 250 cm, and an overall length along the beam direction of 500 cm. The detector is made of a large cylindrical field cage, filled with 90 m^3 of $Ne/CO_2/N_2$ (90/10/5), which is needed to transport the primary electrons over a distance of up to 2.5 m on either side of the

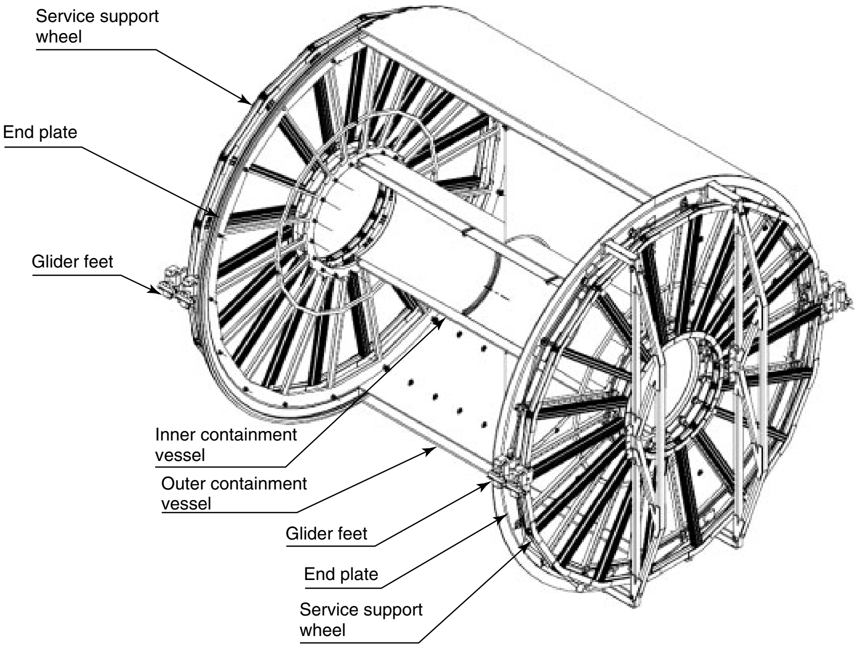

Fig. 23.38 Three-dimensional view of the TPC field cage and service support wheels, without readout chambers (Aamodt *et al.*, 2008).

central electrode to the end plates. MWPCs with cathode pad readout are mounted into 18 trapezoidal sectors of each end plate.

The field cage (Figure 23.38) is based on a design with a central high-voltage electrode and two opposite axial potential dividers, which create a highly uniform electrostatic field in the common gas volume. The central electrode is a stretched Mylar foil to satisfy the requirement of minimal material near 90° relative to the beam direction. The electrical potential in the drift region is defined by aluminized Mylar strips wound around 18 inner and outer support rods, which also contain two resistive potential dividers (inner and outer). Because of the $Ne/CO_2/N_2$ gas mixture used in the TPC, the field cage is operated at high-voltage gradients, of about 400 $V\ cm^{-1}$, with a high voltage of 100 kV at the central electrode, which results in a maximum drift time of about 90 microseconds. The drift gas is optimized for drift speed, low diffusion, low radiation length and hence low multiple scattering, small space-charge effect, and aging and stability properties.

The readout chambers instrument the two end plates of the TPC cylinder with an overall active area of $32.5\,m^2$. The chambers are MWPCs with cathode pad readout. Because of the radial dependence of the track density, the readout is segmented into two readout chambers with slightly different wire geometry adapted to the varying pad sizes. The readout chambers are made of standard wire planes, that is, they consist of a grid of anode wires above the pad plane, a cathode wire plane, and a gating grid. They combine a very tight electrode configuration (anode-to-cathode distance 2

Total pads	5504
Outer readout chamber geometry	Trapezoidal, $1346 < r < 2466$ mm active area
Pad size	6×10 and 6×15 mm ($\varphi \times r$)
Pad rows	$64 + 32 = 96$ (small and large pads)
Total pads	$5952 + 4032 = 9984$ (small and large pads)
Detector gas	$Ne/CO_2/N_2$ 90/10/5
Gas volume	$90\,m^3$
Drift length	2×2500 mm
Drift field	$400\,V\,cm^{-1}$
Drift velocity	$2.7\,cm\,\mu s^{-1}$
Maximum drift time	$92\,\mu s$
Total HV	100 kV
Diffusion	$D_L = D_T = 220\,\mu m\,cm^{-\frac{1}{2}}$
Material budget	$X/X_0 = 3.5\%$ near $\eta = 0$
Front-end cards (FEC)	121 per sector $\times$ 36 = 4356
Readout Control Unit (RCU) scheme	6 per sector, 18–25 FEC per RCU
Total RCUs	216
Total pads–readout channels	557 568
Pad occupancy (for $dN/dy = 8000$)	40–15% inner/outer radius
Pad occupancy (for pp)	$5-2 \times 10^{-4}$ inner/outer radius
Event size (for $dN/dy = 8000$)	~90 MB (conditions see text)
Event size (for pp)	~1–4 MB (depending on pileup and noise threshold)
Total bandwidth	$\sim 30\,GB\,s^{-1}$
Trigger rate limits	200 Hz Pb–Pb central events
	1000 Hz proton–proton events
ADC	10 bit
Sampling frequency	5–10 MHz
Time samples	500–1000
Conversion gain	6 ADC counts/fC
Position resolution (σ) in $r\varphi$	1100–800 μm inner/outer radii
in z	1250–1100 μm
dE/dx resolution, isolated tracks	5.0%
$dN/dy = 8000$	6.8%

and 3 mm for inner and outer readout chamber, respectively) with an operating gain of up to 20 000. To keep the occupancy as low as possible and to ensure the necessary dE/dx, position and two-track resolution, there are about 560 000 readout pads of three different sizes: 4×7.5 mm^2 in the inner chambers, and 6×10 mm^2 and 6×15 mm^2 in the outer chambers. The readout chambers are normally closed by a gating grid for electrons coming from the drift volume and for ions from the amplification region. The gate is opened only by a valid trigger for the duration of one drift-time interval, thus reducing the building up of space charge due to positive ions drifting back from the multiplication region for nontriggered interactions and background. It has been verified that the closed gate cuts the drift of electrons by a factor better than 10^5. The main parameters of the TPC design are summarized in Table 23.2.

23.3.2
The Silicon Tracker and Vertex Detector

Bunches of 10^{11} protons will collide 40 million times per second inside the LHC to provide 14-TeV proton–proton collisions at the LHC design luminosity of 10^{34} cm^{-2} s^{-1}. Around 1000 charged particles will emerge from the collision points every 25 nanoseconds, within a volume defined by $|\eta| < 2.5$, where pseudorapidity η is a logarithmic measure of the polar angle of the emitted particle relative to the beam axis, $\theta : \eta = -\ln(\tan(\theta/2))$.

The main challenges for the inner detector parts are the high particle rates, the radiation tolerance needed, and the control of aging effects. The central trackers of ATLAS and CMS, the two large general-purpose experiments, are similar in size and features. They are located in the central part of the detector surrounding the beam pipe and are about 2 m in

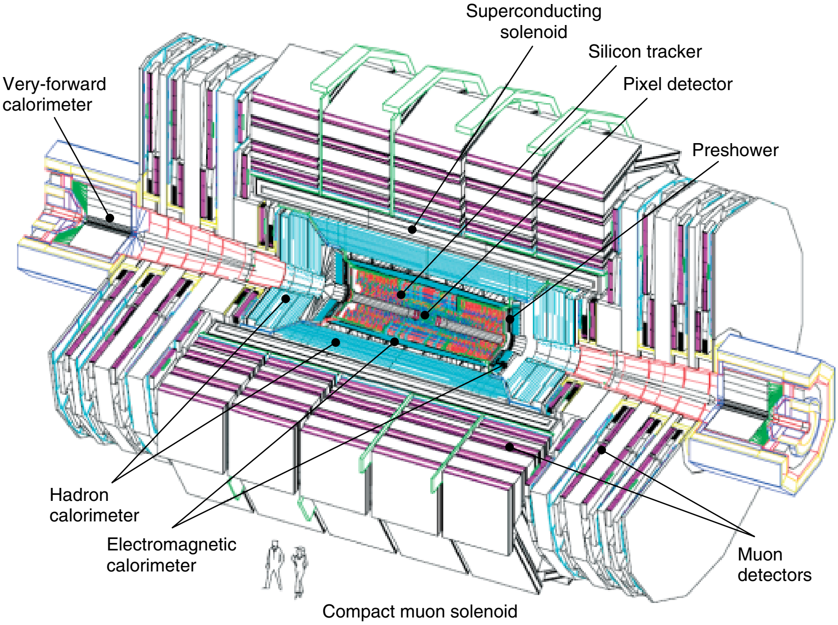

Fig. 23.39 The CMS (Compact Muon Solenoid) detector at LHC (Chatrchyan *et al.*, 2008).

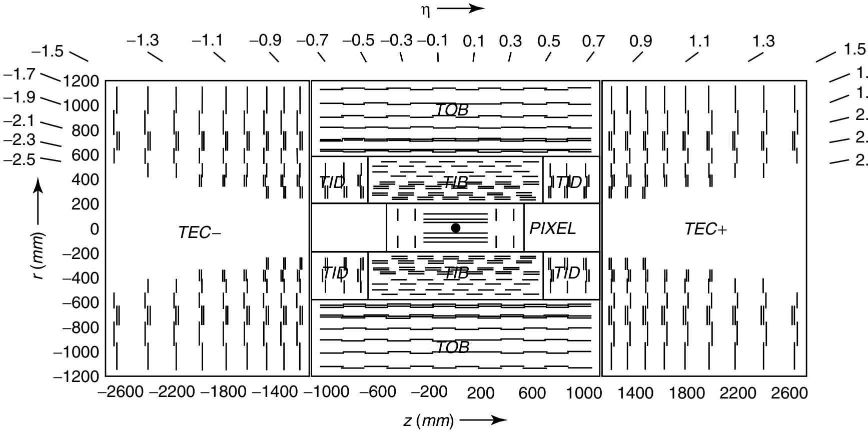

Fig. 23.40 Schematic cross section through the CMS tracker. Each line represents a detector module. Double lines indicate back-to-back modules that deliver stereo hits (Chatrchyan *et al.*, 2008).

diameter and 6 m in length. They cover the angular range $|\eta| < 2.5$ and are both immersed in a solenoidal magnetic field which is 4 and 2 T for CMS and ATLAS, respectively. Figure 23.39 shows the overall layout of the CMS detector (Chatrchyan *et al.*, 2008); the inner tracker is located inside the bore of the magnet coil of the 4 T superconducting solenoid. In both trackers – ATLAS and CMS – the innermost detector layers are built with silicon pixels and the intermediate layers with silicon strip detectors with high strip density (see Figures 23.40 and 23.43a). The pixel detectors that surround the interaction point with a set of three measurements per primary track at small radii have a pixel size of $50\,\mu\text{m} \times 400\,\mu\text{m}$ (ATLAS) and $100\,\mu\text{m} \times 150\,\mu\text{m}$ (CMS) in $R\varphi \times z$. The inner silicon strip detectors provide high-resolution measurements ($\sim 25\,\mu\text{m}$).

The barrel of ATLAS is located between $r = 30$ and $r = 50$ cm and provides eight measurements while that of CMS is located between $r = 20$ cm and $r = 50$ cm and provides six points. The technology used for the outer layers is different as well: CMS uses silicon strip detectors with coarse pitch providing eight precise measurement points ($\sim 50\,\mu\text{m}$) between $r = 60$ and $r = 110$ cm, while ATLAS uses a transition radiation detector (TRT) with 4-mm diameter gas straw tubes providing 35 points with $\sim 170\,\mu\text{m}$ resolution located between $r = 55$ and $r = 105$ cm (Ragusa and Rolandi, 2007 and references therein). The main parameters of the ATLAS and CMS tracking systems are given in Table 23.3.

Figure 23.41 illustrates the tracking capabilities of the ATLAS inner detector. A charged particle of 10 GeV/c transverse momentum, produced at the primary vertex, successively traverses the beryllium beam pipe, the three cylindrical silicon-pixel layers with individual sensor elements of $50 \times 400\,\mu\text{m}^2$, the four cylindrical double layers (one axial and one with a stereo angle of 40 mrad) of barrel silicon-microstrip sensors (SCT) of pitch $80\,\mu\text{m}$, and approximately 36 axial straws of 4-mm diameter contained in the barrel transition–radiation tracker modules.

Tab. 23.3 Main parameters of the ATLAS and CMS tracking systems (Froidevaux and Sphicas, 2006).

Parameter	**ATLAS**	**CMS**
Dimensions (cm)		
-Radius of outermost measurement	101–107	107–110
-Radius of innermost measurement	5.0	4.4
-Total active length	560	540
Magnetic field B (T)	2	4
BR^2 (T_m^2)	2.0–2.3	4.6–4.8
Total power on detector (kW)	70	60
Total weight in tracker volume (kg)	≈4500	≈3700
Total material (X/X_0)		
-At $\eta \approx 0$ (minimum material)	0.3	0.4
-At $\eta \approx 1.7$ (maximum material)	1.2	1.5
-At $\eta \approx 2.5$ (edge of acceptance)	0.5	0.8
Total material (λ/λ_0 at maximum)	0.35	0.42
Silicon microstrip detectors		
-Number of hits per track	8	14
-Radius of innermost measurement (cm)	30	20
-Total active area of silicon (m^2)	60	200
-Wafer thickness (microns)	280	320/500
-Total number of channels	6.2×10^6	9.6×10^6
-Cell size (μm in $R\phi \times$ cm in z/R)	80×12	$80/120 \times 10$
-Cell size (μm in $R\phi \times$ cm in z/R)		and $120/180 \times 25$
Straw drift tubes (ATLAS only)		
-Number of hits per track ($\lvert\eta\rvert < 1.8$)	35	
-Total number of channels	350 000	
-Cell size (mm in $R\phi \times$ cm in z)	4×70 (barrel) 4×40 (end caps)	

The innermost layer(s) of the tracking system nearest to the interaction vertex are usually called *vertex detectors*, even though they provide tracking information. The purpose of such a detector is to measure the starting point of an event with great accuracy and, in addition, to track the decay origin of any short-lived particles that may have been created. Typically, a resolution of $\leq 50\,\mu$m is required of such a detector, measuring particles with lifetimes of around 10^{-13} seconds. Figures 23.42 and 23.43b show examples of such vertex detectors that consist of silicon pixel detectors. Table 23.4 summarizes the main parameters of the ATLAS and CMS pixel systems.

23.3.3
Large-Volume Muon Trackers – the ATLAS Muon Spectrometer

Muon detection in high-energy physics experiments is usually accomplished by using thick absorbers as particle filters followed by MWPCs or planar drift chambers. The dimensions of these absorbers (typically iron) are in the order of meters to prevent “punch through” of hadrons. Therefore, muon detectors tend to be

large and rather costly if good coverage in solid angle is required for muon detection.

The choice of magnet in ATLAS was motivated by the measurement method of muons with momenta up to teraelectronvolt scales (Figure 23.44). ATLAS opted for a high-resolution, stand-alone measurement independent of the rest of the subdetectors, resulting in a large volume with low material density. The ATLAS toroidal magnetic field provides a momentum resolution that is essentially independent of pseudorapidity η to a value of 2.7. The muon system consists of three large superconducting air-core toroid magnets, which are instrumented with different types of chambers to provide two necessary functions, namely, high-precision tracking and triggering (Figure 23.45). The central (or barrel) region, $|\eta| < 1.0$, is covered by a large barrel magnet consisting of eight coils that surround the hadronic calorimeter. In this region, tracks are measured in chambers arranged in three cylindrical layers (stations) around the beam axis. In the end-cap region, $1.4 < |\eta| < 2.7$, muon tracks are bent in two smaller end-cap magnets each of which is inserted into one end of the barrel toroid. The intermediate region, $1.0 < |\eta| < 1.4$, is less straightforward because here the barrel and end-cap fields overlap, thus partially reducing the bending power (Stapnes, 2007; Froidevaux and Sphicas, 2006).

23.3.3.1 Precision Chambers for Tracking

The basic element of the precision momentum measurement is the monitored drift tube (MDT) chamber. It combines high measuring accuracy with mechanical rigidity and simplicity of construction. The tubes are operated at an absolute pressure of 3 atm, improving the measuring accuracy by about a factor of $\sqrt{3}$ compared to operation at normal pressure. A resolution of 80 μm per tube has been achieved. In the very forward region ($2 < |\eta| < 2.7$) cathode strip chambers (CSCs) are used because of higher rate capability and time resolution (Aad *et al.*, 2008).

Monitored Drift Tube (MDT) chamber The basic element of the MDT chambers is the pressurized drift tube with a diameter of 30 mm, operating with Ar/CO_2 gas (93 : 7) at 3 bar. Electrons created by ionization are collected at the central tungsten–rhenium

Tab. 23.4 Main parameters of the ATLAS and CMS pixel systems (Froidevaux and Sphicas, 2006).

	ATLAS	**CMS**
Number of hits per track	3	3
Total number of channels	$80\ 10^6$	$66\ 10^6$
Pixel size (μm in $R\phi$ × μm in z/R)	50 × 400	100 × 150
Lorentz angle (degrees), initial to end	12 to 4	26 to 8
Tilt in $R\phi$ (degrees)	20 (only barrel)	20 (only end cap)
Total active area of silicon (m^2)	1.7 (n^+/n)	1.0 (n^+/n)
Sensor thickness (μm)	250	285
Total number of modules	1744 (288 in disks)	1440 (672 in disks)
Barrel layer radii (cm)	5.1, 8.9, 12.3	4.4, 7.3, 10.2
Disk layer minimum to maximum radii (cm)	8.9–15.0	6.0–15.0
Disk positions in z (cm)	49.5, 58.0, 65.0	34.5, 46.5
Signal-to-noise ratio for minimum-ionizing particles (day 1)	120	130
Total fluence at $L = 10^{34}$ ($n_{eq}/cm^2/year$) at radius of 4–5 cm (innermost layer)	3×10^{14}	3×10^{14}
Signal-to-noise ratio (after $10^{15} n_{eq}/cm^2$)	80	80
Resolution in $R\phi$ (μm)	≈10	≈10
Resolution in z/R (μm)	≈100	≈20

wire with a diameter of 50 μm at a potential of about 3080 V. The wire is held in position at the tube ends by a cylindrical element, which guarantees the centricity of the wire with respect to the tube with an accuracy of $\sigma < 10$ μm (Figure 23.46). All regular MDT chambers consist of two packages of tube layers (multilayers) separated by a support structure, where each multilayer consists of three tube layers in the outer and four tube layers in the inner layers of the muon detector. The exact definition of the wire positions in an MDT, due to tight tolerances in production and continued monitoring of global deformations, results in the accuracy of the track segment in the 6 (8) tube layers being only limited by the error of the single tube measurements of about 80 μm. Thus, the resolution of the central point of a track segment in a multilayer of 3 (4) tubes is 50 (40) μm, while the one in a chamber of two multilayers is 35 (30) μm. The limit for safe operation of the MDTs is at counting rates of about 150 Hz cm^{-2}.

Cathode Strip Chamber (CSC) The CSCs are MWPCs with cathodes segmented into strips, the direction in both cathodes being orthogonal to each other. This allows the measurement of both coordinates from the distribution of the induced charge (Figure 23.47). The resolution of the CSCs in the bending plane will be 60 μm. Operation is considered safe up to counting rates of about 1000 Hz cm^{-2}, which is sufficient up to the forward boundary of the muon system at $|\eta| = 2.7$.

23.3.3.2 **Trigger Chambers**

RPCs in the barrel region and thin gap chambers (TGCs) in the end-cap region provide a fast response with good time resolution (inside 15–20 nanoseconds) and can therefore unambiguously identify the

correct bunch crossing and are invaluable for triggering.

Resistive Plate Chamber (RPC) The trigger system in the barrel consists of three cylindrical layers of RPCs around the longitudinal axis. Two resistive plates made from plastic laminate are kept parallel to each other at a distance of 2 mm by insulating spacers. The electric field between the plates of about $4.9\,\mathrm{kV\,mm^{-1}}$ allows avalanches to form along the ionizing tracks toward the anode. The signal is read out via capacitative coupling to metallic strips, perpendicular to each other, on both sides of the detector, that is, on the outer face of the resistive plates. The gas used is a mixture of $C_2H_2F_4$/Iso–C_4 H_{10}/SF_6, which combines relatively low operating voltage, nonflammability, and low cost, while providing a sufficient plateau for safe operation. An RPC trigger chamber consists of two rectangular detectors, contiguous to each other. Each unit has two independent resistive plate structures, so-called gas volumes, which are each read out by two orthogonal groups of pickup strips (Figure 23.48).

In the high-background environment encountered at the LHC, the RPCs are operated in the avalanche mode that offers the benefit of higher rate capability and rate-independent time resolution. At the nominal operating voltage of 9.7 kV, a signal with a width of about 5 nanoseconds is generated by the track with a streamer probability of less than 1%.

Thin Gap Chamber (TGC) Thin gap chambers provide two functions in the end-cap of the muon spectrometer: the generation

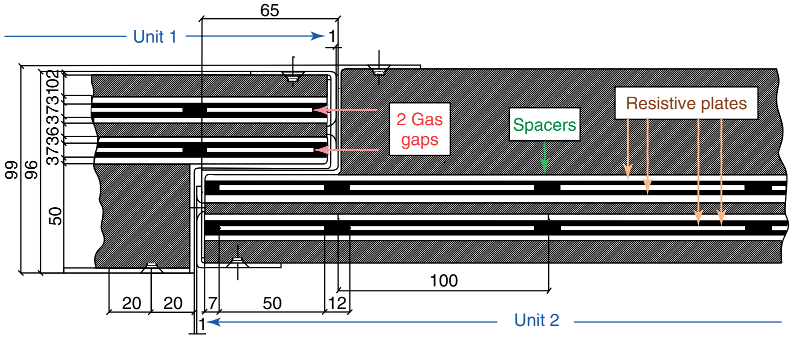

Fig. 23.48 Cross section through an RPC, where two units are joined to form a chamber. Each unit has two gas volumes (gas gaps), supported by spacers, four resistive electrodes and four readout planes, reading the transverse and longitudinal direction. The sandwich structure (hashed) is made from paper honeycomb (Aad *et al.*, 2008).

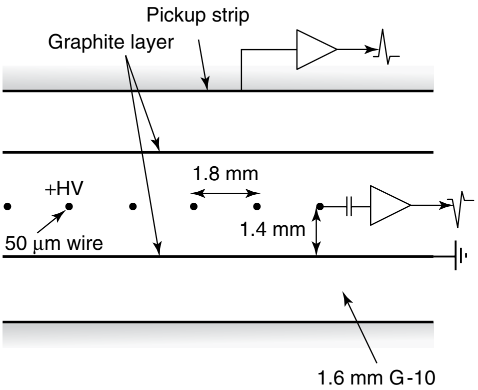

Fig. 23.49 TGC structure showing anode wires, graphite cathodes, laminate (G-10) layers, and a readout strip, orthogonal to the wires (Aad *et al.*, 2008).

of a muon trigger and the determination of the second, azimuthal coordinate to complement the measurement of the MDTs in the bending direction. TGCs are MWPCs with the characteristics that the wire-to-wire distance (1.8 mm) is larger than the wire-to-wall distance (1.4 mm) (see Figure 23.49). With a highly quenching gas mixture of CO_2 and n-C_5 H_{12} (n-pentane), this cell geometry allows for operation in saturated mode, that is, with a very high gas gain ($\sim 10^6$), which makes pulse heights highly uniform and nearly independent of the amount of primary ionization.

23.4
Applications of Particle Detectors in the Future

Particle tracking is, in its true sense, a visualization of complex event structures in nuclear and subnuclear reactions. To disentangle and measure individual tracks with increasingly higher precision has been the aim of every tracking detector in the past and continues to be so at present. As a result of continuous improvement in the hardware technologies combined with powerful pattern-recognition algorithms, tracking systems have acquired state-of-the-art performance in terms of accuracy and speed. Nearly reaching the grain size of particle tracks as ‘‘seen’’ in holographic bubble chambers (in the order of microns), today’s electronic detectors measure, filter, and analyze track data within microseconds or even less.

The R&D activity in the field of tracking detectors is mainly defined by the requirements of detection systems for e^+/e^- Linear Colliders in the TeV or even multi-TeV energy range and the upgrade of LHC detectors, but there are many other detector systems currently being developed for, for example, neutrino experiments, flavor studies at high intensity and lower energy, and heavy-ion collisions at low energy and high intensity.

The proposed luminosity upgrade of the LHC by a factor of 10 will require significant upgrades for the LHC detectors, especially the replacement of the inner tracker systems. New trackers will have also to be redesigned to handle the increased occupancy rates and the increased radiation background. For the innermost layers of the vertex detectors in, for example, ATLAS and CMS, the levels of radiation background are so high that new technology is required. The current favorites are three-dimensional silicon and diamond, but other options are being considered such as micromegas and thin Si planar detectors (Dawson, 2008).

Detector R&D for the ILC is concentrated in three different design studies (ILC, 2008). The requirements for the tracking system and the vertex detector are challenging: robust and highly efficient tracking in a large acceptance, excellent space point resolution (better than 4 μm for the vertex detector), excellent impact parameter resolution, and a very low material budget ($\sim$0.1% X_0 per layer of the innermost layers). The three different detector concepts are conceptually very similar with respect to the tracking and vertex detector, but they pursue different implementations. One design relies completely on silicon sensors, and the other two consider a combination of silicon and gaseous tracking detectors. A number of candidate technologies are being developed for ILC vertex detector applications, all based on the integration of the detecting element with the electronics: DEPFEPs, MAPS, CCDs, and SOI technology (Collins, 2007). A TPC is a candidate for a large and robust tracking system. Traditional TPCs are equipped with MPWCs for gas amplification and a gating grid where two consecutive wires are polarized at opposite voltages, thus creating a transverse field that stops most of the secondary ions produced in the amplification region before they reach the drift space. Especially in high-rate applications and under high-background conditions, like at the ILC, it is very important to have a very limited ion backflow from the secondary ions in order to avoid distortions of the drift electric field. A Micromegas micromesh has the intrinsic property to naturally stop a large fraction of the secondary positive ions and is therefore studied to read out the TPC instead of an MWPC (Colas *et al.*, 2004). Another approach is to use GEMs for the readout (Ledermann *et al.*, 2006). The fine granularity and high-rate capability of micropattern devices can be fully exploited using a high-density pixel readout with a size corresponding to the intrinsic width of the detected avalanche charge. A CMOS pixel chip assembled directly below the GEM or Micromegas amplification structure serves as an integrated charge collecting anode. With this arrangement, avalanche electrons are collected on the top metal layer of the CMOS ASIC and every input pixel is then directly connected to the amplification, digitization, and sparsification circuits integrated in the underlying active layers of the CMOS technology. Using this approach, gas detectors can reach the level of integration typical of solid-state pixel devices and a high spatial resolution that allows to count individual clusters can be achieved (Titov, 2007 and references therein, Visschers *et al.*, 2007).

23.4.1
Future Trends

Technology, especially microelectronics, has and will in the future enable advances in detectors: segmentation, speed, feature size, and new materials. For example, the emerging new technique of three-dimensional integration of thin ASICs makes it possible to stack different layers of sensors and ASICs together to form a sandwich, allowing the choice of the optimal technology for each tier (Umemoto *et al.*, 2004). Integration issues – mechanical stability of very thin and large detector systems, power supply, and cooling will become even more important – not to speak about the readout and transfer of large amounts of data produced by a (self-triggered) many-channel front-end electronics. The boundaries between vertex and tracking detectors will become even more blurred – vertex detectors are stand-alone trackers. Large volume gaseous detectors will be combined with high-granularity CMOS pixel readout. Calorimeters will provide three-dimensional space point information: the particle flow calorimetry (Thomson, 2008; Schätzel, 2008).

Glossary

Affinity: Ability to bind charge carriers to neutral molecules. Oxygen and Freon, for example, are known to capture free electrons in drift gases. These charges are lost in the final signal arriving at the anode.

ALEPH: A large (about 4000 tons) 4π solenoidal detector for the LEP electron–positron storage ring facility.

ALICE: Experiment at the LHC designed especially to study heavy ion collisions.

ATLAS: A large general-purpose experiment at the LHC.

Bunch: In most particle accelerators and storing ring facilities, particles are accelerated in a noncontinuous way. For optimum efficiency and luminosity, particles are injected and accelerated in discrete packages or bunches that, depending on their number, are separated in time from several milliseconds to tens of nanoseconds. The spatial dimensions of a bunch are typically a few micrometers laterally and of order centimeters longitudinally (i.e., along the direction of motion).

Calorimeter: In particle physics, a detector to measure the total energy of neutral (photons) and charged particles by total absorption in a dense medium such as iron, lead, uranium, or others. One distinguishes between two classes of calorimetry: electromagnetic calorimetry for the energy measurement of photons and electrons (positions), and hadronic calorimetry for the interaction of charged hadrons (primarily pions).

CERN: Centre Européenne pour la Recherche Nucléaire: The world's largest laboratory in high-energy particle physics, based in Geneva, Switzerland.

Chemical Vapor Deposition (CVD): A catalytic process to produce thin sheets (up to 100 μm) of diamond from carbon-based raw materials.

Cherenkov Light: Electromagnetic radiation emitted by a particle moving (with constant velocity) through a material medium at a velocity greater than the phase velocity of light in that medium. This phenomenon is exploited for the identification of charged particles passing through matter.

CMOS, NMOS, PMOS: Complementary-metal-oxide-semi-conductor (CMOS) uses complementary and symmetrical pairs of p-type and n-type metal-oxide semiconductor field effect transistors (MOSFETs) for logic functions. PMOS logic uses p-type, NMOS logic n-type MOSFETs to implement logic gates and other digital circuits.

CMS: A large general-purpose experiment at the LHC.

DESY: (Deutsches Elektronen-Synchrotron): A German-based research facility for high-energy particle physics similar to CERN.

Electron-Beam Lithography: A process known in semiconductor technology to produce by means of photographic masks thin metal layers (order micrometers) on solid-state or insulating substrates. The short wavelength of the electron beam allows accuracies below 1 μm.

Flash Analog-to-Digital Converter (FADC): A device that samples and digitizes the time response and pulse height of analog signals (coming from a detector) in time slices comparable to the speed of the signal itself. The reconstruction of the time buckets allows, a recovery of the original signals and their timing history.

FWHM: Full width at half maximum.

Gaussian Curve, Gauss Function: The "normal," bell-shaped distribution, which is symmetric about its mean value.

Hadron Collider: An accelerator primarily for protons (antiprotons) and heavy ions. These machines are in contrast to electron (positron) facilities, which are lower in energy because of energy losses from synchrotron radiation.

HERA (Hadron-Electron Ring Accelerator): Facility for colliding electrons of 30 GeV on protons of 820 GeV at DESY, Germany.

Hodoscope: An arrangement of detectors, usually an array of scintillators with photomultipliers, used to count and measure the position and trajectory of incoming particles to an experiment.

Holographic Bubble Chamber: Photographic method of recording particle tracks in a bubble chamber using interferometry. This improves the spatial resolution (bubble size) significantly.

Jet: In most cases, the fragmentation products of a quark decay into hadrons. Depending on the initial energy of the parent particle, jets appear as collimated particle tracks with high multiplicity. Their high density of tracks makes them particularly difficult to measure in common detectors because of insufficient separation of tracks.

LHC (Large Hadron Collider): This storage ring accelerator will make use of the present underground tunnel built for LEP. Bunches of 10^{11} protons will collide 40 million times per second to provide 14-TeV proton–proton collisions at the LHC design luminosity of $10^{34}\,\text{cm}^{-2}\,\text{s}^{-1}$. The acceleration of nuclei will provide Pb + Pb collisions at $\sqrt{s_{NN}} = 5.5$ TeV; the interaction rate is expected to be 8 kHz.

Luminosity: In analogy to optical terms, luminosity describes the probability of accelerated particles to interact with each other in head-on collisions. The luminosity depends on the particle density (usually confined in a bunch) *and* the interaction cross section. Since rare phenomena have very low production cross sections, accelerators and colliders are designed for maximum luminosity.

LHCb: Experiment at the LHC designed especially to study b-quark systems.

Minimum-Ionizing Particle: Charged particles whose energy loss (depending on their velocity) in a medium is near or inside the minimum of the Bethe–Bloch function. Most charged particles produced in a high-energy physics interaction have a velocity range where the ionization from energy losses (dE/dx) falls into this minimum. This makes them difficult to detect, predominantly in gas-filled detectors, where only about 100 electrons/cm are liberated by these particles.

Occupancy: Term describing the ''busy time'' of a single detector channel due to ionizing radiation, noise, and pickup, thus creating true plus uncorrelated hits. It is commonly expressed in percent and depends primarily on the incoming flux of particles and the intrinsic speed of the detector itself; that is, gaseous detectors with long signal-processing time (e.g., drift time, pulse shaping) suffer from higher occupancies than fast devices such as scintillators. High occupancies (i.e., $>10\%$) result in substantial detector dead time and lead to confusion in the pattern recognition of genuine tracks. To reduce detector occupancy in high-background environments to tolerable levels, small cell sizes must be chosen.

Pattern Recognition: Sophisticated software algorithms to disentangle complex event structures and select physically interesting tracks from confusing backgrounds.

Photomultiplier: A device consisting of a photosensitive surface inside a vacuum tube where electrons are liberated from the cathode. Each electron is multiplied in a succession of dynodes by secondary emission under the influence of the electric field. Photomultipliers are essentially sensitive to single photons and provide very fast signals in the nanosecond or lower range.

Pitch: The distance between adjacent cells in detectors with repetitive cell structures. Also known as *cell width*.

Pseudorapidity: Pseudorapidity η is a logarithmic measure of the polar angle of the emitted particle relative to the beam axis, $\theta : \eta = -\ln(\tan(\theta/2))$. Emission at 90° corresponds to $\eta = 0$; 45° to $\eta \approx 0.9$.

RHIC: Relativistic Heavy-Ion Collider at Brookhaven National Laboratory, New York. Provides beams of heavy ions and polarized protons (Au + Au collision at $\sqrt{s_{NN}} = 200$ GeV).

Scintillation Light: Light produced by quantum effects in atoms excited by charged particles traversing the medium.

SLAC: National Accelerator Laboratory at Stanford is home to a two-mile linear accelerator, the Stanford Linear Collider and the Babar experiment.

Strongly Ionizing Particle: Typically low- (megaelectronvolts) and medium-energy (order 100 MeV) charged particles whose energy loss in matter is large enough to produce a high rate of electron–positive-ion pairs. These are in contrast to minimum-ionizing particles (order gigaelectronvolts), which are more common in high-energy physics.

Tevatron: Proton–Antiproton Collider with 2-TeV center-of-mass energy located at Fermi National Laboratory, Batavia, Illinois.

Vertex: The origin of a particle interaction. This interaction can be the collision of two accelerated beam particles or the location of a parent particle prior to its decay. In the latter case, the position of the decaying particle is reconstructed from the tracks of its decay products.

12.1
Introduction

In the past century, there has been a revolution in our understanding of the microscopic nature of matter, and much of this new insight was gained by observing the impact of beams of particles and photons on surfaces. Rutherford made his historic discovery of the nucleus by studying the scattering of a beam of α particles as they passed through thin foils. Davisson and Germer confirmed the existence of de Broglie matter waves by observing the diffraction of a beam of electrons by crystalline targets. In fact, many of the most important experiments of the twentieth century relied on impact phenomena.

While high-energy particle beams continue to be the vanguard of research into the fundamental nature of matter, the techniques that played major roles in the development of modern physics have now become indispensable tools for materials analysis in nuclear, atomic, medical, and condensed-matter physics, as well as physical chemistry and materials science (Kittel, 2004). Much of the new technology that defines the modern world resulted from progress in these fields, and, in turn, this progress depends upon a basic understanding of impact phenomena. In fact, impact phenomena play a prominent role throughout this Encyclopedia. This discussion, however, focuses on the rich variety of phenomena associated with beam interactions with condensed matter.

Analysis techniques that employ impact phenomena have in turn relied heavily upon progress made in related fields (Feldman and Mayer, 1986). Useful particle beams can only be produced in vacuum, and surfaces are difficult to characterize in the presence of air at normal temperatures and pressures. Therefore, vacuum technology has been particularly important to the development of impact techniques. Also, the emerging laser technologies and synchrotron-radiation sources are revolutionizing the way materials are characterized. Of course, progress in particle accelerator designs in both the high- and low-energy regimes has been crucial. Finally, the development of a tremendous variety of detectors and measurement devices has greatly expanded the range and sensitivity of experiments.

The nature of the interaction between a particle or photon beam and a target is highly dependent on the wavelength of the incident species. For a particle beam, the de Broglie relation gives the wavelength

$$\lambda = \frac{h}{\sqrt{2mE}} \tag{1}$$

Encyclopedia of Applied High Energy and Particle Physics. Edited by Reinhard Stock
Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40691-3

where h is Planck's constant, m is the mass of the particle, and E is the energy (Shankar, 1994). The wavelength of a photon is just

$$\lambda = \frac{hc}{E} \quad (2)$$

where c is the speed of light. If the wavelength is much larger than the interatomic distance, then the incident particle wave function interacts with several target atoms at the same time. Consequently, in the infrared, visible, and ultraviolet atomic resolution is not possible. For photons, near-field techniques can circumvent this restriction to some extent. If the wavelength is the same order of magnitude as the interatomic distance in the target material, as it is in the X-ray region of the electromagnetic spectrum, then interference effects occur, allowing diffraction experiments, which can reveal periodic atomic structure. If the wavelength is much smaller, collisions can be characterized as simple two-particle interactions, and true atomic resolution is possible. Table 12.1 shows, for several beam species, the energy required to obtain wavelengths of 1 Å, which is about the size of an atom, and 5 Å, which is typical of interatomic distances in crystals.

As the table indicates, with photons only X-rays have short enough wavelength for diffraction experiments. Electrons, on the other hand, have a very convenient mass so that diffraction and atomic resolution are possible with modest energies easily achieved in the laboratory. In contrast, nucleons have such large mass that interference effects are difficult to produce. Nevertheless, neutrons at thermal energies can be collimated into beams and used for diffraction experiments. For example, the energy for a 1-Å neutron given in the table would correspond to a temperature of 650 °C. This illustrates that each species has inherent difficulties and advantages.

Another central issue is the degree to which the probe itself modifies the target. Almost all experiments damage the target on a microscopic level, and high-energy or high-flux beams can do macroscopic damage. With the recent developments in constructing and characterizing nanostructures, minimizing even microscopic damage from analysis techniques has become crucial. Unfortunately, a useful description of damage requires a very thorough description of the extremely complicated dynamics and is beyond the scope of this chapter.

Section 12.2 describes the basic Coulomb interaction, which is the basis for most simple models of particle impact and is therefore applicable to several of the subsequent sections. The remaining sections are organized by the identity of the impacting beam. Section 12.3 treats electron bombardment. Section 12.4 deals with ion–solid interactions. Section 12.5 discusses photon interactions, and Section 12.6 presents neutron interactions. Although the chapter is organized in this manner, many of the concepts

Tab. 12.1 The energy (in electron volts) required to achieve wavelengths of 1 and 5 Å for various species.

Wavelength (Å)	Photon	Electron	Nucleon	Helium	Argon
1	12 400	150	0.0819	~0.02	~0.002
5	2 480	6.02	0.00328	~0.0008	~0.00008

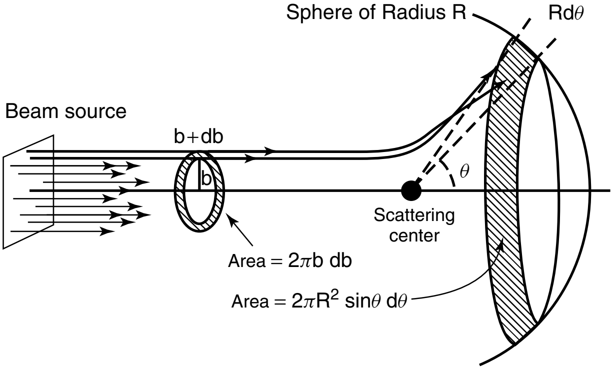

Fig. 12.1 The relationship between differential cross section and impact parameter.

of impact are applicable to more than one beam species. Within each section, the basic mechanisms of interaction are described, the observed phenomena are indicated, and finally, the most common applications are outlined.

12.2
Scattering from a Coulomb Potential

Many of the impact phenomena treated in this chapter begin with two-particle Coulomb scattering (Fetter and Walecka, 1980). Since this model is central to the discussion, a basic description is included. Charged particles traveling through a target material will feel a Coulomb repulsion or attraction to the electrons and nuclei in the material. Because materials are typically macroscopically neutral, it is assumed that long-range interactions are screened, and only individual classical two-particle collisions are significant. Because of the limited validity of this assumption, some of the later treatments will include correction factors that will not be derived.

Low-mass particles scattering from heavy target particles will transfer very little energy. Large scattering angles are possible, and scattering behavior can be determined from the relation of impact parameter to scattering angle. The impact parameter b is defined as the perpendicular distance from the target particle to the initial line of flight. Figure 12.1 indicates the relationship between impact parameter and scattering angle. The differential cross section $d\sigma$ can be defined by

$$d\sigma = 2\pi b\, db \tag{3}$$

From this model, it is seen that the differential cross section per unit solid angle is

$$\frac{d\sigma}{d\Omega} = \frac{b}{\sin\theta}\left|\frac{db}{d\theta}\right| \tag{4}$$

The integration of this over all solid angles yields the total cross section. The scattering problem is now reduced to determining $db/d\theta$, which can be inferred from the equations of motion in a Coulomb potential. In the center-of-mass frame, a particle with mass m and charge ze scattering from a particle of mass M and charge Ze will satisfy the equation

$$\mu\ddot{\mathbf{r}} = zZe^2\frac{\mathbf{r}}{r^3} \tag{5}$$

where μ is the reduced mass, $\mu = mM/(M+m)$, and $\mathbf{r}$ is the vector from the scattering center to the incident particle. The resulting orbits lead to the following relation between b and θ:

$$b = \frac{|zZ|e^2}{\mu v^2} \cot \frac{\theta}{2} \tag{6}$$

where v is the velocity of the incident particle. Note that the sign of the charges is indistinguishable. With reference to Figure 12.1, an attractive potential would draw the particle down rather than push it up, but the scattering angle would be the same. Using this relation, the differential cross section may be written as

$$\frac{d\sigma}{d\Omega} = \left(\frac{zZe^2}{4E \sin^2(\theta/2)} \right)^2 \tag{7}$$

where E is the energy of the incident particle in the center-of-mass frame. If the scattering center is much more massive than the incident particle, the center-of-mass energy is approximately equal to the laboratory energy. Thus, this derivation is extremely useful for describing the scattering of light particles from heavy particles.

On the other hand, a heavy particle scattering from a light particle will change direction only slightly. In this case, the interesting parameter is the amount of energy transferred. Assume that the heavy particle does not deflect at all and that the interaction is sudden so that the target particle cannot move very much. The net impulse in the direction of travel is zero as a result of the symmetry of the incoming and outgoing paths. However, integrating the Coulomb force, the momentum transfer in the perpendicular direction $\Delta; p$ is

$$\Delta p = \frac{2zZe^2}{bv} \tag{8}$$

This then gives the transferred energy directly:

$$\Delta E = \frac{\Delta p^2}{2m} = \frac{mz^2 Z^2 e^4}{Mb^2 E} \tag{9}$$

where the velocity of the incident particle has been written in terms of its kinetic energy:

$$E = \frac{1}{2} mv^2 \Longrightarrow v^2 = \frac{2E}{m} \tag{10}$$

Equation (9) may be inverted to find the impact parameter in terms of the transferred energy. Using this for the impact parameter in Eq. (3), the differential cross section may be written in terms of the energy transfer as

$$d\sigma = \frac{\pi mz^2 Z^2 e^4}{ME\Delta E^2} \, d\Delta E \tag{11}$$

12.3
Electron Impact

12.3.1
Interaction Mechanisms

12.3.1.1 Collisions with Electrons in the Solid

The interaction of a beam of electrons impinging on a solid or liquid target can be modeled to a good approximation by classical two-particle scattering from target electrons. Although the masses of the incident particle and target particle are identical, the impulse approximation applies if the energy of the incoming electron is sufficiently high. Here, the change in momentum Δp and thus the change in energy $\Delta; E$ as a function of impact parameter b reduce to

$$\Delta p = \frac{2e^2}{bv} \Longrightarrow \Delta E = \frac{e^4}{Eb^2} \tag{12}$$

where e is the electron charge, v is the velocity of the incident electron, and E is the energy of the incident electron. Thus the differential cross section $d\sigma$ is

$$d\sigma(E) = -2\pi b\, db = \left(\frac{\pi e^4}{E\Delta E^2}\right) d\Delta E \quad (13)$$

Integrating this gives the cross section for a particular transition with energy E_t:

$$\sigma = \pi \frac{e^4}{E}\left(\frac{1}{E_t} - \frac{1}{E}\right) \quad (14)$$

If the beam energy is much greater than the transition energy, the cross section simplifies to

$$\sigma \cong \frac{\pi e^4}{EE_t} \quad (15)$$

The possible electronic transitions are determined by the electronic structure of the target. The transition corresponding to E_t could be from a bound state, valence-band state, or conduction-band state to any higher energy state including free-particle states, which, if the surface is nearby, may result in the escape of electrons. For example, a valence-band electron could be promoted to the conduction band resulting in an electron–hole pair, or a bound core electron could be ejected from the solid.

Assuming that one transition dominates the absorption, the rate of energy loss as a function of distance traveled in the target may also be estimated by integrating energy times the differential cross section. This yields

$$-\frac{dE}{dx} = \frac{2\pi e^4 n}{E} \ln\left(\frac{E}{E_t}\right) \quad (16)$$

where n is the density of electrons in the initial state. Since energy can only be transferred in discrete amounts, the mean free path can be estimated from the rate of energy loss. For example, the dominant interaction in a metal is plasmon excitation, and so the mean free path λ can be estimated from the plasmon energy $\hbar\omega$:

$$\frac{1}{\lambda} = -\frac{m\omega e^2}{2\hbar E} \ln \frac{4E}{\hbar\omega} \quad (17)$$

where m is the mass of the electron. For a 1-keV electron incident on a typical metal, this initial penetration depth is a few nanometers. This formula applies equally well to the escape depth of ejected electrons in the solid.

Note that the cross section and thus the mean free path depend on the energy of the incident particle. Since the particle loses energy after each collision, λ must be integrated to find the average range of travel of the incident electron in the target. This yields an equation for the path length (range) R of the form

$$R = \left(\frac{K}{\rho}\right) E^{\gamma} \quad (18)$$

where ρ is the density of the material and K and γ are constants. Since this derivation is approximate, the form of the electron range as shown in Eq. (18) is assumed, but the parameters K and γ are fitted empirically. The parameter K is dependent on the material's density and atomic weight, but for R in microns, ρ in grams per cubic centimeter, and E in electron volts the value for K is approximately 0.064 for all materials. The parameter γ depends on the target material and is typically between 1.2 and 1.7. While this estimates the length of the electron's trajectory, each interaction results in a random scattering angle so that the trajectory is generally not straight.

12.3.1.2 Scattering from the Lattice

Because of the wave nature of the incident electron, it may also scatter from the atoms in the target without exciting an electronic state. Quantum mechanically, the wave function interacts with many atoms at the same time (Wichmann, 1971). The scattered wave function interacts with itself, resulting in quantum interference effects, and scattering is enhanced in those directions for which the interference is constructive. Since the mass of the target is so much greater than the mass of the electron, the momentum transfer is negligible, and the electron will lose almost no energy. Electrons are well suited to diffraction studies of crystals because diffraction requires that the wavelength of the incident particle must be near the size of the structure to be investigated. At 150 eV, an electron will have a wavelength of about 11 Å. Electron backscatter diffraction (EBSD) has been used effectively for texture, stored energy, and grain characterization on small scales down to ∼200 nm (Humphreys, 2004).

If the atoms in the target are regularly spaced in a lattice, the interference will also have a regular pattern. This can easily be demonstrated by considering Bragg reflection from adjacent planes of atoms (Figure 12.2). A beam reflecting from parallel planes separated by a distance d will have a path-length difference of $2d\sin\theta$, where θ is the angle of incidence. If these paths are such that constructive interference occurs, the path-length difference must equal an integer number of wavelengths:

$$n\lambda = 2d\sin\theta\,\text{(Bragg condition)} \qquad (19)$$

In a three-dimensional lattice, there are many ways to choose parallel planes of atoms, and each of these facets imposes another Bragg condition. Constructive interference will be greatest in scattering directions that best match all of these Bragg conditions, so that scattering in those directions is highly probable. On a detector screen, the set of favorable scattering directions forms a distinct pattern of points referred to as a *diffraction pattern*. The Bragg condition along with some simple geometry indicates that the distance between adjacent points in the diffraction pattern is inversely proportional to the distance between planes in the lattice.

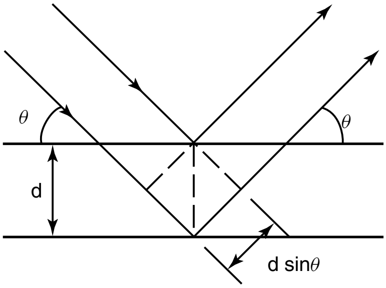

Fig. 12.2 Bragg reflection.

12.3.1.3 Bremsstrahlung

In scattering from the target atoms, the incident electron is decelerated, and so it must emit radiation. While this is true for any charged particle, it is particularly important for electrons whose light mass readily allows them to experience large decelerations. A continuous spectrum of radiation will be produced in which the intensity decreases monotonically as a function of increasing energy up to the energy of the incident electron (Jackson, 1999). The radiation spectrum can be calculated from classical electromagnetic theory. For nuclear scattering of nonrelativistic electrons, the radiation spectrum is characterized by the Bethe–Heitler theory (Bethe and Heitler, 1934)

$$I = \frac{16Z^2e^6}{3m^2v^2c^3} \times \ln\left(\frac{2-(\hbar\omega/E)+2\sqrt{1-(\hbar\omega/E)}}{\hbar\omega/E}\right) \tag{20}$$

where I is the spectral intensity and Z is the atomic number of the target species. Note that the effect is greatest for high atomic number targets. The ratio of bremsstrahlung energy E_B to other losses is approximately

$$\frac{dE_B}{dE_{\text{other}}} \approx \frac{4Z}{3\pi 137}\left(\frac{v}{c}\right)^2 \tag{21}$$

For an energy of 100 keV and a target with $Z \approx 30$, roughly 4% of the beam power goes into bremsstrahlung.

12.3.2
Phenomena

12.3.2.1 Plasmons

A plasmon is a density wave in the quasi-free gas of conduction electrons. It is important to note that electrons interact and produce correlated behavior in insulators as well as in metals; however, the following discussion applies only to metals. In metals, plasmon excitation will dominate the electron interactions. Consider a volume of negative charge embedded in a stationary positive charge of similar volume. Displacing the negative charge creates a dipole field that in turn produces a linear restoring force. The plasmon is thus a harmonic oscillation with frequency

$$\omega = \sqrt{\frac{4\pi ne^2}{m}} \tag{22}$$

where n is the density of electrons. The energy of these oscillations is $\hbar\omega$. For typical metals, this falls in the range of 10–15 eV. Because of the surface boundary conditions, there is a separate surface-plasmon mode that has a characteristic frequency of $\omega/\sqrt{2}$. For very small particles, boundary conditions complicate the plasmon model, and the plasmon frequency will depend on the size and shape of the particle. Plasmons have been proposed for use as data interconnects in nanoscale transistors (Ozbay, 2006).

12.3.2.2 Radiative Transitions

Electrons in the solid excited by impact may relax by emitting a photon. Also, if a core target electron is ejected, other electrons in the solid from either the same atom or neighbors may fall into the vacancy, emitting a photon. For radiative transitions, the energy of the photon will equal the difference in energy of the initial and final states of the radiating electron.

The easiest of these transitions to understand conceptually and interpret experimentally is a transition of a bound electron to fill a vacancy in the same atom. From perturbation theory, assuming only dipole interactions, the rate R for a spontaneous transition from a filled state to an empty state is found to be

$$R = \frac{4e^2}{3\hbar^4c^3}\Delta E^3|\langle f|\mathbf{r}|i\rangle|^2 \tag{23}$$

where ΔE is the transition energy and the labels i and f refer to the initial and final electron states, respectively.

The rate depends heavily on the transition energy, but many transitions are disallowed by the dipole matrix element. Thus, the transition energy dependence is most apparent when comparing similar transitions in atoms with differing atomic number. The dipole matrix element between the initial and final state indicates that transitions between highly overlapping states are preferred. Since the change in angular momentum of the absorber (or emitter) must equal the angular momentum of the photon, the matrix element automatically imposes dipole selection rules. The allowed dipole transitions have $\Delta l = \pm 1$ and $\Delta j = \pm 1$ or 0, where l and j are the angular-momentum quantum numbers. However, other multipole transitions may occur with different restrictions.

12.3.2.3 Auger Processes

An electron making a transition to a core vacancy may also release the excess energy by exciting another electron. This is called an *Auger process*, and the resulting excited electron is called an *Auger electron* (Figure 12.3). The electron that falls into the vacancy can most easily transfer energy to an electron in the same subshell. One falls into the vacancy, and the other carries the excess energy to a higher state, possibly the vacuum state, leaving two new vacancies in the higher shell or band. The transition rate also depends on the overlap of the initial and final states of the electron that fills the vacancy. Unlike radiative transitions, a vacancy may be filled by an electron from a higher orbital substate of the same primary shell as the vacancy. Since the initial and final states for such an intrashell transition are very similar, these transitions have higher rates than might be expected from the previous argument. These intrashell transitions are called *Coster–Kronig transitions.*

To first order, the energy of an escaping Auger electron can be estimated from the binding energies of the initial and final states. If a vacancy in state a is filled by an electron originally in state b, resulting in an electron in state c being ejected, the energy of the liberated electron is

$$E = E_a - E_b - E_c \tag{24}$$

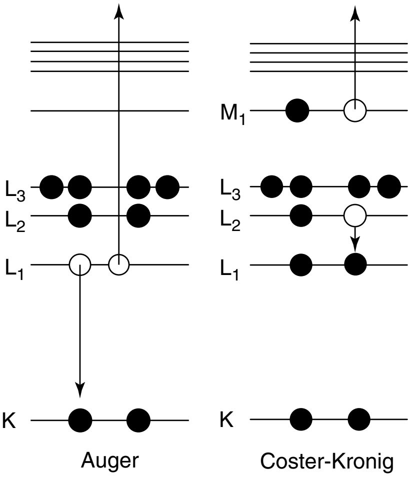

Fig. 12.3 Auger processes.

where these are the normal binding energies of the states. However, there is a significant correction due to the vacancies, which alter the normal binding energies. A fairly good estimate can be constructed from the binding energies of similar states in an atom with one more proton:

$$E = E_a^Z - E_b^Z - E_c^Z - \frac{1}{2}\left(E_c^{Z+1} - E_c^Z + E_b^{Z+1} - E_b^Z\right) \quad (25)$$

12.3.2.4 Desorption Induced by Electronic Transitions (DIET)

When a *localized* excited state is created in a solid, it dramatically changes the local electronic environment. If the state is sufficiently long lived, the electromagnetic forces can alter the position of an atom or molecule in the lattice, resulting in defect formation or even desorption (Tolk *et al.*, 1983). Consider an atom adsorbed on a surface. An electron in some bonding orbital holds the atom to the surface. If that electron is excited to a weaker-bonding or even an antibonding state, the bond may break, resulting in desorption. Somewhat more spectacular is the highly repulsive state that results when the electron of one atom makes a transition into the core vacancy of a neighboring atom. Several other mechanisms exist by which the electronic energy can be channeled into the kinetic energy of the atoms or molecules in the lattice, resulting in damage.

12.3.2.5 Secondary Electron Emission

In addition to directly ejected electrons or Auger electrons, a target will also emit a broad band of electrons with energies less than 100 eV that are relatively insensitive to the energy of the incident beam. These low-energy electrons are called *secondary electrons* because they clearly do not result from a single-step process or even a two-step process like Auger electrons. Although secondary electrons arise from several sources, an argument based on plasmons provides a clue to their origin. One or more plasmons may couple to a single electron, thus giving that electron enough energy to escape from the surface. Since plasmons have fixed energies, the shape of the energy spectrum of emitted electrons would not depend on how the plasmons were created. This and other similar processes result in an energy spectrum of which only the amplitude depends on the incident energy.

12.3.3
Applications

12.3.3.1 Scattered-Beam Electrons

Since the probability for electron scattering depends on the density of electrons in the material, the scattering of electrons for a fixed target thickness will vary with different materials. For example, this effect provides the contrast for transmission electron microscopy (TEM).

The incident electron can only lose energy in discrete amounts determined by the allowed transitions in the target material. Thus, one can learn a great deal about the electronic structure of the target by measuring the energy of beam electrons that pass through the target. This is the basis of electron energy-loss spectroscopy (EELS). If the same measurement is made for the reflected portion of a low-energy beam, the measurement is surface sensitive. This is the principle behind high-resolution electron-energy-loss spectroscopy (HREELS).

Since elastically scattered electrons may interfere, the structure of the lattice can be determined from the spatial distribution of scattered electrons. This is the basis of electron diffraction. For example, the transmitted-beam electrons in a transmission electron microscope demonstrate a diffraction pattern. Low-energy electrons reflected at normal incidence from a crystalline surface will also show a diffraction pattern, which is primarily surface sensitive. This is called *low-energy electron diffraction* (*LEED*). Because the component of energy into the surface is small, a high-energy electron beam reflected at grazing incidence will also produce a surface-sensitive diffraction pattern. This technique, called *reflection high-energy electron diffraction* (*RHEED*), provides a more convenient geometry than LEED in that the surface is more accessible for simultaneous experiments.

12.3.3.2 **Electrons from the Target**

In addition to scattered-beam electrons, Auger electrons may also escape from the target. Measuring the energy of electrons reveals peaks at energies corresponding to the Auger transitions, which are characteristic of the target atoms. Thus Auger-electron spectroscopy (AES) can detect target species down to the 0.1% level. Elaborate techniques are usually required to separate the Auger peaks from the background of scattered-beam electrons.

12.3.3.3 **Fluorescence Measurements**

To avoid the background problem of Auger-electron spectroscopy, the characteristic photons produced by similar radiative transitions may be detected. Since the size of the target volume probed by the electron beam can be reduced to about a micron, this technique is referred to as *electron microprobe analysis* (*EMA*). Characteristic photons are typically in the hard ultraviolet or X-ray region and thus have their own detection challenges.

12.4
Ion Impact

12.4.1
Interaction Mechanisms

12.4.1.1 **Elastic Collisions with Target Atoms**

Particles such as ions or molecules striking a surface will interact primarily by elastic collisions with target atoms. By conservation of energy and momentum, it is easily shown that the fraction of initial energy retained by the incident particle is

$$\frac{E_1}{E_0} = \left[\frac{(M_2^2 - M_1^2 \sin^2\theta)^{1/2} + M_1 \cos\theta}{M_1 + M_2} \right]^2 \qquad (26)$$

where M_1 is the mass of the incident particle, M_2 is the mass of the target particle, and θ is the scattering angle. This ratio is referred to as the *kinematic factor* and is often denoted by K. The kinematic factor as a function of angle for several choices of the ratio M_2/M_1 is plotted in Figure 12.4 The fraction of energy transferred to the target particle is similarly given by

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2} \cos^2\phi \qquad (27)$$

where ϕ is the recoil angle. For particular scattering angles, these relations become quite simple. For example, in the case of backscattering, $\theta = \pi$ and $\phi = 0$, so

$$\frac{E_1}{E_0} = \left(\frac{M_2 - M_1}{M_1} \right)^2 \quad \text{and}$$

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2} \qquad (28)$$

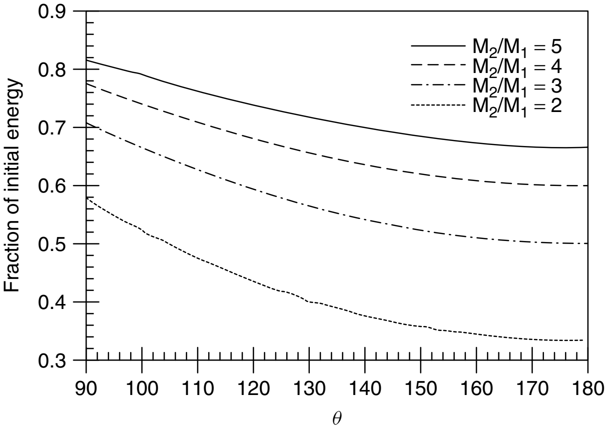

Fig. 12.4 The kinematic factor as a function of scattering angle for several choices of the ratio M_2/M_1.

Electron screening of target nuclei complicates heavy particle scattering. Nevertheless, if the energy of the incident particle is high enough to penetrate well within the electron cloud, the simple scattering model will be approximately correct. This condition will be met if

$$E_0 > \frac{zZe^2}{a_0} \tag{29}$$

where z is the atomic number of the incident atom, Z is the atomic number of the target species, and a_0 is the Bohr radius. In any case, screening will produce some deviation from the simple model, and, in general, a correction factor must be included. Ignoring electron screening, the cross section is as given above:

$$\sigma(\theta) = \left(\frac{zZe^2}{4E\sin^2(\theta/2)}\right)^2 \tag{30}$$

12.4.1.2 **Collisions with Electrons in the Solid**

An incident heavy particle will also collide with electrons in the solid. However, as a result of momentum conservation, a heavy particle can transfer only a small fraction of its momentum to an electron. Thus, as a high-energy particle traverses a target, it will slowly lose energy through numerous electron collisions in an almost continuous fashion. These collisions may also be modeled with the impulse approximation. The derivation of the rate of energy loss is completely analogous with that for electron–electron scattering. Thus the rate of energy loss as the particle traverses the target is

$$-\frac{dE}{dx} = \frac{2\pi z^2 e^4 n}{E}\frac{M}{m_e}\ln\frac{4Em_e}{IM} \tag{31}$$

where M is the mass of the incident particle, z is its atomic number, I is the average excitation energy of electrons in the solid, and n is the density of electrons in the solid. I is complicated, but, for heavier elements, it is approximately equal to $10Z$. This is usually converted to a ‘‘stopping power’’ per atom (Figure 12.5). The stopping power ε per atom is defined as

$$\varepsilon = \frac{dE/dx}{N} \tag{32}$$

where N is the density of the target atoms. The stopping power can then be used to determine dE/dx for compounds.

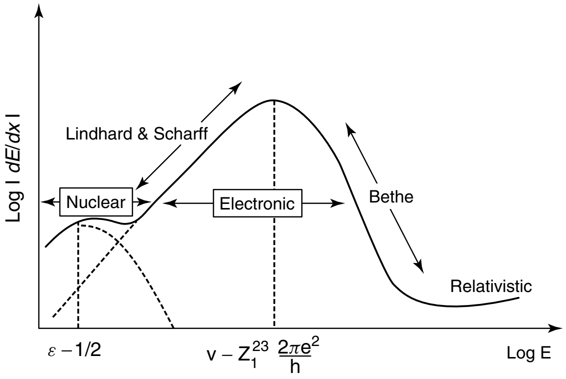

Fig. 12.5 Stopping power.

According to Bragg's rule, for a compound A_nB_m, the stopping power is

$$\varepsilon_{A_nB_m} = n\varepsilon_A + m\varepsilon_B \tag{33}$$

where n and m are the relative atomic abundances of the respective constituents. Thus, multiplying by the molecular density, the rate of energy loss in a compound target may be determined.

Although electronic stopping is the most important contribution to the energy loss for a large range of energies, other factors such as scattering from the atomic cores are also important. The convoluted path resulting from numerous scattering events further complicates this picture. To compute the total depth beneath the surface attained by an incident particle, all of these factors must be considered. Table 12.2 indicates the median penetration depth for various species and energies of particles incident on amorphous alumina.

12.4.2
Phenomena

12.4.2.1 Depth Dependence of Backscattering

Since a heavy particle will lose energy to electrons as it penetrates a target, the electron scattering produces depth dependence in the energy of atomic scattering. For example, consider a light ion with energy E scattering from an atom at a depth d within the target. To find the total energy lost to electron scattering, dE/dx

Tab. 12.2 Penetration depth in μg/cm² for various incident species and energies, derived from implantation of amorphous alumina.[a]

Energy (eV)	Na	K	Kr	Xe
10	4.5	2.6	2.5	2.3
100	35	20	14	11
1000	500	260	170	100

[a] (Jespergard and Davies, 1967).

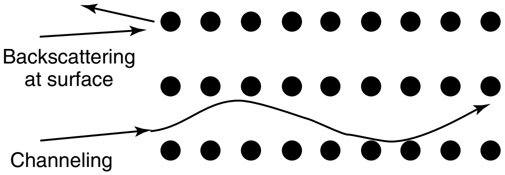

Fig. 12.6 Channeling.

should be integrated to the penetration depth. However, for modest depths, the fractional energy loss will be small, and the total energy loss is approximately

$$\Delta E \cong \frac{dE}{dx} d \tag{34}$$

where dE/dx is evaluated at the incident energy E . The particle with this reduced energy now backscatters from a target atom, and the energy is reduced by the kinematic factor above. The particle then traverses the target again before escaping. Since the particle may have been scattered at an angle to the surface normal, the distance traveled on the way out is $d/\cos\theta$. The energy loss is approximated as above with dE/dx now evaluated at the appropriate backscattered energy. Thus, the total energy lost to the electrons both in entering and exiting the sample is

$$\Delta E = d\left(K\left.\frac{dE}{dx}\right|_{\text{in}} + \frac{1}{|\cos\,\theta|}\left.\frac{dE}{dx}\right|_{\text{out}}\right) \tag{35}$$

where K is the kinematic factor and ''in'' and ''out'' indicate at which energy dE/dx should be evaluated. Note that the total energy lost to electron scattering is directly proportional to the penetration depth.

12.4.2.2 **Sputtering**

Atomic collisions impart significant energy to the target atoms, and, in general, they will in turn collide with other target atoms. The resulting collision cascade can give some atoms sufficient momentum to escape from the target, and so the ion beam erodes the target. This process is called *sputtering* (Behrisch, 1981). The sputtering yield is defined as the number of target atoms emitted per incident particle. This depends not only on the nature of the target material but also on the beam species and energy, and the possible values vary tremendously. Although calculation of sputtering yields is understandably daunting, theory has produced good results. Nevertheless, for practical applications, empirical values are used.

12.4.2.3 **Channeling**

If the target is crystalline, an interesting phenomenon known as *channeling* may occur (Figure 12.6). If the incident particles are aligned along one of the highly oriented directions of the crystal, they cannot collide solidly with atoms in the bulk of the target. Essentially, the atoms on the surface shadow the rest of the atoms. However, the effect is greater than that simple explanation indicates. Consider the regular lattice to be parallel planes of atoms. If the incident particle is moving nearly tangential to these planes, it will merely glance off the planes at a shallow angle. This requires very little energy, and the incident particle will move down this channel, making a series of shallow collisions with the ''walls''. Thus, a particle incident in a channeling direction may penetrate very deeply into the target. The ultimate depth achieved is primarily determined by electron stopping. Furthermore, backscattering will only occur at the surface.

12.4.2.4 Damage and amorphization

For sufficiently energetic ion beams, energy loss can occur through defect creation. Depending on the temperature during ion bombardment, both point and complex defects may be created. Consequences include deteriorated electronic and optical properties, a problem especially relevant in high-energy particle detectors (such as at LHC or GANIL). For increased dosage, enough damage may occur such that the amorphous state becomes energetically favorable. However, this threshold varies with relative target-ion mass difference, temperature, and dosage. Finally, many materials exhibit interesting nonlinear behavior when irradiated with swift (0.1–1 GeV) ions. Such effects include latent tracks and phase changes to metastable lattice configurations.

12.4.2.5 Electronic Excitations

In colliding with the electrons, a heavy particle excites electronic states in the target just as in the case of electron bombardment. Therefore, many of the same phenomena are seen in each case. Electrons will be ejected, electron–hole pairs will be created, plasmons will be stimulated, secondary electrons will be produced, and most of the other previously discussed electronic excitations will occur. Of particular interest are the radiative transitions to fill a core hole created by the incident particle. The origins of the core hole are irrelevant, and the process is exactly as described in the Section 12.3.

12.4.3
Applications

12.4.3.1 Measuring Beam Particles

The energy of a light ion that has been scattered is uniquely determined by the species from which it scattered. If the energy of scattered-beam particles is measured, the composition of the target can be determined. This is the basis of Rutherford backscattering spectrometry (RBS). For simplicity, the measurement is usually made as close to the backscattering direction as possible. Since the energy has a simple dependence on depth due to electron scattering, depth profiling is also possible. Finally, since subsurface atoms cannot readily backscatter when the beam is aligned along a channeling direction, channeling can enhance the surface sensitivity of RBS. For example, RBS can easily detect whether a surface is reconstructed, relaxed, or covered with an adsorbate.

To enhance surface sensitivity, an ion beam with energy in the range of one to a few kiloelectron volts may be used in conjunction with an electrostatic energy analyzer. Since particles that penetrate the surface are almost always neutralized, the electrostatic energy analyzer will detect only particles scattered from the surface. The low-energy beam ensures that most of the ions will be scattered from the surface. This is the basis of low-energy ion scattering (LEIS).

12.4.3.2 Recoil Target Atoms

Backscattering is inefficient for lighter target materials and kinematically impossible if the target material is lighter than the beam species. Rather than measuring backscattered beam particles, measuring the energy of forward recoiling target atoms gives the same kinematic information. This is the basis of forward recoil spectrometry (FRS). The beam is usually incident at a shallow angle to the target surface, and the recoiling atoms are detected at some small angle from the surface in the forward direction.

12.4.3.3 Fluorescence Measurements

Heavy particles may also produce core-hole vacancies in target atoms. The mechanisms for filling the vacancy are exactly the same as described above. In particular, the target may be characterized by measuring the radiation from such transitions. This is the basis of proton- (or particle)-induced X-ray emission (PIXE). Because the larger mass of the incident particle results in far less bremsstrahlung, PIXE has less background noise than electron microprobe analysis.

12.5
Photon Impact

12.5.1
Interaction Mechanisms

12.5.1.1 Electronic Absorption

A photon incident on a target atom or molecule may excite higher electronic states in the target. If the photon is modeled as an oscillating perturbation $H'e^{-i\omega t}$, from first-order perturbation theory, the probability of stimulating a transition is given by Fermi's "golden rule,"

$$P_{i\to f} = t\frac{2\pi}{\hbar}|\langle\langle f|H'|i\rangle|^2\delta(E_f - E_i - \hbar\omega) \tag{36}$$

where t is the length of time that the perturbation is applied, and the labels i and f indicate initial and final states of the *unperturbed* system. The terms E_i and E_f are the energies of the unperturbed initial and final states. Note that the transition energy must be equal to the energy of the photon. This seems to imply that the whole photon must be absorbed, and scattering will not occur. However, the excited state may relax by emitting another photon with either equal or lower energy, resulting in an effective scattering. Also, according to the uncertainty principle, noneigenstates can exist for a short time, so photons may be scattered even when no resonant transition exists. Nevertheless, the probability of interaction is much greater at resonance, that is, when there exists a transition with a difference in energy equal to the energy of the photon. Therefore, light will be strongly absorbed at frequencies that correspond to the allowed electronic transitions. The matrix element indicates the strength of coupling of the photon to the electronic states. In general, the coupling is proportional to the dipole moment. However, as in the case of atomic hydrogen, time dependence allows some coupling where no dipole moment exists. Finally, because a photon has angular momentum, only transitions with $\Delta l = 1$ are allowed with high probability in the dipole approximation.

12.5.1.2 Nuclear Scattering

An incident photon may also scatter from the target atom without leaving the atom in an excited state. The large mass of the nuclei allows momentum to be conserved without significantly changing the energy of the photon. Since the energy does not change, the photon maintains its initial wavelength, and interference may occur. As with electrons, the resulting diffraction pattern is indicative of the long-range order of the target. The diffraction relations are exactly the same as discussed previously for particle interference (see Section 12.3.1.2).

12.5.1.3 Coupling to Vibrational and Rotational Modes

Molecular bonds may have many modes of vibration and rotation, each with one or more natural frequencies. If a given bond has electric dipole characteristics, the electric field of a photon with a frequency resonant to the bond may excite these bonds to higher vibrational and rotational states. A photon is absorbed in the process.

12.5.2
Phenomena

12.5.2.1 Photoelectric Effect

If the incident photon has greater energy than the binding energy of electrons in the target, electrons may be liberated. The maximum energy of the ejected electron will be

$$E = E_b - \hbar\omega \tag{37}$$

where E_b is the binding energy of the electron. Since the final state is a free particle, selection rules can always be satisfied, and all electrons with binding energy less than or equal to the photon energy may be liberated. Applying Fermi's "golden rule" to hydrogenic states yields the cross section for a photon of energy $\hbar\omega$ liberating an electron with binding energy $E_b < \hbar\omega$:

$$\sigma = \frac{128\pi e^2 \hbar E_b^{5/2}}{3mc(\hbar\omega)^{7/2}} = \frac{7.45\text{eV}\text{Å}^2}{\hbar\omega}\left(\frac{E_b}{\hbar\omega}\right)^{5/2} \tag{38}$$

12.5.2.2 Compton Scattering

For photon-electron scattering, if the energy transferred to the electron is much greater than its binding energy, the scattering will be nearly identical to scattering from a free electron. The resulting scattering behavior can be deduced simply from energy and momentum conservation. If a photon initially with energy $\hbar\omega$ scatters at an angle θ from an electron initially at rest, conservation of energy requires

$$\begin{aligned} E_p + E_e = E_p' + E_e' \Longrightarrow \hbar\omega + mc^2 \\ = \hbar\omega' + E' \end{aligned} \tag{39}$$

where the subscripts refer to photon and electron, and unprimed and primed stand for before and after the collision, respectively. The term E' is the subsequent relativistic energy of the electron. Momentum conservation requires

$$\mathbf{p}_p = \mathbf{p}_p' + \mathbf{p}_e' \Longrightarrow (\mathbf{p}_p - \mathbf{p}_p') = \mathbf{p}_e'^2 \tag{40}$$

which may be written as

$$\frac{\hbar^2\omega^2}{c^2} + \frac{\hbar^2\omega'^2}{c^2} - \frac{2\hbar^2\omega\omega'}{c^2}\cos\theta = p_e'^2 \tag{41}$$

Combining Eqs. (39) and (41) yields

$$\omega' = \frac{\omega}{1 + (\hbar\omega/mc^2)(1 - \cos\theta)} \quad \text{or}$$
$$\lambda' = \lambda + \frac{2\pi\hbar}{mc}(1 - \cos\theta) \tag{42}$$

Note that the wavelength of the scattered photon depends on the scattering angle. Also, the wavelength shift is independent of the initial wavelength. The shift only becomes significant for fairly short initial wavelengths, and hard (high-energy) X-rays must be used to see the effect.

12.5.2.3 Raman Scattering

For a photon to couple to one of the collective nonlocalized vibrational modes of a lattice, momentum must be conserved. A photon traversing a material can emit or absorb an optical phonon, but in order to conserve momentum and energy, the frequency and direction of the photon must change. If a phonon is created, the interaction is called a *Stokes process*. If a phonon is absorbed, it is an anti-Stokes process (Figure 12.7). Conservation of energy requires $\omega = \omega' \pm \Omega$ where ω is the frequency of the incident photon, ω' is the frequency of the scattered photon, and ω: is the frequency of the phonon that is created or absorbed by the photon. To conserve momentum, $\mathbf{k} = \mathbf{k}' \pm \mathbf{K}$, where $\mathbf{k}$, $\mathbf{k}'$, **and** $\mathbf{K}$ are the wave vectors for the incident photon, scattered photon, and phonon, respectively.

12.5.2.4 **Two-Phonon Absorption**

Similarly, a photon cannot be completely absorbed into a single phonon because a phonon with the same energy will not have the same wave vector. In order to conserve momentum, the photon must create two phonons (Figure 12.8).

12.5.2.5 **Resonant Bond Breaking**

Desorption induced by electronic transitions (DIET) (see Section 12.3.2.4) is possible with photons as well (Tolk *et al.*, 1983). If the incident photon has the appropriate resonant energy to excite an electron initially in a bonding state to an antibonding state, the bond may be broken.

12.5.2.6 **Laser Ablation**

An incident photon may liberate electrons and desorb ionized target atoms. With a high-intensity laser beam, electrons and ions may be created in sufficient quantity to make a dense plasma near the surface of the target. Once the plasma exists, the laser may couple directly to the plasma, and the superheated plasma then ablates the target by collisions with plasma particles.

12.5.2.7 **Exciton Creation**

If photons are incident on a semiconducting material, and the photon energy is slightly below the energy of the material's band gap, an electron may be excited from the material's valence band to an energy level immediately below the band gap, where it will form, with the resulting hole, a bound pair state very similar to a hydrogen atom. This bound state is called an *exciton* (Kittel, 2004).

12.5.2.8 **Pockels and Kerr Effects**

Under intense photon irradiation, materials may experience a change in their refractive indices, although the effect is generally very weak. There are some materials, however, where the effect is very strong. If λ is the wavelength of light to be refracted, K is a measure of the strength of the Kerr effect in the material (the Kerr constant), and E is the electric field due to the photon irradiation, the change in refractive index is given as

$$\Delta n = \lambda K |E|^2 \tag{43}$$

12.5.2.9 **Coherent Phonon Generation**

Massive excitation of electron energy levels through photon bombardment may result in coherent multiple phonon generation as the excited electrons rapidly decay to the conduction band, shedding phonons in the process. This coherent acoustic phonon (CAP) wave may be used to probe materials and activate interesting events (Xu *et al.*, 2008).

12.5.2.10 **Sum Frequency Generation**

In certain nonlinear media under intense photon irradiation, photons with frequencies higher than the incident photon frequencies may be produced in the material itself. If the material is under irradiation of two or more frequencies, the resulting photon frequency may be any of the sums of the incoming frequencies. For instance, if the incoming frequencies are ω_1 and ω_2, the resulting frequency could be

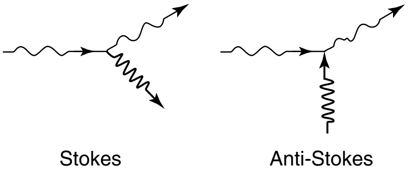

Fig. 12.7 Raman processes.

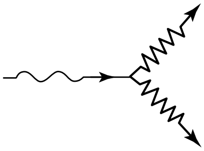

Fig. 12.8 Two-phonon absorption.

$\omega_1 + \omega_2$. This is sum frequency generation. If the material is under monochromatic irradiation with frequency ω, the resulting radiation may have a frequency of 2ω or even 3ω;. These special cases are called *second-* and *third-harmonic generation*, respectively (Shen, 2002).

12.5.3
Applications

12.5.3.1 **Scattered or Absorbed Incident Light**

Photons with energies resonant with electronic transitions in the target will be strongly absorbed. Thus, if the transmission of light as a function of frequency is measured, the electronic structure of the target may be indirectly mapped. This is the basis of absorption spectroscopy. Because the resonances correspond to the difference in energy of two electronic states, rather than the absolute energy of a single electronic state, the information is somewhat convoluted. However, absorption spectra for most materials are well known, and so information about the target can be obtained without a detailed knowledge of the electronic structure. If the target is not transparent, the same information can be inferred from reflection.

12.5.3.2 **Electrons from the Target**

In order to map the electronic states directly, the energy of photoelectrons can be measured. Since the energy of a photoelectron is just the energy of the photon minus the electron-binding energy, the spectrum of photoelectron energies is a direct measure of the electronic states of the target. This is the basis of X-ray photoelectron spectroscopy (XPS). However, this will only indicate filled states. In order to map the normally empty excited states, the excited states can be populated prior to measurement in a pump–probe experiment. For example, the density of states of the conduction band in a semiconductor can be mapped in this manner.

In semiconductors, some of the electronic structure of the target can be directly mapped without reverting to X-rays as in XPS. If a target is biased with a small voltage and the current flow is measured, the current will be enhanced when photons promote electrons to the conduction band. If this photocurrent is measured as a function of photon energy, the derivative of the resulting spectrum is a direct map of the density of states below the band gap. This is the basis of internal photoemission (IPE) spectroscopy. The simplicity of the measurement and the lower photon energy make this method preferable to XPS.

The energy spectrum of photoelectrons will also have some additional structure. This is due to a characteristic energy loss as an electron is liberated from an inner shell, coupled with an interference effect as the photoelectron interacts with target atoms as it escapes from the target. This is the basis of extended X-ray absorption fine-structure (EXAFS) measurements. The advantage of EXAFS is the extremely localized sensitivity due to the short range of electrons in solids. Thus, the primary peak indicates the species of the scattering atom from the characteristic energy loss, and the fine structure indicates the lattice positions of its neighbors.

12.5.3.3 Measuring Scattered Light

Since the phonon-dispersion relation is a unique function of the target material, Raman scattering will also be unique to the target material. The shift in energy of a scattered photon is a direct measure of the energy of the optical phonon with wave vector nearly equal to zero. This is the basis of Raman spectroscopy. If the incident beam is focused to a small spot, the identity of crystallites in a heterogeneous target may be spatially mapped as well.

Exactly as in the electron case, the diffraction pattern of X-rays scattered from a crystalline target is a measure of the long-range order of the target. This is the basis of X-ray diffraction.

12.5.3.4 Mode Locking Lasers

The optical Kerr effect may be used to create self-focusing ultrafast lasers. If a material with a strong Kerr constant (a Kerr lens) is employed in a laser cavity, the stronger standing wave modes in the laser cavity are more tightly focused, and the weaker modes may be therefore filtered out by geometric means, with the result that the strongest modes become stronger and the weaker modes disappear. This is the phenomenon of mode locking.

12.6
Neutron Impact

12.6.1
Interaction Mechanisms

12.6.1.1 Scattering from Target Nuclei

Unlike ions or electrons, Coulomb scattering does not apply to neutrons because of their charge neutrality. A complete discussion of the neutron-scattering process is not possible here, but a few points should be made. A neutron can only scatter from the atomic nuclei in the target, which means neutron scattering is insensitive to the electronic structure of the target material. Since the cross section for neutron scattering is relatively small, neutrons usually penetrate well into the target, and neutron bombardment consequently is not surface sensitive. In addition, the scattering amplitude depends on the relative orientations of the neutron spin and nuclear spin so that a polarized neutron beam is sensitive to magnetization. In many cases, neutron beams may have very low energies of less than 0.1 eV per particle. With other beam particles, interactions could be treated as simple two-particle collisions. For a low-energy neutron beam, this is not the case. In fact, interactions with phonons dominate.

12.6.1.2 Elastic Scattering from a Lattice

A low-energy neutron may also scatter from the nuclei in the target as a whole. As in the case of electrons, this elastic scattering results from the wave nature of the neutron, and as before, quantum interference effects result. For constructive interference, the Bragg condition must be satisfied, and specific scattering angles are preferred, resulting in a diffraction pattern. Note that the Bragg condition depends on the de Broglie wavelength, which in turn depends upon the energy. Thus, while electrons are much preferred for diffraction studies, neutron diffraction is still very important as a means of monochromatizing a neutron beam.

12.6.1.3 Neutron Activation

For many target atoms, energetic neutron bombardment may produce a nuclear reaction, resulting in an unstable isotope (*see* Chapter 10). The unstable isotope will then decay producing radiation. Since the target is now said to be ''radioactive'' or ''activated,'' this process is called *neutron activation*. If N_x is the number of atoms available to be activated in the target and N_γ is the number of activated atoms, then the growth of the number of activated nuclei is given by

$$\frac{dN_\gamma}{dt} = N_x\sigma\phi - N_\gamma\lambda_\gamma \tag{44}$$

where σ is the reaction cross section, ϕ is the flux of neutrons, and λ_γ is the decay constant of the unstable nuclei. The first term in this equation is the rate of activation, while the second term is the rate of decay of already activated atoms. Integrating this gives the number of activated atoms as a function of the time of bombardment t:

$$N_\gamma = \frac{N_x\sigma\phi}{\lambda_\gamma}(1 - e^{-\lambda_\gamma t}) \tag{45}$$

The activity A_t, which is the number of decays per second, is just the number of activated atoms times the decay constant:

$$A_t = N_x\sigma\phi(1 - e^{-\lambda_\gamma t}) \tag{46}$$

It is apparent that after a long bombardment time, the activity saturates. In fact, the activity reaches 50% of saturation in one half-life and 75% in two half-lives. This gives experimental control over other undesired processes. Processes with much longer half-lives than the desired reaction can be avoided by stopping activation after two half-lives. Processes with much shorter half-lives than the desired reaction may be eliminated by waiting to measure the activity until a full half-life after bombardment ceases.

12.6.2
Neutron-Bombardment Phenomena

12.6.2.1 Phonon Emission and Absorption

Excluding nuclear processes, a low-energy neutron will interact with target nuclei primarily by inducing normal-mode vibrations or phonons. In a given direction in a given lattice, only particular phonon energies and momenta are allowed. Since momentum must be conserved, neutrons will scatter most readily in those directions for which the change in momentum of the neutron corresponds to an allowed phonon in the lattice. In addition, during absorption or emission of a phonon, the lattice as a whole may give or take specific quantities of momentum as indicated by the reciprocal lattice vectors **G**. Thus, if **q** is the wave vector of an allowed phonon and **k** is the propagation vector of the neutron, then the change in the propagation vector of the neutron $\Delta\mathbf{k}$ satisfies the following condition:

$$\Delta \mathbf{k} = \pm \mathbf{q} + \mathbf{G} \quad (47)$$

The plus–minus sign indicates that the neutron may either absorb or emit a phonon. The above condition specifically applies to the bulk phonon structure since neutrons penetrate deeply into the target, and neutron bombardment is not sensitive to surface phonons.

12.6.2.2 Decay-Product Energy Loss

If the decay product of an activated nucleus is a charged particle, then it will lose energy as it escapes from the target through scattering from electrons in the target material. This is exactly the same as the electronic energy loss discussed in Section 12.4. Assuming that the fractional energy loss is small and that the target material is fairly uniform, the energy loss is found to be proportional to the distance traveled through the material. Decay-product energy loss differs from the Rutherford backscattering case in one very important way: the charged particle only has to travel through the target material once. Typically, these decay products have energies of a few mega electron volts and can escape from depths up to a few microns beneath the surface.

12.6.3
Applications

12.6.3.1 Elastic Scattering

Diffraction of neutrons by a crystal depends on the energy of the neutrons. In order to produce low-energy neutron beams with well-defined energies, a beam of thermal neutrons is scattered from a crystal and collimated. The diffraction angle determines the energy and can be varied by rotating the crystal and apertures. Neutron monochromators operate according to these principles.

12.6.3.2 Inelastic Scattering

Measuring the scattering angle and energy of neutrons scattered from a crystal maps the phonon structure of the lattice. The change in momentum of the neutron corresponds to the momentum of the phonon, and the change in energy of the neutron is the energy of the phonon. Such measurements are routinely carried out with a triple-axis neutron spectrometer.

12.6.3.3 Reaction Products

If the cross section for activation and the lifetime of the unstable isotope are known, then the concentration of a particular species in a target can be calculated directly from the measured activity. This is the basis of neutron activation analysis. Some care is necessary to reduce the background of other activation processes.

If the reaction product is a charged particle, then a depth profile of the activated species can be obtained by measuring the energy of the escaping particles. This is the basis of neutron activation depth profiling.

12.6.3.4 Spallation

In addition to fusion- and fission-based neutron sources, a process known as *spallation* may be utilized to produce high-energy pulsed neutron beams. Firing 1.0 GeV protons (as opposed to decay product neutrons, as in a chain reaction) into a high atomic mass target releases tens of neutrons per proton as the target is vaporized. This provides an efficient source of pulsed neutrons for research purposes. The Spallation Neutron Source (SNS) at the Oak Ridge National Laboratory recently came online and represents the most powerful neutron source available (Mason *et al.*, 2000).

12.7
Conclusion

Particle impact onto condensed matter results in a great variety of phenomena. In this chapter, the most important effects have been presented, but these are by no means all of the possible results of an impact event. More importantly, the reader should understand that any given impact experiment will produce many of the phenomena described above. Experiments are usually designed to emphasize one particular aspect of the impact event. However, while an electron energy-loss experiment may emphasize plasmon excitation, the experimenter must be aware that the electron beam may also be diffracting, undergoing collision cascades, ejecting core electrons, creating electron–hole pairs, or producing lattice defects. It is this great variety of effects that makes directed particle or photon beams powerful probes for measuring the properties of materials.

Glossary

AES (Auger-Electron Spectroscopy): An experimental technique for measuring the atomic species in the region near the surface of a solid by measuring the energies of Auger electrons.

Anti-Stokes Process: A Raman scattering process in which a photon is scattered by absorbing a phonon.

Auger Electron: An electron excited and possibly even liberated by the energy released when another electron falls into a vacant low-energy state.

Auger Process: When an electron falls into a lower energy vacancy, energy is liberated. If that energy is transferred to another electron, resulting in that electron being excited to a higher state or the vacuum state, the process is called an *Auger process*, and the excited electron is called an *Auger electron*.

Bragg Reflection: The reflection of light or particles from parallel planes that have spacing such that self-interference determines the allowed scattering angles.

Bremsstrahlung: German for ‘‘braking radiation.’’ Bremsstrahlung is the broad spectrum of electromagnetic radiation produced when charged particles are decelerated by impact with a target.

Channeling: Phenomenon in which particles incident on a crystal in a high-symmetry direction reach unusually great depths by traveling through the spaces between the atoms.

Coster–Kronig Transitions: A particular Auger transition in which the vacancy is filled by an electron from the same subshell.

Coulomb Scattering: A model for scattering of charged particles in which the Coulomb repulsion or attraction due to the electric charge is assumed to dominate.

Depth Profiling: A technique in Rutherford backscattering experiments that exploits the nearly uniform deceleration of a charged particle in a solid to map the distribution of atomic species as a function of depth into the target.

DIET (Desorption Induced by Electronic Transitions): The ejection of an atom or molecule from a surface by a repulsive Coulomb force resulting from an electronic excitation.

Diffraction Pattern: The interference pattern produced at a detector or phosphor screen by particles or light elastically scattered from a lattice.

Dipole Approximation: Approximation of the interaction of light with electronic states that only considers the dipole term in the expansion of the electronic state.

EELS (Electron Energy-Loss Spectroscopy): An experimental technique for determining the electronic structure of a material by measuring the change in energy of a beam of electrons as they pass through a material.

EMA (Electron Microprobe Analysis): An experimental technique in which a tightly focused electron beam produces vacancies in the target atoms, and the radiation produced when other electrons fill the vacancies is spectroscopically analyzed.

EXAFS (Extended X-Ray Absorption Fine Structure): An experimental technique for measuring the lattice structure in the neighborhood of a particular impurity by carefully measuring the energy of photoelectrons produced by X-rays.

Exciton: In a semiconducting material, an electron and hole that are bound in a hydrogen-like state.

Fermi's "Golden Rule": An approximation of the probability of a photon producing a particular electronic transition calculated by treating the photon as a short-lived oscillatory perturbation and considering only dipole interactions.

FRS (Forward Recoil Spectroscopy): An experimental technique for measuring light atomic species in a thin film by measuring the energy of particles ejected in the forward direction by a high-energy ion beam.

HREELS (High-Resolution Electron Energy-Loss Spectroscopy): An experimental technique for measuring the electronic structure of the surface of a solid by measuring the change in energy of a low-energy beam of electrons reflected from a surface.

Impact Parameter: The perpendicular distance from the target particle to the initial line of flight of the incident particle.

Impulse Approximation: An approximation based on the assumption that the interaction between a fast-moving beam particle and a stationary target particle happens so quickly that neither particle has time to change its initial motion much while the interaction is occurring.

IPE (Internal Photoemission): An experimental method for mapping the density of states of the valence band of a semiconductor by measuring the photocurrent produced by a tunable light source.

Kinematic Factor: In an elastic two-particle collision, the fraction of energy retained by the incident particle.

LEED (Low-Energy Electron Diffraction): An experimental technique for measuring the near-surface lattice structure of a crystal by diffracting a low-energy beam of electrons from the surface.

LEIS (Low-Energy Ion Spectroscopy): An experimental technique for measuring the atomic species near the surface of a solid by reflecting a low-energy beam of ions from the surface and measuring the ion energy electrostatically.

Mean Free Path: The average distance traveled between interactions.

Mode locking: A laser generation technique where weaker pulses are filtered out of the laser cavity allowing the stronger pulses to become even stronger.

Neutron Activation Analysis: An experimental technique for measuring the concentration of atomic species in a sample by neutron bombardment activation.

Phonon: A collective vibration of a lattice that carries momentum and energy and is therefore treated as a virtual particle.

PIXE (Proton- or Particle-Induced X-Ray Emission): An experimental technique for measuring the atomic species in a target, in which particle bombardment produces vacancies in the target atoms, and the radiation produced when other electrons fill the vacancies is spectroscopically analyzed.

Plasmon: A collective oscillation of the electrons of a material, which carries momentum and energy and is therefore treated as a virtual particle.

Quantum Interference: Interference effects that result from the quantum wave nature of particles.

Raman Scattering: Photon scattering from the lattice either producing or absorbing a phonon.

Reconstruction: The rearrangement of the lattice structure at the surface of a crystal into a symmetry that differs from the bulk solid.

RBS (Rutherford Backscattering): An experimental technique for determining the atomic species in a target by measuring the energy of reflected ions.

RHEED (Reflection High-Energy Electron Diffraction): A convenient technique for determining the surface structure of a sample by diffracting a grazing-incidence high-energy beam of electrons from the surface.

Scattering Angle: The angle between the initial line of flight continued through the scattering center and the subsequent line of flight.

Second Harmonic Generation: The process by which photons with a doubled frequency is produced from a material under irradiation by a single original frequency.

Spallation: The splitting of heavy atoms into smaller nucleons by a proton or ion beam. Provides an efficient source of pulsed neutrons.

Spectral Intensity: The radiative power per unit frequency.

Sputtering: The ejection of target atoms from a surface by collision cascade.

Sputtering Yield: The number of target atoms sputtered from the surface per incident particle.

Stokes Process: A Raman process in which a photon is scattered from the lattice by emitting a phonon.

Stopping Power: The distance rate of energy loss normalized to the number of atoms.

TEM (Transmission Electron Microscopy): The classic electron microscopy in which a high-energy beam of electrons is passed through a very thin sample and the beam is then imaged on a phosphor screen.

XPS (X-Ray Photoemission Spectroscopy): An experimental technique for determining the electronic density of states of a sample by measuring the energy of photoelectrons produced by X-rays.

6.1
Introduction

The goal of particle physics is to discover the most elementary particles and to study their basic interactions. Over the past 30 years, remarkable strides have been made, culminating in what is called the *standard model* (SM) of particle physics. This model, which exhibits a deep simplicity and beauty, along with the classical theory of gravity (general relativity, GR), together explain all phenomena that have been observed to date with a compelling economy and power. The SM is valid at all distances down to $\sim 10^{-16}$ cm, or by uncertainty-principle arguments up to energies $\sim 200\,\text{GeV} = 2 \times 10^{11}$ eV, which corresponds to a time 10^{-12} s after the Universe was born in the ''Big Bang.'' The development of the SM should be ranked as one of the great scientific triumphs of twentieth century science.

The SM is both a stunning success and the goad to further progress. A brief description of the SM is given below, followed by a discussion of the present frontier issues in the field. The experimental program that has been mounted to confront those issues is then described with a subsequent explanation of the experimental tools that are presently in active use in particle physics. Finally, new facilities are mentioned as are the questions that they are designed to explore.

6.2
The Standard Model – Synthesis and Overview

6.2.1
The SM Constituents

All matter is assumed to be made up of pointlike elementary particles. The great complexity and diversity exhibited by the world are assumed to proceed from the interaction of only a few basic entities. At normal energy scales, the world can be described as composed of neutrons and protons, the electron, and the photon, which is the quantum of the familiar electromagnetic (EM) interaction between charged particles. The SM asserts that neutrons and protons are themselves the composite bound states of pointlike u and d (up and down) quarks. That belief is partly attributed to the fact that the properties of proton and neutron are very similar.

At higher energies (shorter distances), the strong interactions that are responsible for binding the nucleus together must be considered. An analogy is perhaps useful. In atomic physics, the EM interaction

ISBN: 978-3-527-40691-3

between charged protons and electrons binds atoms together. A residual van der Waals force exists between neutral atoms, which, in turn binds atoms into molecules. Similarly, quarks strongly interact by means of a quantum number called *color* through a messenger field with quanta called *gluons*. The bound-state ''neutral'' colorless composites – for example, protons and neutrons – interact to form bound nuclei. The fundamental theory is called quantumchromodynamics (QCD), which is the theory of the interaction of colored pointlike quarks via massless gluons (see Chapter 3).

Gluons and quarks are believed to be permanently confined by the strong forces that they experience. However, their existence has been inferred from the observation of pointlike behavior in experiments scattering electrons off protons. These experiments are the direct analog of the famous Rutherford scattering experiment by which the nucleus within the atom was inferred by scattering of atoms (Friedman and Kendall, 1972). Even if atoms could not be ionized, and the nuclei and electrons were separately examined, the Rutherford scattering experiment would allow one to infer the existence of the nucleus. Quarks were also inferred by the observed regularities and multiplet structure exhibited by several hadrons, or strongly interacting colorless quark composites (Gell-Mann, 1964; Zweig, 1964).

The discovery of radioactive decay required the existence of a new force, the weak interaction. The weakness of this interaction can be seen by comparing the lifetime of a typical strongly interacting hadron resonance to that of a neutron, where the lifetime ratio is $\sim 10^{26}$. The decay products of weak decays were found to include neutral, approximately massless neutrinos. For example, the neutron is unstable, decaying into a proton, an electron, and a neutrino. One of the profound insights that led to the formulation of the SM was that the weak and EM interactions are unified (Glashow, 1961; Weinberg, 1967; Salam, 1968) despite their apparent great disparity in strength. The Fermi coupling constant describing the strength of weak interactions, G_F, is describable at a deeper level as due to a dimensionless coupling constant g_W, just as is the EM coupling constant e. The weak and EM interactions have approximately the same basic strength. The ratio is measured by the Weinberg angle, θ_W (Prescott *et al.*, 1978) and M_W is the mass of the weak force carrier, the W boson.

$$\begin{aligned} G_F &\sim \frac{g_W^2}{M_W^2} \\ e &= g_W \sin\theta_W \\ M_W &\sim e/\sqrt{G_F} \sim 90\,GeV \end{aligned} \tag{1}$$

Therefore, electromagnetism and the weak force are unified into the electroweak (EW) theory. This great triumph of the SM is akin to the prior unification of electricity and magnetism by Maxwell. It culminated in the discovery of the charged and neutral quanta of the weak force, the W and Z gauge bosons (Arnison *et al.*, 1983; Banner *et al.*, 1983). The EW unification is evident only at the very high energies probed by accelerators. At lower energies, the unification is masked by the large mass of the W and Z, and the weak and EM forces appear to have vastly different interaction strengths. It seems that Nature becomes simpler and more symmetric at higher energies. The EM and weak potentials differ only slightly in coupling strength, α and α_W, $\alpha = e^2/\hbar c$, $\alpha_W = g_W^2/\hbar c$, but profoundly in the range of the interaction:

$$\begin{aligned} V_{\mathrm{EM}} &= \frac{\alpha}{r} \\ V_W &= \left(\frac{\alpha_W}{r}\right) e^{-r/\bar{\lambda}_W} \\ \bar{\lambda}_W &= \frac{\hbar}{M_W} \end{aligned} \qquad (2)$$

At low energies, much less than M_W, the exponential factor causes V_W to be $< V_{\mathrm{EM}}$, while at high energies, $V_W \cong V_{\mathrm{EM}}$.

The constituents of the SM are given in Table 6.1. The quanta, or force carriers, of the two basic interactions, QCD and EW, are the gluons, the photon, and the massive W and Z weak bosons. There are three dimensionless coupling constants, describing the strength of the strong, EM, and weak forces. All three basic interactions are mediated by spin-1 quanta.

The antiparticle partners that exist for each quark and lepton are not shown in Table 6.1. For example, the positron is paired to the electron. The leptons have only EW interactions, while the quarks also possess strong QCD interactions. Both quarks and leptons are spin-1/2 fermions.

The first-generation quarks and leptons (e, ν_e, u, d) describe our world at low energies, as mentioned before. What has been discovered by experiment is that this basic pattern is repeated in "generations," whose members differ from those of the first largely only in mass. For example, the muon appears to interact exactly as if it were a heavy electron. Why the pattern recurs is unknown. How many generations are there? Recently, both cosmology (primordial helium abundance) and high-energy physics (Z decay width) have converged on the conclusion that there are three and only three generations (Burkhardt and Steinberger, 1991; Steigman, Schrammn, and Gunn, 1977). Thus, the "periodic table" of the SM, as given in Table 6.1, is complete except for the Higgs boson, which is discussed in Section 6.7. In fact, the discovery of the top quark, t, has very recently completed the entries in Table 6.1 (CDF Collaboration, 1995; D0 Collaboration, 1995). Indirect inferences of the top mass had previously been available (Burkhardt and Steinberger, 1991).

Tab. 6.1 The SM constituents.

	Three generations			**Charge[a] Q**	
Matter (spin 1/2)[b]	$\begin{pmatrix} e \\ \nu_e \end{pmatrix}$	$\begin{pmatrix} \mu \\ \nu_\mu \end{pmatrix}$	$\begin{pmatrix} \tau \\ \nu_\tau \end{pmatrix}$	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}$	Leptons
	$\begin{pmatrix} u \\ d \end{pmatrix}$	$\begin{pmatrix} c \\ s \end{pmatrix}$	$\begin{pmatrix} t \\ b \end{pmatrix}$	$\begin{pmatrix} 2/3 \\ -1/3 \end{pmatrix}$	Quarks

[a] Units are electron charge, e.
[b] Units are $\hbar$.

6.2.2
SM Forces

The unfolding of the SM has also resulted in a much deeper understanding of the basic forces. It is remarkable that all forces now thought to be fundamental appear to be derivable from a single principle. The similarity of all the fundamental forces holds out the hope that they can one day be unified into a grand unified theory (GUT). The gauge principle is one of the great organizing insights brought about by the development of the SM. What exactly is the gauge principle, expressed nonmathematically?

As a familiar example, consider classical relativity. If the global space–time coordinate transformations of special relativity are required to hold at arbitrary local points, then a new field, the gravitational field, is required, and the interaction of that field with matter is largely specified (Utiyama, 1956). Clearly, local gauge invariance is a powerful and compact principle.

In quantum mechanics, the overall phase of the wave function Ψ is irrelevant because only $|\Psi|^2$ is an observable. The requirement that physics be unchanged under an arbitrary local choice of overall phase implies the existence of the EM field A_μ and specifies the interaction of that field with the basic charged fermions (Weyl, 1929). The gauge replacement of the derivative is familiar from both classical Hamiltonian mechanics and introductory quantum mechanics and indicates that gauge invariance requires a new field A_μ:

$$P_\mu \longrightarrow P_\mu - eA_\mu, \quad \partial_\mu \longrightarrow \partial_\mu - ie A_\mu \tag{3}$$

Making this replacement in the free Lagrangian density specifies the interactions of the gauge field with the fermions.

This elegant and simple gauge principle then defines the theory of electromagnetism. Similar considerations allow one to write the gauge theories of the QCD and EW forces. In these cases, the quanta themselves couple together, in contrast to the photon, which is uncharged. This type of behavior is familiar from the prototypical gauge theory, GR. The gravitational field possesses energy, and because all energy has mass ($E = mc^2$), the field itself gravitates. Thus, GR is a nonlinear theory, as is QCD, for example, because the gluons themselves carry color. Nonlinear theories are difficult to treat mathematically but imply a very rich phenomenology – perhaps as rich as the world itself.

6.2.3
QCD Calculations and Other States of Matter

As formulated, QCD has no free parameters except the coupling constant. Thus, for example, one should be able to calculate the bound-state hadron mass spectrum from first principles. However, the fact that the quarks and gluons are permanently confined well explains the strength of the forces involved. Hence perturbation theory, a familiar tool used throughout all areas of physics, is not generally applicable. The strong force becomes strong at an energy scale of about 200 MeV.

At present, the mass spectrum and quantum numbers of the hadrons are found by experiment. Similarly, the distribution of quarks and gluons bound in the proton is determined by scattering experiments. Recently, using strong-coupling techniques adopted from solid-state physics, a cutoff approximation to the full QCD theory has been formulated. QCD is formulated on a mesh with finite spacing

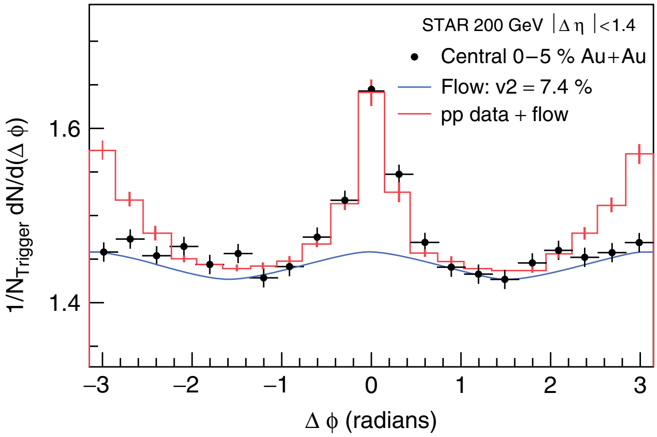

Fig. 6.1 The azimuthal distribution of particles in proton–proton and heavy ion, Au–Au, collisions. Note the depletion of particles "away" from the peak at 0° in the heavy-ion collisions compared to p–p collisions indicating strong absorption.

(limited momentum) in a "lattice gauge theory." The numerical problems are still formidable and massively parallel computing is needed to complete the calculations, but preliminary indications are heartening in that the spectrum of the lowest lying two- and three-quark bound states can now be accurately calculated from first principles.

Given that we possess the complete theory of QCD, it is appropriate to begin to explore its full nonlinear richness. For example, it is an open question whether there exist phase transitions in the quark–gluon system at high temperatures. For example, the propagation of quarks and gluons in high-temperature heavy-ion collisions has recently been studied at the Relativistic Heavy Ion Accelerator (RHIC) located at Brookhaven National Laboratory (BNL). As seen in Figure 6.1, there appears to be strong quark absorption in this new medium. More complete studies are planned in upgraded experiments to run in the near future.

6.2.4
CP Violation

The generations shown in Table 6.1 refer to quantum-number labels of states produced in strong interactions where quark–antiquark pairs are produced. As stated above, decays are due to the weak interactions, whose conservation laws are different from those obeyed by the strong interactions. Thus, the weak eigenstates are not necessarily the same as the strong-interaction eigenstates listed in Table 6.1.

In general, there is a unitary 3×3 (three generations) mixing matrix that connects the strong and weak eigenstates: the Cabibbo–Kobayashi–Maskawa (CKM) matrix. The SM does not give us any guidance about this matrix; its elements are determined purely experimentally (Cabibbo, 1963). For example,

$|V_{du}|^2$ and $|V_{su}|^2$ represent, respectively, the relative strengths of $d \to u$ and $s \to u$ weak transitions. The CKM matrix is almost diagonal. Because there are three generations, the matrix can be complex. If it is complex, then invariance under the operation of charge conjugation followed by parity inversion (CP) is violated in the SM because of the CKM matrix. CP violation has been known for 30 years (Fitch, 1981; Cronin, 1981), but a deeper explanation of the phenomenon still eludes us.

Recently, "B factories" have been built to explore the consistency of the CKM description as the complete explanation of CP violation. The current state of the art is summarized in Figure 6.2. The unitarity of the CKM matrix implies relations between complex matrix elements, in particular, there is a closed triangular constraint. At the limit of experimental accuracy, the "unitary triangle" is indeed closed, which implies that the CKM model of CP violation fully explains the present data. Moreover, CP nonconservation has profound cosmological implications. It is required for the presently observed preponderance of matter over antimatter in the universe and the matter-to-entropy ratio to appear elegantly (Sakharov, 1967). However, the CKM strength of CP violation is insufficient to explain the matter dominance of our Universe, leaving it unexplained in the SM.

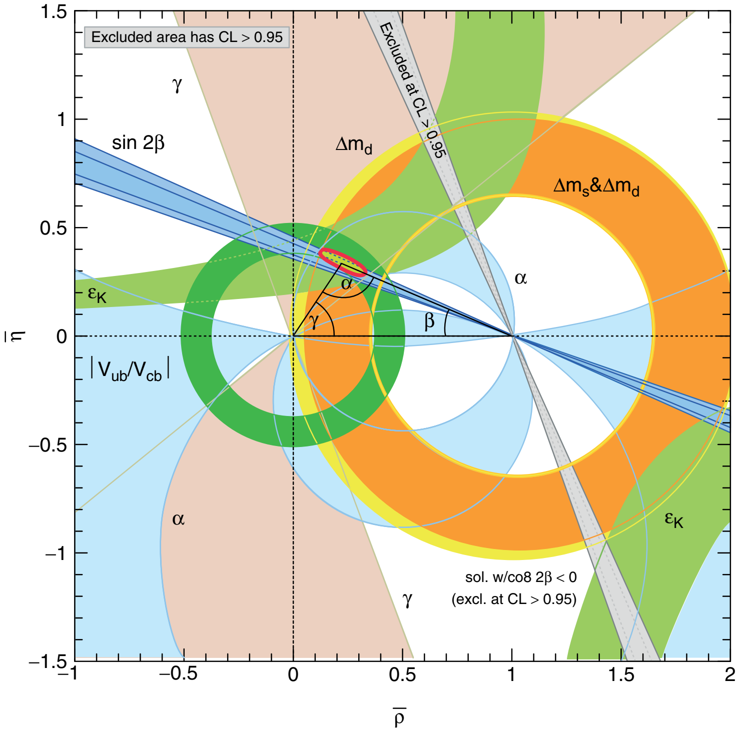

Fig. 6.2 The present constraints on the CKM matrix elements placed by experiment. Unitarity of the matrix requires a triangular relationship among the matrix elements.

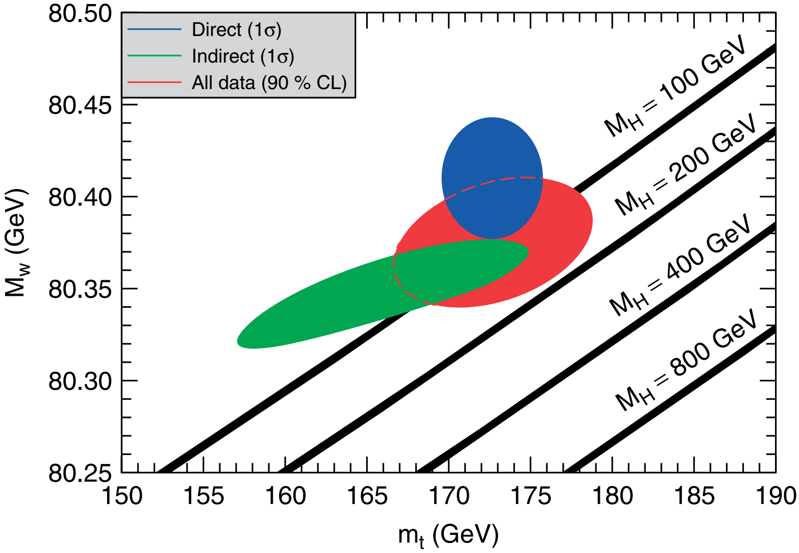

Fig. 6.3 Allowed contour in the *W* and top mass plane for different Higgs masses. Note that a light Higgs boson is weakly favored.

6.2.5
Higgs Boson

The *W* and *Z* are believed to gain their mass by interacting with the hypothesized Higgs boson, H^0. This interaction allows for the evasion of the rule that gauge bosons, for example, the photon and gluon, are massless. The situation is similar to that for a massless photon propagating in a superconductor (Meissner effect), wherein the photon acquires a mass by interacting with the medium. The Higgs ground-state field is considered to be nonzero and to pervade all of space–time. This background field is held responsible not only for the generation of the *W* and *Z* mass, but also for the generation of the masses of all SM particles. A more basic understanding of the Higgs field and its coupling to quarks and leptons should shed light on the regularities of the masses, which range from 0.51 MeV for the electron to 175 GeV for the top quark. Note that the Higgs boson has not yet been discovered and there is no prediction for the Higgs mass in the SM. The mass scale is set by the vacuum value of the Higgs field, $<\phi> \sim 174$ GeV.

The masses of the *W* and top quark acquire contributions from "quantum loops" (emission and virtual reabsorption) containing the Higgs boson. The data for masses allows for indirect constraints on the Higgs mass, shown in Figure 6.3. A light Higgs mass is favored by the data. The Higgs boson is also being directly searched for. A limit of 114 GeV was set at the Large Electron–Positron (LEP) collider at CERN. At the Fermilab Tevatron, searches are being made in several final-state channels where the Higgs boson should decay. The exact search strategy depends on the Higgs mass, which is unknown. Present limits are as not yet sensitive to the cross section of a SM Higgs particle, and so t more data is needed.

6.2.6
Neutrino Oscillations

In the SM, neutrinos are assumed to be massless, although there is no known symmetry that requires this. Indeed, quite recently, neutrinos have been observed to change their generation type (or "oscillate") as they propagate in vacuum (Hosaka *et al.*, 2005).

This behavior requires that the neutrinos have a finite mass. Therefore, we now know that neutrinos have small masses and that they mix their eigenstates in a way analogous to the quarks. This new 3 × 3 unitary neutrino matrix must have its matrix elements determined experimentally just as for the CKM matrix. The oscillation experiments measure the difference of the squares of the neutrino masses. At present, both atmospheric and solar neutrino mass differences are known and the mixings are large, in stark contrast to the quark mixings.

$$\sqrt{\Delta m^2_{\nu\mathrm{atm}}} \sim 0.05\,\mathrm{eV},$$
$$\sqrt{\Delta m^2_{\nu\mathrm{sol}}} \sim 0.008\,\mathrm{eV} \qquad (4)$$

Data from the Fermilab Main Injector Neutrino Oscillation Search (MINOS) experiment are shown in Figure 6.4. The neutrino oscillation is measured by observing a deficit of the produced neutrinos after a long flight path; the produced neutrinos "disappeared" in that they oscillated into a neutrino of another flavor that was not observed.

There is now a program to explore the matrix elements of the "neutrino CKM" matrix. For example, two mixing angles are known to be large, but the third is only known to be small. The implication of the small neutrino mass, m_ν, implies the existence of heavy neutrinos at a very

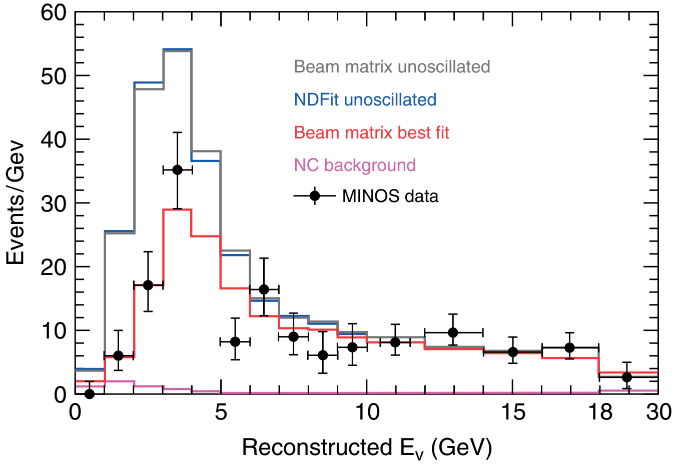

Fig. 6.4 Energy distribution of neutrinos observed after a long flight path subsequent to production at Fermilab. The disappearance of low-energy neutrinos is evident.

large energy scale, M_R by the "seesaw" mechanism relating to the quark mass, m_q:

$$m_\nu \sim \frac{m_q^2}{m_R} \tag{5}$$

Assuming that the actual masses are near the mass differences, taking 0.008 eV for the neutrino mass and 1 GeV for the quark mass yields a heavy neutrino mass of 1.2×10^{13} GeV.

This is an energy scale very far above that associated with the SM forces and is a first experimental indication that the SM is incomplete. Recall that we have ignored gravity so far. A completely naïve extrapolation of Newtonian gravity, which increases in strength as the square of the energy scale to the point where the gravitational coupling is as strong as the EM, yields a scale of 1.05×10^{18} GeV, which is another example of a very high-energy scale.

6.2.7
Frontier Issues in Particle Physics

6.2.7.1 Unification

The SM has been spectacularly successful as a synthesis of our understanding of all fundamental phenomena. However, it is incomplete. For example, why are there only three generations of quarks and leptons? The SM gives us no answer to this question. Why is the top quark so heavy (or why are the other fermions so light?) A basic understanding of the mass spectrum of the SM constituents eludes us.

Note that the SM is mute about any relationship between leptons and quarks, yet the masses of quarks and leptons seem to exhibit a pattern, for example the near equality of masses of u quark and e or strange quark and muon. The situation is akin to that in which atomic spectroscopists found themselves before the advent of quantum mechanics. Clearly, there were patterns in the spectra, but the underlying dynamics was not available.

Dramatic progress in physics in the past has occurred when a unification of forces has taken place, such as the recent EW unification. It is possible that the similarities in mass between quarks and leptons indicate that they are related in some more basic manner. In that case, the heavier quarks would eventually decay into light leptons and, the proton, for example, would not be absolutely stable. Present experiments set a lower limit of $\sim 10^{31}$ years on the proton lifetime. Note that some violation of baryon-number conservation is in fact also needed along with CP nonconservation, if the observed excess of matter in the universe is to be explained. Although the idea of unification of QCD and EW forces is tantalizing, no truly compelling evidence for such unification exists as of now.

6.2.7.2 Dark Energy

Cosmological data have recently been taken, which require that 73% of the energy density of the Universe is an unknown "dark energy (DE)" that is accelerating the expansion of the Universe. This is a new fundamental field that we are completely ignorant of. Is it related to inflation of the early Universe? Is it a cosmological constant? The accuracy of present data is consistent with that hypothesis, but the implied background field is $<\phi> \sim 0.002$ eV, which is 10^{14} times smaller than the Higgs field. Why is the Higgs field gravitationally inert? Clearly, our theories of gravity or the SM are either incomplete or incorrect. The exploration of the Higgs boson, therefore, has a high priority in particle physics with implications outside the SM.

6.2.7.3 Dark Matter

Cosmology tells us that 22% of the energy density of the Universe is ‘‘dark matter (DM),’’ whereas only 4.6% is ‘‘normal’’ baryonic matter. Clearly, there must be new fundamental fields beyond those contained in the SM. DM was first inferred from galactic rotation curves (Fich and Tremaine, 1991). Experiments have been mounted to detect the elastic recoils of the supposed DM particles off laboratory material and limits have been set, as yet without positive detection.

If the DM particles have masses at the 1000 GeV scale, then standard cosmology tells us that the 22% relic density requires that the DM annihilate with a cross section characteristic of weak processes. There is a SM extension with a new symmetry relating particles differing by spin 1/2 called *supersymmerty* (SUSY). Because that model requires doubling the number of fundamental particles, it provides a neutral, stable, and weakly interacting candidate for the DM. The mass scale for SUSY also gives the correct relic density. Perhaps this is a coincidence or a strong hint. Clearly, future searches for SUSY particles are of high priority in particle physics.

6.3
Accelerators and Other Facilities

After this very brief explanation of the state of the art and frontiers of particle physics, we turn to a description of the facilities available to confront those frontier issues. Experimental particle physics is the subject of worldwide study, which takes place in a variety of facilities. The primary focus for experimental particle physics has traditionally been the accelerators of ever-increasing energy. The increase in energy is driven by the desire to produce heavier particles together with the Einstein relation between mass and energy, $E = mc^2$. This growth in energy will, naturally, have some ultimate limits. Hence, other avenues for research may gain in importance in the future.

The program described below constitutes a broad-based attack on the validity of the SM following up on strong hints from Higgs, DE searches, neutrino oscillations, and DM. It is focused on the outstanding problems alluded to in Section 6.2.

6.3.1
Accelerator-Based Particle Physics

The locations and energies of the accelerator facilities operating at the highest energies are shown in Table 6.2. There are two broad categories of particle physics experiments: fixed-target experiments, where a beam of accelerated particles strikes a stationary target, and collider experiments, where beams of particles collide head-on. The former type of experiment is unrivaled in the study of rare interactions, while the latter is the technique of choice in exploring high mass scales because all the beam energy in such a collision is available for particle production. This distinction appears in Table 6.2, where beam energy is distinct from center-of-momentum (CM) energy, which is roughly the energy available to create new particles.

6.3.1.1 Fixed-target Experiments

Fixed-target experiments are currently in progress at several facilities in Russia, Europe, Japan, and the United States. Secondary beams of unstable particles of different types are the exclusive purview of fixed-target experiments. Examples include photon, muon, pion, kaon, and neutrino (γ, μ, π, K, ν) beams. Following the discovery of neutrino oscillations, a strong

Nucleus–nucleus collider	BNL, United States	RHIC	200	Quark–gluon plasma

international program using intense neutrino beams is being mounted.

6.3.1.2 e^+e^- Collider Experiments

Heavy quarks form quark–antiquark bound states, ''onia,'' in analogy to the electron–positron bound states of positronium. These states occur at high enough mass scales that QCD perturbation theory may be expected to apply. The QCD force becomes weaker at high mass, as is discussed in Section 6.7. The explication of the spectroscopy of the bound-state systems is a vital test of QCD, just as positronium spectroscopy was a crucial test for quantum electrodynamics (QED).

At present, an international effort to study CP violation in the b quark system is nearing completion at Belle and BaBar. The beautiful data on the ''unitary triangle'' that comes from these ''B factories'' is shown in Figure 6.2. Searches for rare c quark decays at experiments Cornell (CLEOC) and Beijing (BEPC) are also nearing program completion.

At elevated CM energies, the Z are resonantly formed. Very precise EW tests were performed at these Z ''factories,'' which yield the most accurate determinations of the EW parameters. The LEP accelerator was then upgraded and data was taken at higher energies. That data produced a W mass determination, a determination of the nonlinear self-coupling of the gauge bosons, and the best current limit on the Higgs mass (greater than 114 GeV). The LEP program was terminated in preparation for the Large Hadron Collider (LHC) at CERN.

6.3.1.3 *ep* Collider Experiments

At present, the distribution of quarks and gluons in the proton is determined experimentally. The data come from lepton–proton scattering with fixed proton targets, and neutrino, electron, and muon incident beams. The range of such experiments is limited by the available CM energy.

6.3.1.4 $p\bar{p}$ Collider Experiments

The proton is a composite object and can be considered to consist of valence *uud* quarks, quark–antiquark pairs, and gluons of different momenta. Therefore, $p\bar{p}$ colliders are capable of performing simultaneous studies of many aspects of current investigations in particle physics. Examples include QCD studies in jet phenomena, $W/Z/\gamma$ production and decay properties, heavy-flavor (b) quark production dynamics and decay spectroscopy, studies of the top (t) quark, and searches for new phenomena outside the SM. Most notably, the Tevatron experiments are making precision measurements of the W and t quark mass, searching for the Higgs boson and for evidence of SUSY particles (see Figure 6.3).

6.3.1.5 Applications

Accelerators have also been a fruitful source of applications to areas outside particle physics. The large-scale use of superconductivity was pioneered in accelerators for high-energy physics. Large-scale high-vacuum and distributed-control systems are another outgrowth of accelerator ''technology transfer.'' Electron accelerators are used as synchrotron light sources. These new facilities are heavily subscribed to by materials and solid-state physicists at many locations worldwide.

In addition, there are numerous examples of medical applications. The detectors used in particle physics are widely used in medicine. High-field magnets similar to those built for accelerators are used in magnetic resonance imaging. Finally, accelerators themselves are used in treatment. Examples include electron, neutron, and proton irradiation. For example, proton beams of variable energy allow precise doses to be placed deep in the body with minimal damage to intervening tissues. Electron linear accelerators are, however, simpler and therefore the most widespread therapeutic devices.

6.3.2
Nonaccelerator Particle Physics

As mentioned above, DE is a new fundamental field. Because it operates only over cosmological distance scales, the studies will, of necessity, be made only using ground- or space-based telescopes.

The DM is a second unknown fundamental field that is unexplained in the SM. Direct measurement of the scattering of DM particles is being attempted at very low background underground facilities. These studies are complementary to the searches for SUSY DM candidate particles produced in accelerator experiments. Further, as with DE, the accelerator, and nonaccelerator experiments are synergistic.

Cosmic rays extend up to energies that are still inaccessible at the accelerator facilities given in Table 6.2. Therefore, it is natural to search for new phenomena at the highest cosmic-ray energies. In addition, stimulated by unification speculations, several experiments have been set up to search for proton decay, and all experienced failure to date. However, they have set useful limits, and because they are located deep underground to minimize cosmic-ray backgrounds, they also function as active neutrino ''observatories.'' Detectors of this type – for example, at Kamioka in Japan, Gran Sasso in Italy, and Soudan in the United States – detected the neutrino pulse from supernova SN1987 A. The utility of these ''observatories'' indicates the increasing interconnection between particle physics, astrophysics, and cosmology. A DM search Cryogenic dark matter search (CDMS) is currently operating in the Soudan facility.

There were tantalizing indications that the number of neutrinos arriving from the sun was not in accord with the standard solar model prediction (Davis *et al.*, 1989). This was confirmed by the observation of atmospheric neutrino oscillations (Hosaka *et al.*, 2005) at Kamioka and of electron-neutrino oscillations at reactors (Eguchi *et al.*, 2003). New data from Canada, at the Sudbury Neutrino Observatory (SNO) (Aharmim *et al.*, 2005), has greatly helped in clarifying the neutrino mixing.

Neutrino beams prepared so that they are composed of only one neutrino generation at an accelerator can be directed toward distant underground observatories, where the appearance of a different generation of neutrino can be searched for. Such long-baseline neutrino experiments will improve the determination of neutrino masses and mixing parameters. These positive results from underground laboratories have stimulated a new generation of accelerator experiments in Japan (K2K), Europe (Gran Sasso), and the United States (MINOS).

6.4
Mapping the SM Constituents onto the Detectors

Having described the SM constituents and the present experimental program, one can now briefly describe the specifics of experimental particle physics. Detectors are used to measure the vector position and momentum of all the constituents of the SM emanating from a collision and to distinguish between them (particle identification, "id"). In principle, a perfect detector would measure and identify all the particles in both the initial and final states of a collision. The design of detectors is dictated by the characteristic interactions that the SM constituents participate in. The different categories are shown in Table 6.3.

Tab. 6.3 Detection/identification methods.

Signature	Detector	Particle
Jet of hadrons	Calorimeter	$u, c, t \rightarrow Wb$ d, s, b G
Missing Energy	Calorimeter	ν_e, ν_μ, ν_τ
Electromagnetic shower	Calorimeter	$e, \gamma, W \rightarrow e\nu$
Only ionization interactions	Muon absorber	$\mu, \tau \rightarrow \mu\nu\overline{\nu}$ $Z \rightarrow \mu\mu$
Decay with $c\tau \gtrsim 100\,\mu\text{m}$	Si tracking	s, c, b, τ

6.4.1
Confinement and Jets – Quarks and Gluons

Quarks(q) and gluons(g) carry the color quantum number and interact strongly. It has been found that quarks and gluons cannot be detected as distinct free states. Rather, they appear in detectors as collimated "jets" of colorless hadrons moving nearly in the direction of and with roughly the momentum as that of the parent q or g. Finely segmented energy-measuring detectors (calorimeters) are used to measure the positions and energies of these ensembles of particles. Thus, one may infer the properties of the q or g parent.

6.4.2
Missing Energy and Neutrinos

Leptons, by definition, interact only via the EW interaction. In particular, neutrinos are uncharged, and therefore interact only weakly. Therefore, neutrinos pass right through a calorimeter system that absorbs and detects all strongly and electromagnetically interacting particles, without interacting with the detecting medium. The presence of neutrinos is then signaled by the existence of the "missing energy" that they carry off undetected

6.4.3
Charged Leptons and EM Interactions

Charged leptons interact electromagnetically. Extremely relativistic photons and electrons interact with a calorimeter medium by pair production and bremsstrahlung, respectively. The resulting cascade is a characteristic signature. Therefore, a calorimeter can be used to perform id of e/γ particle by observation of the characteristic cascade.

The muon is unstable, with a lifetime characterized by the decay length $c\tau \sim 658\,\text{m}$. Therefore, it will typically pass through a detector before it decays. Muons are "heavy electrons" – second-generation leptons identical to electrons save for mass. The large mass means that with the identical forces experienced by e and μ, the acceleration of a muon is much reduced with respect to an electron. Because radiation is caused by acceleration, the muon cascade occurs only at much higher energies than the e cascade. For example, muons at energies below about 300 GeV only ionize the detection medium, thereby leaving a minimum-ionizing particle, (MIP), signal in particle detectors. This signature is the basis for the identification of the muon.

6.4.4
W, Z, and τ Decays

The W and Z gauge bosons rapidly decay into lighter final states containing either lepton or quark pairs. The cleanest experimental signatures are the decays into final-state leptons, $W \rightarrow l + \nu$ and $Z \rightarrow l^{+} + l-$ where l denotes charged lepton. Final states containing quarks, such as $W^{+} \rightarrow u + \overline{d} \rightarrow \mathrm{Jet}_1 + \mathrm{Jet}_2$, are subject to large backgrounds.

The τ lepton often decays into lighter final-state leptons – for example, $\tau \rightarrow \mu + \overline{\nu}_{\mu} + \nu_{\tau}$. Because the τ has a measured lifetime of $c\tau \sim 89\,\mu\mathrm{m}$, the experimental signature is the existence of both a secondary decay vertex (see Section 6.4.5) and a primary production vertex.

6.4.5
Displaced Secondary Vertices

All the elementary constituents of matter except electrons, protons, and massless neutrinos are unstable. The leptons decay, for example, $\mu \rightarrow e + \overline{\nu}_e + \nu_{\mu}$, with a decay rate that scales as the available energy to the fifth power. Therefore, the light muon can be considered as stable during its detection, while the heavy τ must be detected by measuring its decay products.

The separation of light (u, d) from heavy (s, c, b) quark states can be accomplished by the observation of a secondary decay vertex. The quarks can decay semileptonically – for example, $s \rightarrow u + l + \overline{\nu}_l$. Hadrons containing s quarks have lifetime distances, $c\tau$, of the order of centimeters, while c and b quark decays lead to hadron lifetimes, $c\tau \sim 200\,\mu\mathrm{m}$.

6.5
A Model *pp/$\overline{p}$p* Collider Detector

The characteristic interactions of the SM constituents are used in their detection as outlined above. In this section, a ''typical'' detector that is used in experimental particle physics is described. Fixed-target detectors are often special-purpose instruments optimized to explore a specific type of physics – for example, neutrino interactions. Collider detectors tend to be general-purpose instruments that are designed to study a large variety of reactions simultaneously as mentioned above. Therefore, a collider detector can be discussed ''generically.'' Generally, the backgrounds and trigger strategies are more challenging at a hadron collider than at an $e^{+}e^{-}$ collider, and therefore, the former is described. A schematic of a typical detector and event is shown in Figure 6.5.

6.5.1
''Soft'' Backgrounds

At a CM energy of 1800 GeV, the *pp* inelastic cross section is $\sim 50\,\mathrm{mb} = 5 \times 10^{-26}\,\mathrm{cm}^2$. The overwhelming majority of these interactions are soft, that is, they consist of produced hadrons with limited transverse momentum, $\langle p_t \rangle \sim 0.5$ GeV, where p_t is the component of secondary particle momentum transverse to the incident beam direction. The secondary particles are distributed in longitudinal momentum, $p_{|}$, according to single-particle phase space:

$$\begin{aligned}\text{single-particle phase space} \\ &= d^4p\delta\,(p^2 - m^2) \\ &= \frac{d^3p}{E} \sim dydp_t^2 \qquad (6)\end{aligned}$$

where m is the particle mass, E is the particle energy, and y is the rapidity, which is defined by $\tanh y = p_{|}/E$. The nonrelativistic limit for one-particle phase space

is d^3p/m, which is familiar from classical statistical mechanics.

The collisions of greatest interest occur at large transverse momentum because they probe small distances. Therefore, the detection, triggering, and data-acquisition (DAQ) strategy adopted for these detectors puts a strong emphasis on collecting the rare ''hard'' collisions, those containing high-p_t secondary particles.

6.5.2
Magnetic Analysis

Typically, the detector contains a large electromagnet, which provides a volume filled with a magnetic field. A uniform magnetic field causes all charged particles to move on helical paths, with radii of curvature determined by the particle momentum and charge. Thus, determination of the particle trajectories in the field volume determines the charge, vector momentum, and position of all the charged particles produced in the collision.

6.5.3
Si Inner Tracker

Because b and c quarks and the τ leptons have lifetimes of order 200 μm, an inner solid-state detector consisting of strips of Si with a strip spacing of ∼50 μm or pixels with sides of a similar size is often employed as the first detector element encountered by a secondary particle after it exits the vacuum pipe containing the incident beams. The Si detector strip spacing/pixel width is well matched to the decay distances of the particles. The Si detector also serves as the initial element in a tracking system that measures the particle trajectory in the magnetic field.

6.5.4
Outer Tracker

The Si elements are fairly expensive. Therefore, most tracking systems employ a different detector technology at larger radii. Gas-filled wire chambers (see Chapter 23) are the present standard. The size of these outer trackers is typically 1–2 m in radius. However, the high interaction rates of the LHC are pushing detector builders to higher rate capable systems. For example, the CMS detector uses all silicon in the tracking system.

A perfect tracking system in principle allows the experimenter to perform particle id on the c and b quarks and the τ lepton. The e and μ charged leptons are also measured and, by extension, the leptons from τ, W, and Z decays. All charged-hadron trajectories are also determined.

6.5.5
Calorimetry

The next system encountered by the outgoing particles is usually the calorimeter (see Chapter 21). Within the calorimeter, particles cascade in a dense medium and deposit their energy. The calorimeter is segmented transversely so that this system measures, destructively, the position and energy of all particles, both charged and neutral, that possess strong/EM interactions. The calorimetric medium can be either completely active (crystals) or interspersed heavy absorber plates with active detection layers (sampling calorimetry). Particle id is achieved by using the transverse and longitudinal segmentation of the calorimetry to distinguish between the differences in cascade development of the different incident particles – for example, electrons, and hadrons.

6.5.5.1 EM Segment

The first longitudinal segment encountered typically contains Pb or some other element with high atomic number that induces e and photon cascades via the EM interaction. Because hadrons interact differently, the EM segment is used to identify e and γ. The tracking system is then used for e–γ separation because e will leave an ionizing track while the uncharged photon will not.

The depth of the EM segment is sufficient to contain the EM cascade fully. It is typically $\sim$20 radiation lengths or $\sim$12 cm of Pb. By comparison, the ratio of radiation length to hadron interaction length is $\sim$30 in Pb, so that most hadrons will not even begin to produce a cascade in the EM segment. This difference in interaction-length scales, and a similar difference in the transverse size of the EM and hadronic (HAD) cascades, is the basis of clean e/γ particle id with respect to hadrons.

6.5.5.2 Hadronic Segment

The EM segment is followed by a HAD segment. Its task is to absorb all the energy of the hadrons. The scale forHAD interactions defines the size of the calorimeter system. For example, $\sim$10 nuclear absorption lengths (or 167 cm of Fe) are needed to absorb most of the HAD energy. Any particle that passes through the calorimeter unscathed is a candidate for identification as a muon. Muons will deposit ionization energy only in the calorimeter. Thus, a particle that acts like a MIP in the calorimeter can be provisionally identified as a muon.

6.5.6
Muon Detection

Detectors external to the calorimetry are often employed to provide independent muon identification and a redundant measurement of the muon position and momentum. This redundancy is similar to that provided by the two measurements of an electron by tracking in a magnetic field and by the measured energy deposited in the EM segment of the calorimetry. Redundancy is required when looking for rare processes where extremely clean particle id is called for.

Redundant muon information is supplied by a second magnetic analysis of the muon after most of the secondary particles in the interaction are removed by absorption in the calorimeter. This analysis may occur either in air or in a solid steel electromagnet. Wire chambers surrounding this additional magnetic volume typically provide the trajectory.

6.5.7
Trigger and DAQ

Because the inelastic cross section is large and the cross sections for the processes of interest are often small, the trigger for readout must be very selective. The ratio of all events to the events of primary interest may be as small as 10^{-10}. With such a small signal-to-noise value, redundant measurement and particle id are absolutely necessary. The situation for e^+e^- interactions is somewhat more relaxed.

In modern detectors, the trigger is hierarchical. The initial high rate is reduced by specialized electronics built by the experiment. A selection after that is done using digital information, commercial event building switches and ‘‘farms’’ of commercial computers working in parallel.

The trigger hierarchy is designed to reduce the total inelastic rate ($\sim$900 MHz at the LHC) to a rate logged to permanent medium (e.g., magnetic tape) of perhaps 100 Hz. Clearly, the trigger system cannot accomplish this prodigy (reduction by a factor 5×10^5) in one step. Several successively slower but more incisive trigger algorithms are used.

6.5.8
Analysis

Often, crude analysis of complete events consisting of the full set of information supplied by the detector is part of the highest level of triggering. Thus, triggering and DAQ merge smoothly into off-line analysis of the events. Typically, a complete event is assembled from the individual detector systems by the DAQ system and loaded into a high-level workstation where the highest level triggering is performed. Off-line analysis of the events stored on a permanent medium can be more leisurely and more exacting.

Note that these experiments will generate vast amounts of data. In addition, they are operated by large international collaborations with members distributed over the entire globe. Therefore, the task of analyzing and distributing the data is formidable. Indeed, the issues for particle physics are at the frontier of distributed computing and serve as a cutting-edge example for ‘‘grid computing,’’ which features distributed processing and data storage.

6.6
Other Experimental Techniques

Detectors are designed to address specific physics processes. Some detector systems are of a more specialized nature than the generic detectors for collider experiments that were discussed in the previous two sections. All detectors of necessity must utilize the interactions of the particles of interest with a detecting medium. In the previous sections, ionization in the tracking system, EM/HAD cascades in the calorimetric media, and ionization energy loss in the muon system were discussed.

6.6.1
Ionization Detectors

Ionization refers to the interaction of incident charged particles with the atomic electrons in a medium, which leads to ionization of the atoms. The energy loss by ionization varies with incoming particle velocity v as $1/v^2$ for slow incident particles. At high velocity, the ionization loss approaches a minimum and then slowly rises with incident energy.

If the value of the deposited energy is measured several times, the velocity is determined. With the momentum known from the curvature of the path in the magnetic field, the mass of the particle may thus be inferred. Therefore, ionization detectors can be used for slow-particle id if many redundant samples of the ionization are made. The medium used can be gaseous, liquid (e.g., liquid argon), or solid (e.g., silicon). Solid-state detectors using Si or Ge are used to measure ionization in many nonaccelerator experiments. When operated at cryogenic temperatures, the lattice phonon excitation can also be measured, yielding complementary information (e.g., CDMS).

6.6.2
Photomultiplier Tubes, Scintillator

Scintillating plastics coupled to photomultiplier tubes (PMT) can be used to measure the particle time of flight between two sets of counters to subnanosecond (10^{-9} s) accuracy. The measurement of time over a fixed distance is a velocity measurement. Thus, scintillation-counter arrays are also useful in particle id for slow ionizing particles.

6.6.3
Slow-*n* Detection

Neutrons are uncharged and hence do not ionize. Nevertheless, they can be detected by measuring the proton recoils from elastic *np* interactions. The recoil protons take up a significant fraction of the initial neutron energy, about half, on average. Thick organic scintillation counters can both supply the proton targets and detect the recoil protons via their large ionization losses in the plastic.

6.6.4
Cherenkov Detectors

A charged particle with a velocity v that exceeds the velocity of light in a medium of index of refraction n, $v > c/n$, emits a Mach cone of radiation. This is called the *Cherenkov effect*. Cherenkov counters consist, typically, of a gas or liquid-filled vessel outfitted with mirrors to collect the emitted light, and PMT to convert the light into a fast electrical signal. The angle of the emitted light, θ_c, is determined by $\beta = v/c$ and $n : \cos\theta_c = 1/\beta n$. Clearly, a measurement of the angle of the emitted light is a measure of the particle velocity. Such counters are called ring- imaging Cherenkov counters (RICH) (from the Mach cone image).

6.6.5
Transition-radiation Detectors

A transition-radiation detector (TRD) may be considered as utilizing the diffraction pattern arising from the radiation of a Cherenkov detector of finite length. The radiation is confined to very forward angles. In addition, it is in the X-ray frequency range, with an intensity that is proportional to $\gamma = 1/\sqrt{1-\beta^2}$. Therefore, the TRD is a device that is particularly useful for particle id with highly relativistic particles. The TRD is a detector complementary to those, like the Cherenkov detector, which lose discrimination power as $\beta \to 1 (v \to c)$.

6.7
Future Developments

Particle physics is a dynamic and vital field with an extremely broad-based experimental program, as has been shown above. In general, the program seeks to probe the SM either with increasing precision or with higher energies where phenomena appear to become simpler. To date, the SM has withstood this assault and proven itself capable of very precise and testable predictions. To make decisive progress, new facilities are now under construction, as shown in Table 6.4, to press forward on these two complementary fronts. Note also that with the discovery of DM and DE, particle physics is evolving toward a greater emphasis on nonaccelerator experiments.

6.7.1
The Energy Frontier at the LHC

6.7.1.1 Higgs Boson

The SM predicts the existence of a neutral scalar Higgs particle, but does not constrain the mass. One can estimate an upper limit to the requiring Higgs mass by requiring that the EW interactions do not become strong. For example, the *S*-wave amplitude A_0 for the EW process $e^+ + e^- \to W^+ W-$at

Tab. 6.4 New facilities.

Type	**Location**	**CM energy $\sqrt{s}$ (GeV)**	**Experiments**
pp collider	CERN, Switzerland Large Hadron Collider (LHC) – ATLAS, CMS, LHCb	14 000	Higgs, SUSY search t factory

Underground lab	DUSEL – United States SNO – Canada		DM search, p decay, very large neutrino detectors, $\beta\beta 0\nu$ search
Dark energy survey	Several facilities	telescopic	Equation of state of DE

a CM energy squared of s is

$$A_0(ee \longrightarrow WW) = \left(\frac{\alpha_w}{4\pi}\right)\left(\frac{s}{M_w^2}\right) \qquad (7a)$$

Because A_0 increases with energy, we expect that new phenomena will occur to restore partial-wave unitarity. This restoration guarantees that new physics will be seen if the H^0 mass range below about 1000 GeV can be explored:

$$A_0(ee \longrightarrow WW) < 1 \Longrightarrow M_H < \sqrt{\frac{4\pi}{\alpha_w}} M_w \sim 1600 \text{ GeV} \qquad (7b)$$

The discovery of the Higgs boson is crucial if we are to progress to a deeper understanding. The full exploration of the TeV (1000 GeV) mass scale is the province of the next machine at the energy frontier, the LHC. The LHC is the single new facility to operate at the EW-breaking mass scale (set by $<\phi> = 174$ GeV) so that the LHC is truly a discovery machine.

Note that a one-year run at design luminosity of the LHC provides an exposure of $100 fb^{-1}$. All Higgs masses from the LEPII limit to 1000 GeV will be discovered at the LHC with only 10% of this exposure. When and if the Higgs is discovered, the mass and width and quantum numbers as well as interactions with other SM particles will need to be determined. Note that in the SM, the only unspecified parameter is the Higgs mass, so that completely unambiguous predictions are made for all these quantities after the mass is measured. Thus, very incisive tests of the SM become available after the discovery.

6.7.1.2 **Supersymmetry and DM**

Evidence for a very high mass scale comes from the small neutrino masses and from extrapolating Newtonian gravity. There is a third hint that high masses bring new simplifications beyond the SM indicating new symmetries or interactions as yet unknown. This third scale requires some explanation. It is well known (vacuum polarization) that the EM coupling constant is not a constant but increases with decreasing distance of observation because of the screening effect of the virtual cloud of e^+e^- pairs present in the vacuum polarization. For example, $\alpha(M=0) \sim 1/137$, while $\alpha(M=M_z) \sim 1/128$. We have asserted that the QCD quanta are colored gluons, whereas the EM quanta are uncharged photons. This implies that QCD is weak at large mass and strong at small mass, that is, $\alpha_s(M=0) \to \infty$, which leads to q and g confinement. Therefore, since $\alpha_s(M=M_z) \sim 1/10$, as the mass increases further, α_s will drop and α will rise to meet it at some mass. Because the W and Z self-couple similarly to the gluons, α_w will also drop. It is remarkable that within errors α_s, α_w, and α, roughly meet at a mass scale $\sim 10^{15\pm1}$ GeV.

At this scale, QCD and EW forces are expected to be fully unified (Pati and Salam, 1973; Georgi and Glashow, 1974). Extrapolation by 13 orders of magnitude to the GUT scale leads to a potential unification of all forces, if no new physics intervenes. In fact, precision measurements of the coupling constants may decisively allow the conclusion that new physics does intervene. This is an example of the use of precision studies to probe presently inaccessible mass scales. For example, SUSY leads to a rather better unification than the SM alone and at a higher mass.

SUSY also predicts the value of the Weinberg angle (Eq. 1) rather precisely. It slows down the predicted rate of proton decay to be consistent with experiment. Most importantly, it protects the Higgs mass from radiative corrections coming from particles at the high mass scales contributing to the mass from quantum loops. SUSY provides this protection mechanism naturally if the SUSY particles have masses of about 1000 GeV. SUSY also provides a DM candidate, a stable neutral weakly interacting boson of mass about 1000 GeV.

The LHC provides a great discovery potential for SUSY particles. A one-year exposure at the design capability of the LHC will allow for the discovery of SUSY particles up to ~1000 GeV and thus either decisively disprove or prove the SUSY hypothesis. Therefore, the LHC is also a discovery machine for SUSY.

6.7.2
International Linear Collider (ILC)

As in the past (see Table 6.2), it is important that electron–positron as well as hadron colliders are operating. The ILC is being designed and will soon be formally proposed. It will operate in the crucial 1000 GeV mass range, where we have many hints that new physics beyond the SM will occur and where the LHC will make an initial study. This collider will have a ‘‘cleaner’’ environment with a well-defined fundamental initial state. The initial state polarization can also be prepared, allowing for new and more incisive tests than are available at the LHC. With the new LHC results being available in 2009–2010, the ILC can be built knowing in advance how to design the machine and detectors so as to maximize the impact on the new physics (Dawson and Oreglia, 2004).

6.7.3
Heavy Ions at the LHC

The search for a deconfined quark–gluon plasma will continue at the CERN LHC, which will also take data with nucleus–nucleus (A–A) collisions. The CM energy will be more than 20 times larger than the RHIC experiments. Therefore, at the LHC, higher initial temperature and higher energy probes of the medium will be available, for example, quarks with transverse momenta >200 GeV. There will be three experiments studying A–A collisions, ATLAS and CMS (general-purpose experiments), and ALICE, specifically designed to study heavy-ion collisions.

6.7.4
CP Violation After BaBar and Belle

At a fundamental level, one asks why the universe is composed of matter and not of antimatter. The violation of CP invariance is a necessary ingredient (Sakharov, 1967; Primakoff and Rosen, 1981). CP nonconservation has been extensively studied at ''B factories'' operated at the Stanford Linear Accelerator Center (SLAC – BaBar) and the Japanese National Laboratory for High-Energy Physics (KEK – Belle). To date, there appears no indication of CP violation beyond that allowed by the complex CKM matrix. More data and redundant measurements will overconstrain the ''unitary triangle'' and put ever tighter constraints on extensions to the SM.

The effects to be studied are so small that they may require the higher reaction rates available at hadron colliders. The LHC program contains an experiment dedicated to the study of b decays (LHCb) with smaller branching fractions and with higher statistics than the present experiments. Indeed, if SUSY is found in direct production at the LHC, then CP nonconserving effects would most likely be observable in b decay modes due to virtual quantum loops containing the SUSY particles. Thus the LHC experiments can be quite complementary.

6.7.5
The Future Neutrino Program

With the discovery of neutrino mass and generation mixing, the possibility of CP violation in lepton decays becomes possible. CP violation in heavy neutrino (seesaw mechanism) decays can cause a lepton asymmetry that can then be transmuted into a baryon asymmetry. For this scenario to be valid, the neutrino mixing matrix must have substantial complex elements. Initially, reactor experiments are being prepared in an attempt to detect the third mixing angle of this matrix.

In addition, accelerator neutrino beams directed toward a detector far away (long baseline experiments) are being prepared in the United States, Europe, and Japan. These experiments also aim to explore the third mixing angle, to study the masses of neutrinos themselves and not just the differences, and to start to attack the measurement of CP-violating terms in the mixing matrix.

Underground experiments, which achieve very low cosmic ray background levels, are also being mounted. Searches for neutrinoless double β-decay, $A_Z \rightarrow A_{Z+2} + e^- + e^-$, $\beta\beta 0\nu$, are made because the rate for these processes is proportional to the neutrino mass and because the reaction clearly violates lepton generation conservation. The scale of mass from cosmological and astrophysical experiments is limited to be <0.2 eV. This reaction cannot occur unless the neutrino is its own antiparticle, a situation not found anywhere else in the SM. Smaller backgrounds are needed, leading to a proposed deep underground science and engineering laboratory (DUSEL). This facility could house next generation DM, p decay, $\beta\beta 0\nu$, and neutrino detectors.

6.7.6
DE Experiments

At present, DE appears to be consistent with a classical Einstein ''cosmological term'' with a constant background field. To sharpen that conclusion, many experiments are being contemplated to determine the equation of state of the DE and to find out whether it has evolved in time as the Universe unfolds. These surveys are telescopic, either ground- or space- based. More data on this basic new field, outside the realm of the SM, are very important to achieve.

6.7.7
The Far Future

New fundamental particles and/or interactions are expected to appear at the EW-breaking mass scale of $\sim$1000 GeV or below. It is impossible to predict the shape of this new physics. One possibility is that the objects that are now considered to be elementary are really composites. At each point in the past – atoms to nuclei to nucleons to quarks – this hypothesis has proved to be true. It remains clear that particle physics will maintain its vitality by again pushing to higher energies and more precise experiments. New facilities beyond those now under construction should include a TeV-scale e^+e^- linear collider (ILC). The choice of the appropriate tools clearly must await the insights provided by the new data produced at the facilities presently under construction.

Many of the questions to be answered depend on the success of the SM. A partial list might include these: what is the origin of EW symmetry breaking? Why are there three generations? What explains the pattern of the fermion masses? What is the origin of the CKM matrix? What is the origin of CP nonconservation? What is the origin of the neutrino-mixing matrix? Are the QCD and EW forces unified at some energy? What is the connection of gravity to the other fundamental gauge interactions? What is the correct quantum theory of gravity?

The high mass scales implied by gravity, neutrino masses, and GUT unification are many orders of magnitude above the capabilities of any feasible accelerator. The intellectual challenge of these scales is to design incisive experiments at available energies. This task will require considerable ingenuity.

It is humbling to note that we do not understand the nature of the basic fields that constitutes 95% of the Universe, the DM, and DE. Clearly, much remains to be understood, and the intellectual vitality of particle physics is assured for the foreseeable future.

Glossary

Baryon: Half-integral spin hadron made up of qqq valence quarks.

Boson: Integral-spin particle.

Calorimeter: A device that provides a signal proportional to the energy deposited by a particle incident upon it.

Color: The quantum number carried by quarks and gluons; the "charge" of QCD.

Confinement: The hypothesis that colored quarks and gluons cannot exist as free particles.

CP Symmetry: A symmetry of interactions under the combined parity and charge-conjugation operation.

Fermion: Half-integral spin particle.

Flavor: Approximately conserved quantum number of quarks. Pair production of strange, charmed, bottom, and top ($s\bar{s}$, $c\bar{c}$, $b\bar{b}$, $t\bar{t}$) quarks is required. Different generations of quarks have different flavor labels.

g_s: Strong coupling constant.

g_W: Weak coupling constant; analogous to e in QED.

Gauge Symmetry: A symmetry arising from requiring that physics be independent of the local phase convention chosen at arbitrary space-time points.

Generations: The replication of the basic quark/lepton four elementary fermions, u, d, e, ν_e, at higher masses.

Gluon: The massless quantum of QCD.

Hadron: A strongly interacting, colorless composite of quarks.

Higgs Boson: A hypothesized particle whose nonzero vacuum field gives rise to the masses of all fermions and bosons.

Interaction Length: The characteristic length of material within which a hadron interacts by a strong interaction with a nucleus.

Jet: An ensemble of hadrons that are the final-state remnants of a quark or gluon parent that is permanently confined. This ensemble approximately retains the direction and momentum of the parent.

Kaon: A meson composed of strange (s) and u or d quarks, for example, $K^+ = (u\bar{s})$.

Lepton: Fermion without color (QCD interactions).

Lifetime: A characteristic time for the exponential decay of unstable particles.

Mach Cone: The characteristic shock-wave pattern at fixed angle that appears when an object exceeds the speed of propagation of a wave in the medium.

Meson: Integral-spin hadron made up of $q\bar{q}$ valence quarks.

Neutrino: Uncharged lepton, assumed to be massless.

"onium": Bound state of heavy quark and antiquark, for example, $c\bar{c}$ is charmonium. Analog of positronium $= e^+e^-$.

Photon: The massless quantum of QED.

Pion: The lightest meson composed of u and d quarks, for example, $\pi^+ = (u\bar{d})$

Planck Mass: The mass scale where gravity becomes strong: $M_{PL} = \sqrt{\hbar c / G_N}$ where G_N is Newton's constant.

QCD: Quantum theory of colored quarks and gluons.

QED: Quantum theory of charged fermions and the photon.

Quark: Fermion with color (QCD interactions).

Radiation Length: The characteristic length of material within which an electron interacts by emission of radiation caused by acceleration by a nucleus.

Rapidity: A variable, conventionally denoted by y, that defines longitudinal velocity and is invariant under Lorentz transformations: tanh $y = (p_\parallel / E)$, where E is energy and $p_\parallel$ is momentum along a defined axis. Nonrelativistically $y \to \beta_\parallel = v_\parallel / c$.

Spin: The intrinsic, quantized angular momentum possessed by SM constituents. Units are $\hbar$.

Structure Function: Experimentally determined distribution of momenta of constituents within a composite bound state (e.g., proton).

Uncertainty Principle: The inverse relationship between the possible simultaneous precision of knowledge of momentum and position, $\Delta x \Delta p_x = \hbar$.

Units: The convention $\hbar = c = 1$ is adopted. The dimensions of energy, momentum, 1/length, and 1/time are then all expressible in electron volts (eV). Conversion using $\hbar c = 2 \times 10^{-14}$ GeV cm, $\hbar = 0.66 \times 10^{-25}$ GeV s is straightforward.

Vacuum Polarization: In QED, the observed charge of an electron is modified by the sea of e^+e^- pairs virtually present in the vacuum. Because the neutral sea reduces the effective charge, and the sea extends only over distances $\sim\hbar/m_e c$, the effective charge increases with decreasing distance.

Wire Chamber: A detector with an array of wires maintained at high electric field that localizes, amplifies, and detects the ionization deposited by charged particles traversing a volume of gas.

***W, Z*:** The massive quanta of the weak force.

Yukawa Coupling: The coupling of fermions to massive quanta analogous to EM coupling. Massive quanta give rise to short-ranged forces.

INTRODUCTION

Ions are formed from neutral atoms by one kind or another of ionization mechanism. The various ways in which the ionization can be done include electron-impact ionization, photoionization, field ionization, surface ionization, and others. When incorporated within an ion source, often the ionization method lends its name to the ion source; thus for example one can have microwave ion sources, field-emission ion sources, vacuum-arc ion sources, and so on. Most ion sources are plasma based. Plasma might be formed from a gas (gaseous plasma) as in microwave, Penning, beam-plasma, and duoplasmatron ion sources, or from a metal (metal plasma) as in vacuum-arc and some laser ion sources. In some ion sources, the ions are formed without going through the plasma state, as in the field-emission or liquid-metal ion source. Because of the predominance of ion sources in which the ions are formed via the plasma state, here we restrict consideration to this kind of source.

Plasma-based ion sources are comprised of two basic parts—a means of plasma production (the "plasma source"), and a means of beam formation (the "extractor"). A simplified schematic of an elementary generic ion source is shown in Fig. 1. The requirements of the plasma source and the extractor may be either trivial or very complicated depending on the required ion-source performance and ion-beam characteristics. For example, the production of a low-energy, low-current (say a few μA at a few keV), singly charged argon-ion beam with no particular demands on beam geometry or divergence is rather easily accomplished; but the generation of a beam of very highly charged ions of low divergence at high energy and beam current is quite a different story.

Note the terminology used. An ion source is a device that produces an ion beam, and it (usually) contains a plasma source. Even though the plasma indeed contains ions and so the plasma source is in a sense a source of ions too, it is more appropriate to refer to the device that produces an extracted beam of more or less energetic ions, i.e., the ion-beam generator, as an ion source, and to use the term plasma source for the generator of charge-neutral plasma.

Here we briefly review the general characteristics of plasma-based ion sources and examine a few specific kinds of sources that have become well known and that are used extensively, including both plasma-based sources as well as one non-plasma-based source, the liquid-metal ion source.

1. PLASMA FORMATION

The plasma formation process is the heart of the ion source. The properties of the ion source and of the extracted ion beam are determined in large part by the plasma source, and the name given to the ion source is often that of the kind of plasma generator used. Some of the most basic ion-beam characteristics, such as ion species, beam current, beam purity, and ion charge state are determined by the equivalent parameters of the plasma

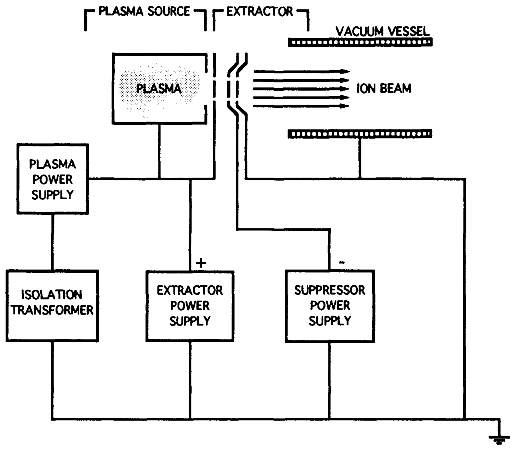

FIG. 1. Simplified schematic of a "generic" ion source.

source—plasma ion species, plasma density, plasma composition, and plasma ion charge-state distribution. For example, in an ECR ion source, the plasma is formed in an ECR (electron cyclotron resonance) plasma discharge and the ion-beam characteristics reflect the properties of the ions that are produced in an ECR plasma device; most notably, they are highly charged. If a high-current ion source is required, the plasma source should be of high density and high ion-production rate. As for all plasma sources, the means by which the plasma is confined is vitally important, and this is no less so when embodied within an ion source. Magnetic field configurations of various kinds have been employed using both electromagnetic field coils and high-field, rare-earth permanent magnets. The "magnetic bucket" geometries that have been used so successfully for the production of large, uniform plasmas have also been used in ion sources for the production of large-area ("broad") ion beams. Such ion sources are often referred to as bucket sources.

Whereas a plasma source as commonly used in plasma physics research is basically at ground potential, in an ion source the plasma and its electrical system are necessarily elevated to extractor potential (see Fig. 1), which might be many tens of kilovolts. This requirement adds complexity and expense to the ion-source configuration. Simple methods of plasma preparation have an advantage in this respect. For high-power dc ion sources, the requirements of the floating power supplies and their control and protection electronics can be a major part of the overall system hardware and cost.

2. BEAM FORMATION AND RELATED ISSUES

The plasma in an ion source is more or less confined within the region in which it is generated except for the place where the beam is to be formed, where the beam-formation electrodes are located. The plasma ion and electron components are separated at the beam-formation electrodes, the ions are accelerated to the required beam energy, and the ion beam is formed. Note that the beam is not really "extracted" from the plasma. What takes place is that the plasma ions drift across a Child–Langmuir sheath at a rate determined by the plasma density and the electron temperature, and not at all by the applied "extraction voltage"; it is only consequent to the ion–electron separation at the sheath that the ions experience the full applied voltage and are thereby accelerated to the requisite beam energy. Thus, the terms "ion extractor," "beam extraction electrodes," etc., are in fact misleading in terms of forming a good conceptual model of the ion source. Nevertheless the terms are used widely, and with the qualifications presented we use this terminology here too.

The ion-beam current that can be extracted from an ion source is given by the Child–Langmuir equation for ion current flow under space-charge–limited conditions (Child, 1911; Langmuir and Compton, 1931; Green, 1974, 1976),

$$I = \tfrac{4}{9}\varepsilon_0 S \left(\frac{2q_i}{M_i}\right)^{1/2} \frac{V^{3/2}}{d^2} \qquad (1)$$

$$= 1.72S \left(\frac{Z}{A}\right)^{1/2} \frac{V^{3/2}}{d^2}, \qquad (2)$$

where ε_0 is the permittivity of free space, S the open extractor area, $q_i = eZ$ the ion charge, e the electronic charge, Z the ion charge state, $M_i = Am_{\text{amu}}$ the ion mass, A the atomic weight (amu), V the extractor voltage, and d the extractor gap (separation between the main beam-forming electrodes), and in the second expression I is in mA, V in kV, S in cm^2, and d in cm. This equation is strictly valid only under special conditions, the most important of which are

1. the assumption of space-charge–limited ion flow, and
2. plane-parallel geometry throughout.

Although condition **1** is often well satisfied, condition **2** is often only poorly met. But nevertheless, the Child–Langmuir equation in its simple form usually provides a good approximation to the ion current that can be expected.

The beam-formation electrodes, or extractor grids, are in the form of aligned apertures in metallic electrodes across which the ion acceleration voltage, or extraction voltage, is applied. A pair of single, circular holes might constitute the extractor, as for example is commonly used in ECR ion sources, or an array of a large number, perhaps thousands, of small holes each producing its own "beamlet," as for example in some rf ion sources, "Kaufman" ion sources, and sources used for space thrusters, or an array of parallel slits as for example in some of the broad-beam ion sources developed for the formation of large, high-power neutral beams used in the controlled thermonuclear fusion research program. A photograph of the large and high-precision extractor used for the 100-keV, 75-A neutral beam source developed at the Lawrence Berkeley Laboratory (Kunkel, 1990) is shown in Fig. 2.

To maximize the beam current produced by the source, the extractor gap needs to be as small as it can be for a given extraction voltage while not allowing breakdown between the grids under a wide range of plasma conditions. Designing for these conditions is where the art and skill come in. The Child–Langmuir equation provides a good estimate of the beam current that can be expected from an ion source when the plasma density and the extraction voltage are optimized with respect to the extraction geometry (also called the perveance match condition). When the mechanical geometry and the plasma and operational parameters are matched to each other in this way, the beam divergence is minimum, determined now by the ion temperature and not the extraction optics, and the beam current density is highest. Calculation of beam formation is a complicated process, and a number of computer codes have been written to predict the extracted ion trajectories (Spädtke, 1989). An example of such a calculation is shown in Fig. 3 (taken from Spädtke, *et. al.*, 1994).

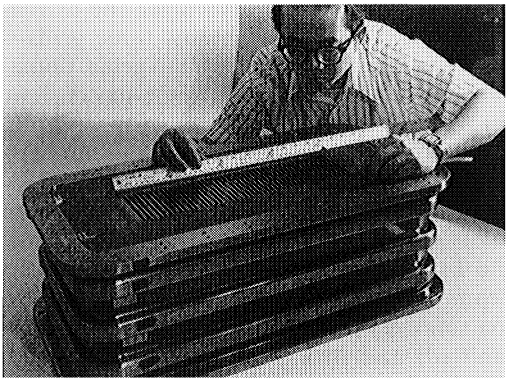

FIG. 2. Beam formation electrodes from a 10 x 40-cm² long-pulse ion source showing the multiple-slot, rail-type plasma grid facing upward.

In the simplest scenario, the ion-beam extractor can be made from just a pair of grids. These are often called the plasma grid and the ground grid, where the plasma grid is in contact with the plasma and the ground grid is held at ground potential. The extraction voltage, typically some tens of kilovolts, is put across the extractor, which means that the whole plasma formation system is now elevated to high positive voltage—ions created in the plasma are accelerated across this high extraction voltage; this is where the beam energy comes from.

It is usual that the ion beam is injected into and transported through a vacuum system in which ionization of the residual gas by the ion beam can occur. The cold electrons so created serve an important purpose, especially for high-current ion beams: they provide neutralization of the positive space-charge potential of the beam due to the ions themselves. In this way, space-charge blowup of the beam is minimized. The tendency of an ion beam to space-charge blowup increases with ion mass and beam current density. An expression has been given by Holmes (1989) for the current density for which the beam space charge of an incompletely neutralized beam would cause a 10% increase in beam diameter, which for the nonrelativistic limit can be written as

$$j_0 = \frac{3.24 \times 10^{-7}\, U^{3/2}\, Z^{1/2}}{A^{1/2}\, z^2\, (1 - h)}, \tag{3}$$

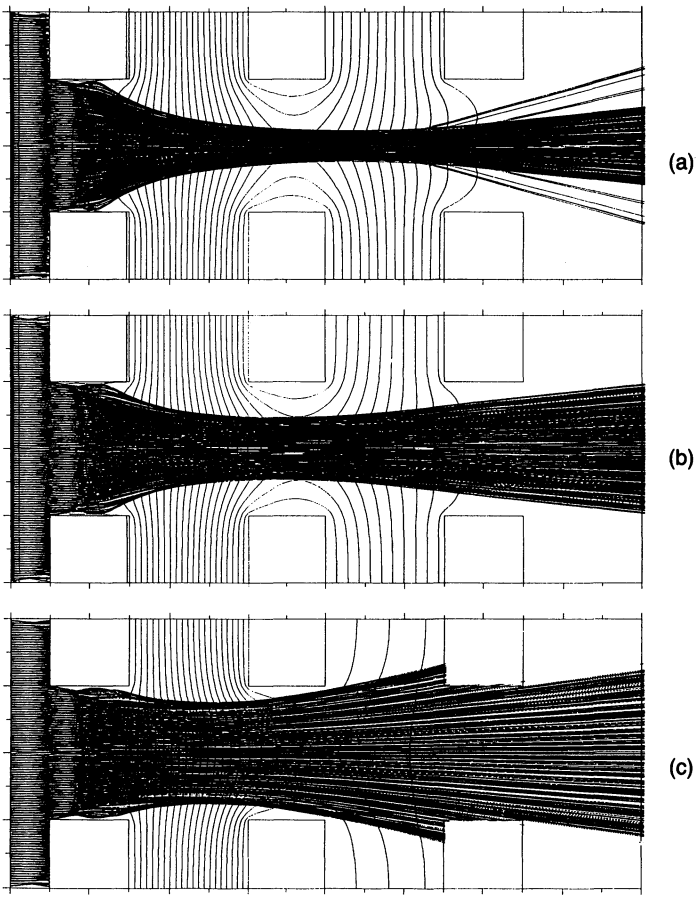

FIG. 3. Ion trajectory plots for extraction from a single hole as calculated by the AXCEL-INP code. Net extractor voltage 5 kV; Ti ions. Suppressor (middle) grid voltage (a) −9 kV, (b) −5 kV, (c) −1 kV.

where j_0 is the beam current density in A/m^2, U is the beam energy expressed in volts, Z is the ion charge state, A is the ion mass in amu, z is the beam propagation distance in meters, and h is the fraction of the beam space charge that is neutralized.

The space-charge–neutralizing electrons form a background sea for the energetic ion beam. The cold electrons can stream backward to the ion-source extractor, where they see an accelerating field in the direction opposite to the extracted ions, i.e., back into the plasma chamber. This electron backflow can sometimes cause damage to the source because of its power deposition, and in any case it shows up as an added electrical load—the measured "extractor current" (power supply drain) is composed not only of the forward ion current but also the backward electron current, and the electron current can easily be several times greater than the true ion current. For these reasons, it is common to make the extractor with a third electrode between the plasma grid and the ground grid, usually called the "suppressor grid," since its function is to suppress the electron backflow. It is biased negatively, say at about 10% or so of the full extraction voltage. The extraction shown in Fig. 3 contains three grids—plasma, suppressor, and ground grids. Sometimes, when design of the beam-ion current flow is particularly critical, yet more grids are added so as to be able to fine-tune the shape of the electric field within the extractor. A cutaway view of an extractor consisting of four rail grids is shown in Fig. 4 (from the Lawrence Berkeley Laboratory neutral-beam development program). In low-current ion sources the suppressor electrode is often omitted; and in ion sources where the extraction is across a magnetic field, the magnetic field serves to suppress electron backflow and so an additional electrostatic suppression is not needed.

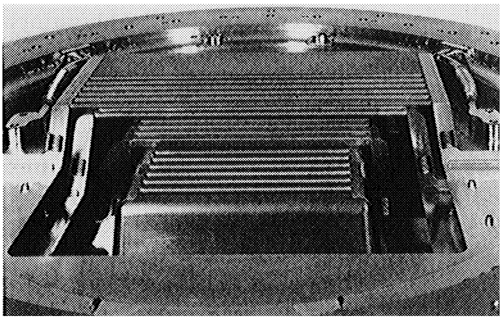

FIG. 4. Cut-away view of a four-grid multiple-slot extractor.

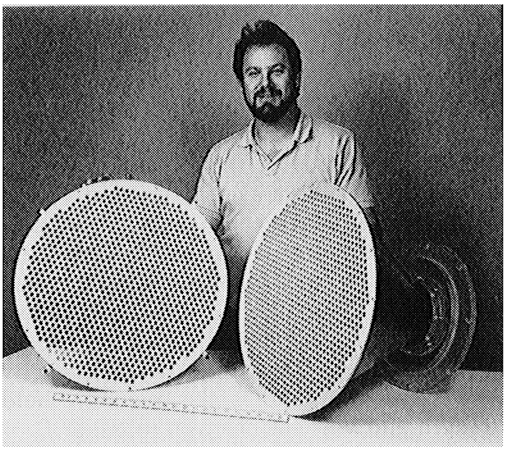

FIG. 5. 50-cm-diam multiple-aperture extractor from a vacuum-arc ion source.

The electron backflow can also give rise to quite substantial x-ray generation when the electron stream is stopped on electrodes within the ion source. This can pose a significant personnel safety hazard. Proper operation of the suppressor can vastly reduce the x-ray intensity. In any case, whenever an ion source is operated at voltages near or above about 20 kV, it is important to monitor carefully the x-ray intensity in the vicinity. Lead shielding is commonly used to reduce the intensity to acceptably low levels.

An ion beam may be focused to submicron dimensions or it may be of very wide area. Ion sources producing small beams often do so by forming the ions at a tiny point, as for example in the liquid-metal ion source where ions are produced by field emission from the pointlike tip of the "Taylor cone" formed electrostatically in the liquid metal. Production of large-area beams is done by ion sources in which the plasma is produced or expanded to large area before being presented to the extractor. The mechanical design of broad-beam extractors is not straightforward, especially when the electrodes can be heated by the beam and suffer thermal expansion while good alignment between the grids must be maintained. The 50-cm extractor from a broad-beam vacuum-arc ion source is shown in Fig. 5. This source produced a pulsed titanium ion beam of energy 100 keV and pulsed current about 10 A (Brown, 1994).

3. SOME REPRESENTATIVE ION SOURCES

Ion sources can be classified in a great many different ways, corresponding to a wide range of source and beam characteristics, parameters, and applications. One can categorize according to beam current intensity, ion charge state, or ion species, or according to whether the source is short pulse, long pulse, or dc, etc. Here we briefly describe several different kinds of ion sources that are broadly used in a number of important fields. These sources are for the most part "mature" in that within their field of use they have been studied and developed by a relatively large number of workers at numerous laboratories around the world. They convey some of the important principles involved in the physics and technology of ion sources. These sources as well as a wide range of other kinds of ion sources also are well described in the Proceedings of the International Conferences on Ion Sources (see Further Reading).

The ECR (electron cyclotron resonance) ion source (Jongen and Lyneis, 1989) has achieved a high degree of prominence because of the very high charge states of the ions produced—species such as fully stripped argon, Ar^{18+}, for example, have been produced (Kutner, 1994). These sources are widely used for accelerator (cyclotron) injection and for atomic physics experiments. They are an outgrowth of the hot-electron plasma source research carried out as part of the world controlled-fusion research effort in the 1960s and 1970s. The early pioneering work to develop these kinds of plasma sources into usable ion sources was led by Geller and his group at Grenoble (Geller, 1976). In the ECR source, a hot-electron plasma is created by the resonant coupling of high-power microwaves to the plasma electrons trapped within a minimum-*B* stabilized magnetic mirror. The electrons can be heated to very high energies, up to hundreds of keV, and it is these hot electrons that provide the ionization energy to strip the plasma ions, also trapped within the magnetic mirror confinement geometry. A small fraction of ions is axially lost from the mirror trap, and it is this plasma loss flux from which the ion beam is then extracted, providing a beam of very highly stripped ions. The electron cyclotron frequency is given by $\omega_c = eB/m$, where B is the magnetic field strength and m is the electron mass, or $f_{ce} = 2.8B$ GHz, where now the field-strength B is in kG; for typical laboratory magnetic fields of, say, 3–10 kG, this means that the resonant frequency is in the low microwave band, around 10 GHz. A schematic of a typical ECR ion source is shown in Fig. 6. The ECR source is a dc source, producing stable beams for long periods of time (up to weeks). Beams of virtually all of the elements of the periodic table can be produced, including the solid elements either by using an oven or by plasma sputtering from an inserted target. Beam currents are typically in the 1- to 100-eμA (electrical microampere) range for a given charge-state component, dropping to fractional microamperes for the highest charge states.

Freeman sources are used extensively in the semiconductor ion implantation field. Their ion beams are particularly quiescent and stable, and they work well with B, P, and As, the ion species most commonly used for semiconductor doping. The source was initially developed at the Harwell Laboratory, U.K., for electromagnetic isotope separation application (Freeman, 1963), and was subsequently adapted for ion implantation when the need arose in the late 1960s. In the Freeman source, electron emission from a thick (several millimeter diameter) filament is used to control the ionization of material admitted to an arc chamber and the plasma so formed is magnetically confined by the field that is the sum of an externally applied homogeneous field parallel to the filament and that due to the filament itself. It is usual for the arc chamber to be fed by vapor from an oven, providing the feed material containing the wanted ion species. Ion extraction is through a long slit, typically several millimeters wide by several centimeters long, in the same direction as the filament and the external field. The extracted beam is thus of rectangular cross section. Typical ion beam current is up to the 10-mA range.

The EBIS, or electron beam ion source, holds the record for the highest charge-state production. These sources were developed initially by Donets and co-workers at Dubna (Donets, 1990). In the EBIS, a high-energy electron beam is injected into a strong, uniform magnetic field so as to compress the beam to high current density. The beam is surrounded by a number of cylindrical "drift tubes" that are electrically biased from an external source. The drift-tube structure is cryogenically cooled to liquid helium temperature so as to keep the background gas pressure very low, in the 10^{-12}-Torr region or less. Neutral gas is injected into the electron beam where a fraction is ionized and trapped

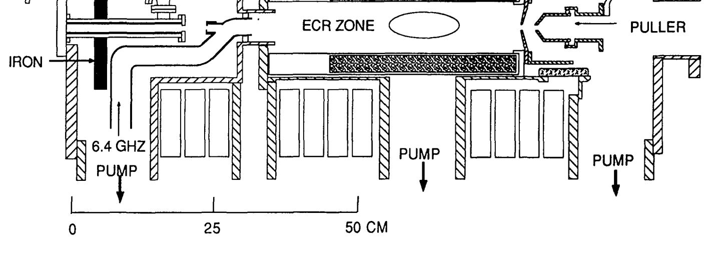

FIG. 6. Simplified schematic of a typical ECR ion source.

within the beam, where the ions are stripped to progressively higher charge states by successive electron impact. After maximal ion charge state is achieved, the drift-tube potentials are switched so as to allow the confined ions to be axially extracted from the device. Fully stripped xenon ions, Xe^{54+}, have been detected (Kutner, 1994).

4. APPLICATIONS

Historically, the first major application of ion sources was for injection into particle accelerators, initially for the relatively simple high-voltage accelerators and later for the growing spectrum of linear and circular machines. To match the capabilities of the accelerators the ion-source parameters required were in general quite modest, for example calling for beam currents only in the microampere range. As the diversity and performance of particle accelerators expanded, so also have the ion-source requirements grown, and sources used in this field today include Penning sources for linear accelerators, ECR sources for cyclotrons, EBIS and laser sources for synchrotrons, and many others. The injection requirements of modern accelerators can be quite severe, calling for very stable and reliable ion beams, often of high charge state and high current. The state of the art of ion sources as relevant to the field of particle accelerators is well presented at regular meetings of the community and can be found in the conference proceedings (see Further Reading).

Electromagnetic isotope separation (the deflection and collection of an ion beam in a magnetic field), in small quantities as an analytical tool and in larger quantities for their production for medical and industrial applications, is a field that also made early use of developments in ion source technology. By far the largest project of this kind was that undertaken in the United States as part of the Manhattan Project in World War II for the separation of uranium isotopes; thereafter these facilities, called calutrons, were used for industrial isotope production. The ion sources first employed were essentially vapor sources with electron-beam ionization. A drawback of the method is the very large investment of electric power required for other than minute quantities. For atomic mass analysis as a research tool, however, the technique is well developed, and the kinds of ion sources employed can be of very low current. The conference series, Electromagnetic Isotope Separators and Techniques Related to their Application, reports well on ion-source developments in this field (see Further Reading).

The field of ion implantation has grown steadily from its introduction in the early 1960s to its wide acceptance as a mature industrial technology for semiconductor material fabrication today. Ion implanters are manufactured and sold by a number of companies throughout the world, and this industrial research community is a well established one. The kind of ion sources used in "mainstream" implanters are the Freeman source and the Bernas source, where the qualities of beam quiescence and stability are paramount; other kinds of ion sources, such as microwave-driven sources, have found niche application. As described above, the beam species of particular application are B, P, and As, and a great deal of development of these sources has been done. The semiconductor ion-implantation community holds a regular biannual conference at which ion-source technology is a significant component; the proceedings of these meetings provide a wealth of detail about ion-source developments in this field (see Further Reading).

Ion implantation is a surface-modification technique with scientific and technological application wider than for semiconductor materials processing alone, and there are active research communities in nonsemiconductor areas such as, for example, metallurgical, ceramic, polymer, superconductor, and electro-optics materials synthesis and modification. For these applications the characteristics of the ion beams required vary widely and so also the kinds of ion sources needed. The field remains largely a research field, having not yet made the transition to widely used industrial application, and the diversity of the experimental configurations investigated and of the ion sources used is great. Relevant major conference series that address ion sources for these applications are those on Ion Beam Modification of Materials and the Surface Modification of Metals by Ion Beams (see Further Reading).

Applications such as ion-beam lithography, micromachining, and materials surface characterization using ion beams call for low-current, finely focused beams, and field-emission liquid-metal ion sources are often used for this purpose. Ion-beam focal spots as small as a few hundred angstroms have been produced.

The quest for propulsion of space vehicles and satellites by ion thrusters has motivated research internationally since the beginning of the space era. Though the size of this effort has decreased with time, work still continues, with emphasis on guidance and steering. A number of different kinds of ion sources have been developed and investigated for this potential application, including rf-driven sources, broad-beam sources, and liquid-metal sources. The requirements of the ion source needed are clear; not surprisingly, a major hurdle is in obtaining the specified ion-beam performance in an adequately small package with adequately high efficiency.

5. SUMMARY

The ion source is the beginning of the ion process, whatever the application is to be. The ion beam is created at the source, transported over distances from a meter or so up to many hundreds of meters, and delivered to the intended device or use. The physics and technology of beam transport is a sibling field to that of ion sources, which attains increasing importance as the required beam transport efficiency and the beam current density increase. The concern of space-charge blowup of the beam due to uncompensated electrostatic repulsive forces between ions is often critical, and as available ion-source beam currents steadily increase, this is becoming more commonly the limiting feature in some ion-beam facilities. In the absence of externally applied electric or magnetic fields, the beam can acquire a high degree of space-charge neutralization from the residual gas in the vacuum system, but the fields that are inherent to beam focusing and bending elements, such as dipole and quadrupole magnets or electrostatic lenses, disrupt the low-energy neutralizing electrons and beam neutralization can be diminished or lost. This concern is more or less limited to the high-current, low-energy regions that can exist in the beam transport line immediately after the ion source. It is usual that as the beam is transported further downstream toward the application, the current becomes lower and often some postacceleration (ion acceleration after initial ion extraction) adds energy to the ion beam; consequently beam space-charge blowup is less of a concern further away from the ion source. Often the ion source provides much more beam, perhaps several orders of magnitude more, than is finally available for the application. Beam loss is a major concern in many cases.

Understanding of the physical principles of ion-source design and operation has increased greatly in recent years, and the technology of their construction and application has similarly flourished. Fields of use both in fundamental science and in applied technology call for increasingly formidable ion-beam parameters and sophisticated ion-source performance, and the field has responded by generating a wide array of ion devices. Whereas in the past it was the case that the field was segmented into distinct and largely noncommunicating application areas, there is now a thriving international community of ion-source researchers with good cross-specialty communication links. The result is a healthy and fertile research area and a steady growth in ion-source technology.

GLOSSARY

ECR: Electron cyclotron resonance. Condition when an applied rf field equals the gyro frequency of electrons in the confining magnetic field. Usually in the microwave band.

Extractor: The electrode structure that forms an energetic, directed ion beam from a plasma.

Magnetic Bucket: Magnetic field geometry formed when an array of permanent bar magnets is distributed around the plasma confinement region.

Magnetic Mirror: Magnetic field geometry formed between two spaced field coils, with maxima in the plane of the coils and a central minimum.

Sheath: Boundary layer between plasma and electrode, where charge neutrality is not preserved.

Taylor Cone: Conical surface shape assumed by a liquid subjected to an electric field.

INTRODUCTION

The term "elementary particles" refers to the entities that are considered to be the fundamental constituents of matter. The definition of elementary depends on the distance scale relevant to the physics of interest. The behavior of bulk matter, under normal terrestial conditions, is largely determined by the properties of atoms, in the form of the chemical elements (the elementary particles of chemistry) and combinations of atoms into molecules. Atoms, with a typical size of 10^{-8} cm, have structure and are comprised of electrons orbiting a nucleus, with a typical size of 10^{-12} cm. Atomic nuclei are known to have structure as well and are built up out of protons and neutrons that are an order of magnitude smaller in size. Finally, protons and neutrons are believed to be made of *quarks*, which, along with electrons, appear to be elementary particles, in the sense that they reveal no internal structure down to distances as small as 10^{-16} cm.

Equally important to an understanding of the structure of matter are the forces of nature. Four forces have been identified, each with its domain of major importance. *Gravity* is the most familiar force, being responsible for the formation of stars and planets and the motion of celestial bodies. The *electromagnetic* force is also familiar and among other things leads to the binding of electrons to nuclei and the structure of atoms. On the subnuclear scale, less familiar forces play a fundamental role. The *strong* nuclear force "glues" quarks together into nucleons (protons and neutrons) and the nucleons together into nuclei. The *weak* nuclear force is responsible for the radioactive transmutation of nucleons and nuclei. At the subnuclear scale, it is also important to understand the *quanta*, also elementary particles, that mediate the fundamental forces. The most familiar example is the photon, the quantum of electromagnetic energy and mediator of the electromagnetic interaction.

Remarkable achievements occurring in the study of subnuclear particle physics over the last several decades have led to the development of what is now known as the Standard Model of elementary particle physics. This model is extremely successful in describing and predicting the relationships and interactions among the observed elementary particles and forces. Most notably, the Standard Model includes the unification of the electromagnetic and weak interactions, a discovery akin to that of Maxwell's unification of electricity and magnetism. The development and verification of the Standard Model is a result of the interplay between experimental and theoretical advances.

On the experimental side, the develop-

ment of high-energy accelerators as well as the sophisticated detectors and techniques used to study these particles has been essential. Progress in the field has largely been set by the development of accelerators capable of producing increasingly energetic and intense beams of particles (electrons, protons, etc.). Very high-energy particles when used as projectiles can serve as probes of subnuclear structures by virtue of their small Compton wavelength, $\lambda = h/mc$ (where h is Planck's constant and m is the particle mass); they can also give rise to very energetic collisions in which the energy released in the collision can materialize as massive particles in accordance with Einstein's equation, $E = Mc^2$, relating mass (M), energy (E), and the speed of light (c). Intense beams of particles are needed for precision measurements and the study of rare phenomena.

On the theoretical side, the development of a relativistic quantum field theory for electrodynamics was crucial. Its success in providing a means to calculate detailed properties of atomic structure led theorists to conclude correctly that there was hope in attempting to formulate the other subnuclear interactions in a similar fashion. The exploitation of symmetries and conservation laws also proved to be most valuable. The plethora of new particles discovered with the advent of particle accelerators was initially bewildering. Fortunately, regularities were uncovered in the systematics of the production and decays of these particles, and these regularities were successfully interpreted as resulting from symmetries (sometimes hidden or partially broken) of the physics underlying the properties of the particles and their interactions.

The development of the Standard Model represents a very important step in achieving a comprehensive understanding of subnuclear physics, but it is not yet the ultimate theory of elementary particles. Continued research will be required in order to answer fundamental questions left open by the Standard Model, such as the origin of the masses of the elementary particles. It is also hoped and suspected that further unification of the fundamental forces should be possible, including gravity.

The field of subnuclear physics, which grew out of the study of nuclear physics and cosmic rays, continues to evolve. For example, the field of particle astrophysics is growing in importance, building on the interplay between particle physics, the physics of the early universe, and cosmology. Collisions occurring at high-energy accelerators can create conditions not experienced since shortly after the Big Bang. In addition, the number and type and properties of the species of particles existing in the early moments of the universe affect its evolution.

1. BUILDING BLOCKS OF THE STANDARD MODEL

The elementary particles of the Standard Model can be divided into two broad classes: the particles that carry the properties (e.g., electric charge) that give rise to the forces of interaction between the particles and the particles that serve to communicate these forces between the particles. The quarks and leptons, discussed in the present section, are in the first class. The gauge bosons that mediate the forces are discussed in the following section.

1.1 Quarks and Leptons

The building blocks of the Standard Model are the *quarks* and *leptons*. Quarks are constituents of protons, neutrons, and related particles (previously considered elementary) known as *hadrons* that feel the strong nuclear force. The leptons form a separate group of particles that are not subject to the strong interactions. Examples of leptons are the electron and the neutrino. The neutrino, being electrically neutral, participates only in the weak interactions. The electron as well as the quarks experiences both the electromagnetic and weak interactions.

The quarks come in six *flavors* named up, down, charm, strange, top, and bottom. Leptons come in three pairs, each pair consisting of a charged lepton and an associated neutrino, and they are named after the charged lepton of the pair: electron, muon, and tau. The electric charges carried by the quarks and leptons are given in Table 1 (in units of the electron's charge). Electric charge is one of several *quantum numbers* associated with the elementary particles. These quantum num-

Table 1. The quarks and leptons[a]

Particle	Symbol	Spin	Baryon number	Charge	Mass (GeV)
Up quark	u	1/2	1/3	+2/3	$\approx 5 \times 10^{-3}$
Down quark	d	1/2	1/3	−1/3	$\approx 10 \times 10^{-3}$
Charm quark	c	1/2	1/3	+2/3	≈1.3
Strange quark	s	1/2	1/3	−1/3	≈0.2
Top quark	t	1/2	1/3	+2/3	≈170
Bottom quark	b	1/2	1/3	−1/3	≈4.3
Electron neutrino	ν_e	1/2	0	0	$<5.1 \times 10^{-9}$
Electron	e	1/2	0	−1	0.511×10^{-3}
Muon neutrino	ν_μ	1/2	0	0	$<0.27 \times 10^{-3}$
Muon	μ	1/2	0	−1	0.106
Tau neutrino	ν_τ	1/2	0	0	<0.031
Tau (lepton)	τ	1/2	0	−1	1.78

bers are found to be conserved quantities in the interactions of elementary particles. The determination of the conserved quantities has played an important role in establishing the relationships among the subnuclear particles. The significance of other quantum numbers such as lepton number and baryon number will be discussed later.

Each quark and lepton also has a corresponding *antiparticle* that carries equal but opposite quantum numbers; the antielectron, also known as the *positron*, carries +1 unit of electric charge. Particles and antiparticles have equal masses. In Table 1, the particle masses are expressed in terms of an energy (millions of electron volts) using the relation $E = mc^2$. Sufficiently energetic collisions of elementary particles can create conditions in the laboratory in which particle–antiparticle pairs are created. When this occurs through the electromagnetic or strong interaction, the various quantum numbers, including quark or lepton flavor, associated with the particles must be conserved. For example, a positron must be created in association with an electron so that no net electric charge is created from energy alone. However, as discussed later, the weak interactions do not conserve quark flavor.

All of the quarks and leptons are *fermions*, obey Fermi–Dirac statistics, and carry an intrinsic angular momentum, or spin, of 1/2 (in units of $\hbar$, Planck's constant divided by 2π). Angular momentum as well as energy and linear momentum are conserved in the interactions of elementary particles.

1.2 Bound States of Quarks: Baryons and Mesons

Spin plays an important role in determining the properties of the hadrons that are formed out of combinations of quarks and antiquarks by the strong interaction. As discussed more fully below, the strong interaction binds together groups of three of quarks (denoted as qqq) and quark–antiquark pairs (denoted by $q\bar{q}$). In principle, any flavor can be chosen for each of the quarks. The three-quark bound states qqq are known as *baryons*; they have baryon number +1 (from the three quarks, each contributing +1/3). The rules of addition for spin angular momentum result in baryons having odd half-integral spin (1/2, 3/2, etc.) and therefore being fermions. The proton and neutron are the most familiar baryons—the proton consisting of two up quarks and a down quark ($p = uud$) and the neutron consisting of two down quarks and an up quarks ($n = udd$). The electric charge of the proton and neutron follows from the algebraic sum of the electric charges of the constituent quarks. A partial list of observed baryons is given in Table 2, including their quark content, spin, and mass.

The quark–antiquark bound states, known as *mesons*, have baryon number equal to zero. They also have integral spin (0, 1, etc.) and so are *bosons* and obey Bose–Einstein statistics. Again, in principle, any flavor of quark can be chosen in forming the mesons. Some examples of mesons readily produced in high-energy particle collisions include the pi me-

Table 2. Some representative baryons and mesons[a]

Particle	Symbol	Quark content	Spin	Charge	Mass (GeV)
Proton	p	uud	1/2	+1	0.938

[a] Extracted from Particle Data Group (1994).

sons, also known as pions. The pions come in three charged varieties: $\pi^+ = u\bar{d}$, $\pi^- = \bar{u}d$, and π^0, a linear combination of $u\bar{u}$ and $d\bar{d}$. It is noted that the π^- is the antiparticle of the π^+, and the π^0 is its own antiparticle. The *K* mesons, or kaons, are also relatively easily produced, being the least massive particles containing the strange quark: $K^+ = \bar{s}u$, $K^- = s\bar{u}$, $K^0 = \bar{s}d$, and $\bar{K}^0 = s\bar{d}$. Table 2 also gives a partial list of some of the observed mesons and their quark contents, spins, and masses.

2. THE FORCES

The interactions among elementary particles are the result of several forces. Three of these forces—the strong, electromagnetic, and weak—have been understood in terms of relativistic quantum field theories and in particular as *gauge* field theories. Each of the forces is described in terms of the exchange of quanta of the gauge field between the interacting particles. The strength of the gravitational force is sufficiently small that gravity can safely be ignored in studying the interactions of small numbers of elementary particles.

2.1 The Electromagnetic Force

The electromagnetic force is the most familiar of the forces relevant to the study of elementary particles. It is the attractive *Coulomb* force between the negatively charged electron and the positively charged proton that gives rise to the bound state known as the hydrogen atom. Ignoring relativistic effects, the potential energy of the bound state can be expressed as $V = e^2/r$, where e is the magnitude of the electron (or proton) charge and r is the distance separating the proton and electron.

The infinite range of the electromagnetic force is in keeping with the masslessness of the photon, the quantum of the electromagnetic field. The electromagnetic field of a charged particle is taken to be the result of the radiative emission and reabsorption of *virtual* photons by the charged particle. Virtual particles are those that do not satisfy the equation $E^2 - p^2c^2 = m^2c^4$; that is, their existence violates energy conservation for a short time interval, as allowed by the uncertainty principle of quantum mechanics: $\Delta E \Delta t \leq \hbar$.

In first approximation, the Coulomb force responsible for the binding of the hydrogen atom is due to the emission of a photon by the proton and subsequent absorption by the electron. The strength of the interaction due to the exchange of one photon is $\alpha = e^2/\hbar c = 1/137$ when expressed in dimensionless form. Here, α is associated with the quantum mechanical probability of one photon being exchanged between two particles with charge e. The full theory, known as quantum electrodynamics (*q.v.*) or QED, is used to determine the contributions to the force arising from the exchange of multiple photons. Perturbative methods can be employed and lead to converging results as a result of the smallness of α.

Even as it is recognized that the definition of what is an elementary particle depends on the distance scale in question, it is also recognized that the definition of the strength of an interaction depends on the distance scale being probed. The strength of the electromagnetic interaction, α, depends on the electric charge e. However, the magnitude of the effective charge can be shown to increase as the distance associated with the measurement of the charge decreases. This is due to the screening of the electron's charge at longer distances by the polarization of the vacuum surrounding the electron. The electron emits virtual photons to give rise to the electromagnetic field, and these photons can themselves create virtual electron–positron pairs. The electron–positron pairs are affected by the presence of the central electron charge and become oriented so as to have the positrons closer to the central electron. The screening effect is measurable, though small, changing α by about 10% for a change in the distance scale by a factor of roughly 100 000.

Quantum electrodynamics (QED) serves as the paradigm in the construction of theories of the strong and weak interactions. The gauge bosons that are involved in these theories are listed in Table 3. The significant differences observed between the interactions result in large part from the different symmetries inherent to the interactions. The properties of quantum electrodynamics result from a local gauge symmetry based on the unitary group U(1). This symmetry requires the invariance of the physics under a redefinition of the quantum mechanical wave functions of particles carrying electric charge by a space-time–dependent complex phase. The U(1) gauge invariance of QED is responsible for the conservation of electric charge.

2.2 The Strong Force: Color

The strong force, also called the nuclear force, is formulated in terms of a gauge field theory known as quantum chromodynamics (QCD) (see STRONG INTERACTIONS). The gauge symmetry for QCD is based on the special unitary group SU(3). In QED, there is one kind of charge, the electric charge, acting as the source for the electromagnetic field. In QCD, there are three kinds of charge, called color; each flavor of quark (u,d,c,s,t,b) can possess one of the three color charges, and the leptons carry no color charge. The three color charges can be named R, G, and B in analogy with the primary colors red, green, and blue. The properties of the color force are such that only color-charge neutral (i.e., colorless) bound states are observed in nature. This has the unusual consequence that free, isolated colored quarks are not observable in nature, a fact that so far has been borne out experimentally. The only color-neutral objects are the baryons and mesons of which more than a hundred different types have been observed.

The baryons are colorless bound states in which each of the three quarks carries a different color charge to obtain equal contributions of R, G, and B color charge. The color charges are independent of the quark flavor and, for example, the lambda baryon, $\Lambda = uds$ is a linear combination of $u_R d_G s_B$, $u_G d_B s_R$, $u_B d_R s_G$, etc. (where the subscript indicates the color charge of the quark). A linear combination of colors is required to assure that the net color charge of the particle is invariant under rotations in the abstract space associated with the color SU(3) symmetry group.

Antiquarks carry "anti"-color charges $\bar{R}$, $\bar{G}$, $\bar{B}$ (or, to follow the visual color theory

Table 3. The gauge bosons[a]

Particle	Symbol	Spin	Force mediated	Electric charge	Color charge	Mass. (GeV)
Photon	γ	1	Electromagnetic	0	0	0
Gluon	g	1	Strong	0	r, g, b	0
W boson	W^+, W^-	1	Charged weak	±1	0	80.2
Z boson	Z^0	1	Neutral weak	0	0	91.2

[a] Extracted from Particle Data Group (1994).

analogy, the complementary colors cyan, magenta, and yellow), just as the positron carries an electric charge opposite to that of the electron. The mesons are colorless objects by virtue of being comprised of a quark and antiquark having "opposite" colors. The positive pi meson is a linear combination of $u_R\bar{d}_R$, $u_G\bar{d}_G$, and $u_B\bar{d}_B$.

The analogue of the photon in QED for QCD is the gluon. The gluon, like the photon, is massless and has spin 1, and color charge is a conserved quantity. However, because of the *non-Abelian* property of the QCD gauge group, SU(3), there are in fact eight distinct types of gluons, and they all possess net color charge: $R\bar{G}$, $B\bar{R}$, etc. Photons do not carry electric charge and can only interact with each other via charged particles. Gluons, on the other hand, can interact directly with each other via their color charges, and this plays a crucial role in determining the properties of the strong force.

In quantum chromodynamics, the chromodynamic fields of quarks are created by the emission and reabsorption of virtual colored gluons. The vacuum can be polarized, as in the case for QED. However, for QCD, the polarization of the vacuum leads to an antiscreening of color charge, a result due to the fact that gluons carry color charge. The antiscreening implies that the strength of the color force decreases as the distance associated with the measurement decreases, and conversely, the force increases with increasing distance. The former result has been proven (by Gross and Wilczek and Politzer; see Wilczek, 1982) and is known as the *asymptotic freedom* property of QCD. The latter result is conjectured and is known as the *confinement* property of QCD. The phenomenological result (consistent with experimental observations) is that quarks are confined in protons and other hadrons at a distance scale of about 1 fm (10^{-13} cm) where the chromodynamic interaction coupling is strong ($\alpha_s > 1$). However, inside the hadrons, the quarks behave relatively freely.

Unfortunately, perturbative methods cannot be used to determine the masses of hadrons because α_s effective at a distance scale of 1 fm is not small. Nonperturbative techniques, such as lattice gauge theory, show promise for addressing these problems. It is expected and has been observed that the masses of hadrons containing the more massive quarks (*c,b,t*) are largely due to the mass of the massive quark.

The strong force that binds protons and neutrons into nuclei (and overcomes the large repulsive electric force existing between protons inside a nucleus) is then related to the structure of the nucleons (and other hadrons), as determined by the more fundamental chromodynamic interaction of quarks and gluons. This is similar to the relation of the forces at play between neutral atoms and molecules and the more fundamental electromagnetic interaction that establishes atomic structure. The nuclear binding force is strong but has a short range; the nucleons must be close enough to detect the distribution of color charge within each other.

Before the advent of the quark model of hadrons, it was suggested that the nuclear binding force could be due to the exchange of mesons between nucleons (protons and neutrons). The finite range of the force could be explained in terms of a potential of the form $V = (\alpha_s^2\hbar c/r)e^{-mc^2r/\hbar c}$, now known as the Yukawa potential, where m is the mass of the exchanged meson. The Compton wavelength, $\lambda = h/mc$, of pi mesons agrees with the observed effective range of the nuclear force between nucleons.

2.3 The Weak Force: Radioactive Decay

Only a few elementary particles are stable; the rest of the particles rapidly decay into other less massive particles. The study of decays has been an essential aspect of elementary particle research and has provided clues to understanding the relationships and interplay among the forces affecting elementary particles. The exponential decay lifetimes observed in the decays of elementary particles can be understood in terms of the forces responsible for the decay. A typical strong-interaction decay time is 10^{-24} seconds. Electromagnetic decays occur over time intervals in the range of 10^{-16}–10^{-20} seconds. Weak-interaction decay times are found in the range of 10^{-13}–10^{-6} seconds. The special properties of the weak interaction were initially revealed in the study of particle decays. The weak interaction was in fact first recognized as being the agent responsible for the radioactive β decay of nuclei. As an example, in the decay $n \rightarrow pe^- \bar{\nu}_c$, a neutron can be transformed by the weak interaction into the less massive proton and an electron (the β ray) plus an anti–electron neutrino.

As in the case of the electromagnetic and strong interactions, the weak interaction is understood in terms of a gauge field theory. The weak interaction is governed by the group SU(2) and mediated by the exchange of three types of spin-1 gauge bosons between the interacting fermions. Two of the gauge bosons, known as the W^+ and W^-, carry electric charge and mediate the *charged-current* weak interaction responsible for nuclear radioactive decay. The third boson, known as the Z^0, has zero electric charge and is responsible for the weak *neutral-current* interactions. Typical decays are given in Table 4.

2.3.1 Flavor Conservation The electromagnetic and strong interactions conserve quark and lepton flavors. The photon can couple with any charged fermion and conserves the fermion flavor: An electron can radiate a photon, or a very energetic photon can materialize as an electron–positron pair or any other particle–antiparticle pair of quarks or charged leptons. Electric charge as well as quark and lepton flavors must be conserved: A muon cannot just radiate a photon and as a result be transformed into an electron. The gluon can couple to any quark, as they carry color charge (leptons do not): A blue up quark can radiate a blue–anti-red gluon and be transformed into a red up quark, or a very energetic green–antiblue gluon can materialize as a particle–antiparticle pair of quarks [e.g., charm (green) plus anticharm (antiblue)]. Color and quark flavor must be conserved: A bottom quark cannot just radiate a gluon and be transformed as a result into a strange quark.

The "weak" charges carried by the quarks and leptons are such that the charged-current weak interactions lead to specific sets of transmutations that do not conserve quark flavor. The weak interactions view the quarks and leptons as coming in doublets:

$$\begin{pmatrix} u \\ d \end{pmatrix}, \begin{pmatrix} c \\ s \end{pmatrix}, \begin{pmatrix} t \\ b \end{pmatrix}; \begin{pmatrix} \nu_e \\ e \end{pmatrix}, \begin{pmatrix} \nu_\mu \\ \mu \end{pmatrix}, \begin{pmatrix} \nu_\tau \\ \tau \end{pmatrix}.$$

Referring to Table 1, it is noted that the elements of each doublet differ in electric charge by one unit. The W bosons carry one unit of electric charge and couple in an equivalent way to each of the weak fermion doublets and thereby give rise to transmutations between the fermions of a weak doublet. For example, a top quark (charge +2/3) can decay into a W^+ boson and a bottom quark (charge −1/3): $t \rightarrow bW^+$; the W^+ can then subsequently decay into a positron and an electron neutrino: $W^+ \rightarrow e^+\nu_e$. The process of neutron β decay, $n \rightarrow pe^-\bar{\nu}_e$, can be described in terms of the decay of one down quark in the neutron into an up quark and a virtual W^- that subsequently materializes as an electron plus an

Table 4. Some representative particle decays[a]

Particle	Decay	Interaction	Lifetime (s)
Photon	—	—	Stable
Electron	—	—	Stable
Neutrinos	—	—	Stable
Muon	$\mu^- \rightarrow e^-\bar{\nu}_e\nu_\mu$	Weak	2.2×10^{-6}
Tau	$\tau^- \rightarrow \mu^-\bar{\nu}_\mu\nu_\tau$	Weak	3×10^{-13}
Pion	$\pi^- \rightarrow \mu^-\bar{\nu}_\mu$	Weak	2.6×10^{-8}
Pion	$\pi^0 \rightarrow \gamma\gamma$	Electromagnetic	8.4×10^{-17}
Kaon	$K^+ \rightarrow \pi^+\pi^0$	Weak	1.2×10^{-8}
Rho	$\rho^0 \rightarrow \pi^+\pi^-$	Strong	4×10^{-24}
Neutron	$n \rightarrow pe^-\nu_e$	Weak	887
Lambda	$\Lambda^0 \rightarrow p\pi^-$	Weak	2.6×10^{-10}
Sigma	$\Sigma^0 \rightarrow \Lambda^0\gamma$	Electromagnetic	7.4×10^{-20}
Delta	$\Delta^+ + \rightarrow p\pi^+$	Strong	5×10^{-24}
Omega	$\Omega^- \rightarrow \Lambda^0K^-$	Weak	8.2×10^{-11}
D meson	$D^0 \rightarrow K^-\mu^+\nu_\mu$	Weak	4.2×10^{-13}
Lambda − c	$\Lambda_c^+ \rightarrow pK^-\pi^+$	Weak	2×10^{-13}
B meson	$B^- \rightarrow D^0e^-\bar{\nu}_e$	Weak	1.5×10^{-12}

---

[a] Extracted from Particle Data Group (1994).

electron antineutrino: $n \rightarrow (ud)d \rightarrow (ud)u + W^- \rightarrow pe^-\bar{\nu}_e$.

The weak interaction, like the strong interaction, and in contrast to the electromagnetic interaction, is very short ranged. The effective strength of the weak interaction is smaller than the electromagnetic interaction by a factor of about 10 000. Both of these properties result from the fact that the *W* (and *Z*) are very massive particles. The intrinsic strength of the weak interaction is in fact comparable to the electromagnetic interaction after one accounts for the suppressed probability of creating a virtual *W* (or *Z*) compared to that for creating a virtual photon.

2.3.2 Conservation of Baryon and Lepton Numbers The weak interactions (as well as the electromagnetic and strong interactions) conserve both the baryon and lepton numbers. In fact, separate lepton numbers are conserved, one for each of the three flavors of leptons: electron, muon, and tau. The electron and its companion neutrino (ν_e) each carry one unit of electron lepton number; the positron and electron antineutrino carry minus one unit while the muon and tau and their companion neutrinos carry zero units of electron lepton number. This pattern continues in the obvious way for muon and tau lepton numbers. The origin of baryon and lepton number conservation is not understood. This is in contrast to the case for electric charge conservation that follows from the local U(1) gauge invariance of electromagnetism.

2.3.3 Parity and Charge Conjugation Another essential difference of the weak interaction is that it violates the discrete symmetries of *parity* (*P*) and *charge conjugation* (*C*). Invariance under parity requires the physics of a system to be unchanged for an inversion of all coordinates through the origin. Invariance under charge conjugation requires the physics to be unchanged if all chargelike quantum numbers are reversed (i.e., particles and antiparticles interchanged). The violation of both symmetries by the charged-current weak interaction is manifest in the properties of the apparently massless neutrinos that partake only in the weak interaction.

Neutrinos are found to be left-handed objects, in the sense that their spin angular momentum is always directed in opposition (or antiparallel) to their line of motion. Under the assumption that neutrinos are massless and therefore move at the speed of light, no object can overtake their motion and thereby change their observed handedness. Antineutrinos are right-handed with their spin angular momentum always directed along their line of motion. A parity-reversed universe (left-handed spins interchanged with right-handed spins) or a charge-conjugated universe (lepton number interchanged with antilepton number) would contain right-handed neutrinos and left-handed antineutrinos—particles that are not observed. It should be noted, however, that a combined operation of charge conjugation and parity inversion (*CP*) transforms the observed left-handed neutrinos and right-handed antineutrinos into themselves.

The quarks and the charged leptons, having nonzero masses, occur in both left- and right-handed varieties. However, only the left-handed variety are subject to the weak force; the right-handed fermions do not carry the weak charge. The charged-current weak interactions are then completely left-handed while the electromagnetic and strong interactions are completely ambidextrous.

The weak transitions among quarks reveal another intriguing aspect of the charged-current weak interaction. For reasons that are not yet understood, the mass *eigenstates* and the weak-charge *eigenstates* of quarks are not identical. This leads to weak transitions among charge $+2/3$ quarks of one weak doublet with charge $-1/3$ quarks of another weak doublet. For example, the charm quark is observed to decay mainly to the strange quark, but it is also found less frequently to decay (about one chance in 20) into the down quark. The effect of the mismatch between the mass and weak-charge eigenstates of quarks can be described in terms of a unitary transformation acting on the charge $-1/3$ quark fields. This transformation can be parametrized as a complex rotation with three Euler-type angles and one complex phase. The values of these angles and the phase are fundamental parameters of the Standard Model. The angles govern the relative frequency of all of the possible transitions between the charge $+2/3$ and charge $-1/3$ quarks, and the complex phase is thought to be connected with a small violation of *CP* invariance, so far detected only in certain decays of neutral *K* mesons. It is believed that *CP* noninvariance is required to explain the gross asymmetry represented by the preponderance of matter over antimatter observed in the universe.

2.3.4 Weak Neutral-Current Interactions and Electroweak Unification The remaining agent of subnuclear interactions, the Z^0, is responsible for the weak neutral-current interactions. The Z^0 is massive enough that after being produced in high-energy collisions, it will decay into particle–antiparticle pairs of any flavor of lepton or quark (except for the very massive top quark.) Precision measurements of Z^0 decays have been used to rule out the existence of any additional flavors of massless neutrinos. These measurements have also been used to determine how the strength of the weak neutral-current interaction differs for various classes of fundamental fermions: the neutrinos, the charged leptons, and the charge $+2/3$ and charge $-1/3$ quarks. In addition, it has been found to be neither left-handed nor ambidextrous. These properties of the neutral-current interactions have a common cause: the unification of the electromagnetic and weak interactions, as proposed by Glashow, Salam, and Weinberg.

In the Standard Model of the electroweak interactions, the theory has an underlying symmetry based on the direct product group SU(2) × U(1). This symmetry requires that the electroweak gauge bosons (two electrically charged and two electrically neutral) and the fermions (quarks and leptons) are all massless—in contrast to what is observed in the real world. The symmetry is broken, however, by the solution nature has chosen from the equations governing the theory, and this gives rise to masses for the quarks and leptons as well as for the *W* and *Z*. The photon remains massless as a result of the fact that the U(1) gauge symmetry of electromagnetism remains unbroken. The breakdown of the initial gauge symmetry is often compared with the case of the spontaneous breakdown of rotational symmetry that occurs in a ferromagnet when the long-range correlation among the spins (and magnetic moments) results in the alignment of the spins along a random direction.

The spontaneous breakdown of the SU(2) × U(1) gauge symmetry in the Standard Model occurs in such a manner that the two electrically neutral gauge bosons associated with the original unbroken symmetry become mixed, leaving two linear combinations, one of which is the photon and the other the Z^0. The "peculiar" couplings of the Z^0 to the quarks and leptons thus reflect the specific "charges" associated with the unbroken gauge symmetries that are carried by the right- and left-handed fermions. In this way, three otherwise phenomenologically distinct interactions—electromagnetism and the charged- and neutral-current weak interactions—are unified in the sense of being inextricably intertwined. The masses of the *W* and the *Z* as well as the weak and electric charges are no longer independent but related in a predictable way that has been very precisely confirmed by experiment.

The price of this unification is the introduction of a new force, and the precise understanding of its origin is not yet clear. In the simplest version of the Standard Model, a set of four spin-0 particles (*scalar* fields) are introduced, and it is the pattern of the scalar boson interactions with the fermions, gauge bosons, and themselves that gives rise to the unification. The scalar fields carry the weak and electric charges; two are electrically neutral, and the other two carry $+1$ and -1 unit of electric charge. Under the spontaneous breakdown of the electroweak symmetry, the two charged scalar fields and one of the neutral scalar fields become absorbed in the definition of the massive *W* and *Z* and the final neutral scalar emerges as a detectable elementary particle known as the Higgs particle. The mass of the Higgs particle is not known, but it is expected to be less than 1 TeV. Discovering the Higgs particle, or whatever agent is in fact responsible for the electroweak-symmetry breakdown, is the next crucial step to make in order to reach a more complete understanding of the nature of matter.

3. BEYOND THE STANDARD MODEL

The development of the Standard Model of elementary particle physics is a great achievement. The quark model of hadrons and the unification of the electromagnetic and weak interactions successfully provide a coherent and simplifying framework in which to view the complex spectrum of subnuclear particles and their interactions. The predictive power of the Standard Model has been and continues to be thoroughly tested; so far, no discrepancy has emerged. However, several questions remain unanswered by the Standard Model. These questions include the following:

1. The origin of mass: What is the physics that causes the top quark to be so heavy or the electron to be so light? Are the neutrinos in fact massless?
2. What is the physical significance of there being three types of each class of fundamental fermions: neutrinos, charged leptons, and the charge +2/3 and −1/3 quarks? Why not four types?
3. What is the underlying rationale for the assignment of quantum numbers (for example electric charge) to the fundamental fermions?
4. What physics determines the magnitude of the Euler angles describing the weak quark transitions?
5. What is the origin of *CP*-invariance violation?

Some of these questions are undoubtedly related, and some extensions of the Standard Model have been contemplated that partially address these questions. It is possible that nature will reveal additional symmetries that will lead to a resolution of these issues. It is useful to mention briefly two examples. The first is supersymmetry: a postulated symmetry of nature between fermions and bosons, so that every fermion with a specific set of quantum numbers has a boson partner. While the symmetry has so far not been observed in nature (the supersymmetric partners have not been produced and identified for any of the fundamental fermions), it imposes constraints that make it very attractive in addressing the question of the origin of mass. A second class of conjectures has to do with further unification of the fundamental forces (see UNIFIED FIELD THEORIES). The possibility of unifying the symmetries governing the strong and electroweak interactions, SU(3) and SU(2) × U(1), into a larger group, such as SU(5), seems very attractive in that it can provide a rationalization for the assignment of quantum numbers to the fundamental fermions. The implication of this type of unification is the presence of additional interactions, most notably interactions that can give rise to proton decay ($p \rightarrow \pi^0 e^+$), which violates baryon (and lepton) number conservation and has so far not been observed in spite of very sensitive searches. Finally, there are even grander schemes involving an extension of quantum field theory (of point fields) to a supersymmetric quantum field theory of strings (*superstrings*), which appears to be the most promising path toward including gravity in the unified theory of the fundamental forces.

4. SUMMARY

The Standard Model in a sense plays a role in particle physics that the periodic table of the elements plays in chemistry. The rules of chemistry are established primarily by the electronic structure of atoms. It is pressing on and trying to understand the relative abundance of specific nuclear isotopes (atoms that differ only by the number of neutrons in the nucleus) that leads to the study of nuclear physics, rich in its own way. As research continues in an effort to understand the questions raised by the Standard Model, we can expect new insights into the properties of matter to emerge, whether it be in the form of massive new particles being produced at high-energy accelerators, unexpected effects discovered in precision experiments or searches for rare processes, or from astrophysical considerations and observations.

INTRODUCTION

"Property" has been defined as the exclusive right to possess, enjoy, and dispose of a thing (Nolan and Connolly, 1979). Thus, property in the legal sense is not so much the thing itself, but rather the aggregate of rights in the thing. Property can be real (land; and whatever is erected on, growing upon, or affixed to the land) or personal (money; goods; stocks and bonds). It can be tangible (a house or an automobile) or intangible (contract rights). Intellectual property—patents, trademarks, copyrights, and trade secrets—is personal property.

The owner of intellectual property has the same rights with respect to the property as the owner of a house has with respect to her property: subject to applicable laws, she may prevent another from using, selling, or otherwise exercising any form of control over the house. However, she may choose to rent the house for a period of time, give it away, or sell it. The owner of intellectual property, like the owner of a house, may assign all her rights in the property to another, or grant a license giving the right to use the property under specified conditions.

1. TYPES OF INTELLECTUAL PROPERTY: PATENTS, TRADEMARKS, COPYRIGHTS, AND TRADE SECRETS

The four generally recognized forms of intellectual property are listed in Table 1. Each protects different aspects of an idea and confers different rights upon its owner.

A patent is a grant from a government that conveys to an inventor the exclusive right to make, use, and sell the patented invention for a specified term, usually a term of years. United States law provides for three types of patents: utility patents, for novel, useful, and nonobvious machines, processes, compositions of matter, and articles of manufacture; plant patents, for new and distinct, asexually reproduced varieties of plant; and design patents, for novel and nonobvious ornamental designs for articles of manufacture.

A trademark or service mark is any word,

Table 1. Patent, trademark, copyright, and trade secret protection.

	Patent	Trade secret	Copyright	Trademark, service mark
Subject matter	Process, machine, article of manufacture, composition of matter	Something that gives its owner an advantage over competitors that do not know it	Literary works; musical and dramatic works; pantomimes and choreographic works; pictorial, graphic, and sculptural works; motion pictures and other audiovisual works; sound recordings	A word, name, symbol, device, or combination thereof that identifies the product or service
Requirements for protection	Novel, useful, nonobvious	Keep it secret	Original; fixed in a tangible medium of expression	Distinctive; used as a mark
What is protected?	The substance of the idea	The substance or the form of the idea, or both	The expression of the idea	The appearance of the mark
How is it protected?	Prevent others from making, using, or selling it	Prevent others from using it, if obtained unlawfully	Prevent others from making copies or derivative works; prevent others from distributing, performing, or displaying the copyrighted work	Prevent others from using later-registered, confusingly similar marks
When is it protected?	Upon the grant of a patent	Upon creation	Upon fixation in a tangible medium of expression	Upon first use
For how long is it protected?	17 years (utility patent) 17 years (plant patent) 14 years (design patent)	As long as it is a secret	Life of author plus 50 years; if a "work for hire," 100 years after creation or 75 years after publication	As long as it is used

name, symbol, device, or any combination thereof, adopted and used to identify goods or services. Trademarks are used to identify the source of goods; service marks are used to identify the source of services. The owner of a trademark or service mark can prevent others from using it or confusingly similar marks, but trademark or service-mark protection alone does not give him the right to prevent others from providing the same product or service *without* the mark.

Copyright law deals with information and ideas reduced to tangible form. Unlike patents, which protect the substance of the idea, copyrights protect the expression of the idea.

A trade secret is any confidential information that gives its owner an advantage over competitors that do not know it. The secret may be a machine or a chemical process, an abstract idea such as a concept for a new consumer product, or a compilation of data such as a list of customers. Matters of common knowledge, or matters of general knowledge in a particular industry, cannot be protected as trade secrets.

Patent law protects the substance of an idea in order to encourage investment in new technology and invention, whereas trademark law is concerned with the protection of symbols that identify products and services. Copyright law protects the original expression of an idea, and trade secret law protects confidential information. A single product may be the subject of more than one form of intellectual property. For example, the design of an automobile body may be copyrightable or protectible by a design patent; the engine, brakes, seat belts, and other parts may be protected by utility patents; some of the parts may be made by secret processes; and the model name may be a trademark (McCarthy, 1990).

2. PATENTS

The United States Patent and Trademark Office (PTO) issues three types of patents: utility patents, plant patents, and design patents.

Utility patents are issued for novel, useful, and nonobvious processes, machines, articles of manufacture, or compositions of matter. A "nonobvious" invention may be the result of inspiration, routine study and experimentation, or pure chance—there is no single test of obviousness. The owner of the patent need not exploit the invention himself. However, he can *prevent others* from making, using, or selling the invention during the term of the patent regardless of whether or not he, himself, does so.

Fundamental laws of nature ($F = ma$; $E = mc^2$) and mathematical algorithms ($\sin^2\theta + \cos^2\theta = 1$) are not patentable, under the rationale that the result would be a monopoly on a scientific truth. This prohibition includes computer programs that are pure algorithms, although such programs may be the subject of copyright protection. However, a process that uses a mathematical algorithm may be patentable if the process itself, not merely the algorithm, is new and useful. Other nonpatentable categories include naturally occurring substances, methods of doing business, forms, and abstract ideas.

Even though naturally occurring substances are not patentable in themselves, highly purified products and extracts thereof may be patentable. In addition, they may form part of a patentable product or be used in a patentable process. Drugs, vitamins, food additives, and other products that are derived from natural products are patentable; processes for making such products may also be patentable. Genetically engineered life forms are patentable if they meet the statutory requirements of novelty, usefulness, and nonobviousness (Miller and Davis, 1983).

Plant patents are issued for new and distinct asexually reproduced plants, including mutants, hybrids, cultivated sports, and newly found seedlings other than tuber-propagated plants or plants found in an uncultivated state (sexually reproduced plants are protectible under the Plant Variety Protection Act). To be patentable, a plant must be nonobvious as well as new and distinct, but it need not be useful. Patent protection applies only to the plants themselves, not to flowers, fruits, bulbs, or seeds *per se*.

Design patents protect new, original, and ornamental designs for articles of manufacture, that is, the *appearance* of a product rather than its function. A design patent can protect surface ornamentation applied to a product or the overall shape of the product, but not a shape that is dictated by the function of the product. For example, a simple bed frame with four legs and a platform for supporting a mattress would not be a proper subject for design patent protection, since a bed needs a mattress support in order to *be* a bed. However, the shape and size of the legs, the headboard, and the footboard may be patentable, since these aspects of the design are not dictated by their utilitarian purpose (the requirement that the frame be capable of supporting a mattress). All of these features could easily be changed or even eliminated without changing the *function* of the product.

An invention may be the subject of both design and utility patent protection: a utility patent, for its function, and a design patent, for its ornamental appearance. When there is a choice between trademark registration of a nonfunctional design and a design patent, trademark protection may be preferred because of the potentially unlimited term (i.e., as long as the mark is used by the trademark owner).

2.1 The Patent Application

In most countries, patents are obtained by filing an application with the appropriate government agency. In the United States, a patent is obtained by filing an application with the Commissioner of the Patent and Trademark Office (PTO). The PTO examines the application to determine whether the three tests for patentability—novelty, utility, and nonobviousness—are met. If the invention in question satisfies these tests and all relevant fees are paid, a patent issues in due course.

In the United States, a patent application must be filed by the inventor or on behalf of the inventor; in some countries, an application may be filed by the owner of the invention—for example, the inventor's employer. A patent application includes a verbal description of the invention (the "specification"), drawings (where needed to understand the invention), and "one or more claims particularly pointing out and distinctly claiming the subject matter which the applicant regards as his invention." The application process is governed by a set of regulations developed by the PTO (see U.S. Patent and Trademark Office, 1992). Some applicants prepare their own patent applications; however, most work with a registered patent attorney or agent.

2.1.1 The Specification, Claims, and Drawings The specification includes the title of the invention, cross-references to related applications (if any), a discussion of the background of the invention explaining the context of the problem that is being addressed, a brief summary of the invention, a description of the drawings, a detailed description of the invention, the claims, an abstract, and the drawings, and an oath or declaration signed by the inventor(s). When included in a patent application, drawings must show every element of the claims. "Drawings" may include not only line drawings, but graphs, flow charts, and photographs where appropriate. The invention should be described as clearly as possible so that it is understandable by the person "of ordinary skill in the art to which it pertains." Either the specification, the claims, or both jointly must constitute an "enabling disclosure," that is, provide an explanation that is sufficient for others to practice the invention.

The claims provide a concise, formal definition of the invention. The claims define the metes and bounds of the invention, much as a deed defines the boundaries of a parcel of land. A claim contains three parts: the preamble, the transition, and the body. The preamble generically defines the invention, for example, "An apparatus for doing X." The transition relates the preamble to the body, typically with the words "comprising" ("including parts A, B, and C, and maybe D, E, . . . "), "consisting" ("including only A, B, and C"), or "consisting essentially of" ("including A, B, and C, and nothing else that matters"). The body describes elements A, B, and C that make up apparatus X. Because the claims describe the invention in words, they are inherently less precise than the description that appears in a deed to real estate. Any given invention can be described by many different combinations of words, ranging from broad ("a chair, comprising means for supporting a person in a sitting position") to narrow ("a chair, consisting of a round wooden seat, and three equally spaced cylindrical legs attached to the bottom of the seat").

It is sometimes helpful to view an invention as a territory analogous to real estate. Thus, a new, useful, and nonobvious widget is located in a region unoccupied by previously known, prior-art widgets A, B, and C (Fig. 1). A broad claim for the new widget encompasses as much previously unclaimed territory as possible, up to (but not crossing) the boundaries of the territories occupied by A, B, and C (Fig. 2). A narrow claim covers much less territory (Fig. 3). A patent application for the new widget might contain a series of claims, ranging from the broadest possible, covering many different ways of practicing the invention, to the narrowest that will protect the actual manufactured product. A single, broad claim would protect the invention, but narrower claims could protect

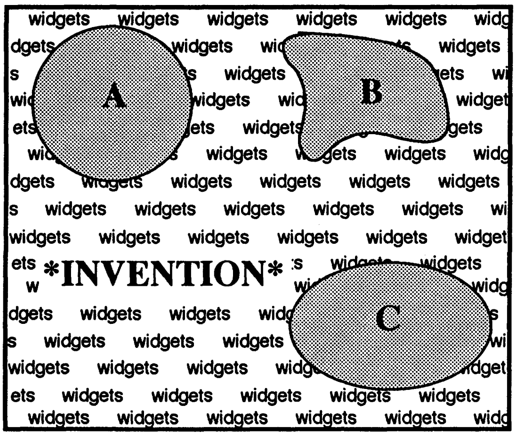

FIG. 1. The field of widgets. Previously known, prior-art widgets (A, B, C) and the invention occupy separate territories. The invention is outside the territories of widgets A, B, and C.

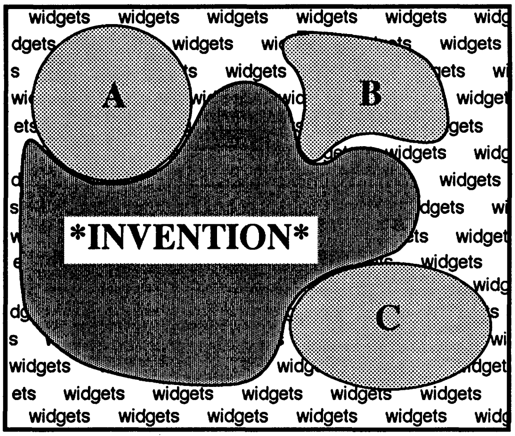

FIG. 2. Broad claim. In addition to the best mode, the claimed territory includes other modes of making the new widget, up to the boundaries of prior art widgets A, B, C.

the actual product if the broader claims are later found invalid.

2.1.2 Examination After a patent application is filed, the PTO conducts a search of prior United States patents, foreign patents, and publications (including the scientific literature) to determine whether the invention is novel and nonobvious. Frequently, an application is rejected and the applicant applies for reexamination. He may submit arguments in response to the examiner's stated reasons for rejection, with or without amending the application to address the reasons for the rejection. This process of examination, rejection, and amendment, known as "prosecution," may be repeated until eventual acceptance or a "final rejection" of the application. Procedures are available for appealing a rejection based on the substance of the application; rejections based on matters of form and procedure must be reviewed by petition to the Commissioner of Patents and Trademarks.

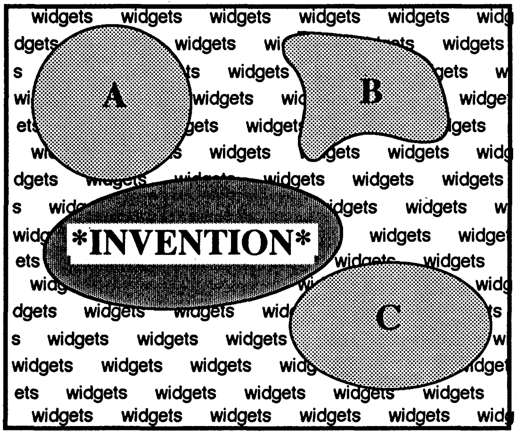

FIG. 3. Narrow claim. The claimed territory includes only the best mode of making the new widget; it does not reach to the boundaries of prior-art widgets A, B, C.

Occasionally an application claims the same invention as is claimed in another pending application or an issued patent. In that case, the PTO may conduct an interference proceeding to determine who is the first inventor and entitled to a U.S. patent on the invention.

If and when the PTO decides that a patent is to be granted, the applicant is sent a Notice of Allowance. If the issue fee is paid, the patent is granted. Thereafter, maintenance fees are due in the 4th, 8th, and 12th years to maintain the patent. If the fees are not paid, the rights lapse and the patented invention enters the public domain.

2.2 Enforcing Patent Rights

An issued patent is intellectual property having all the attributes of other forms of property. Most importantly, the owner has the right to exclude others from making, using, or selling the patented invention for a specified term (at present, 17 years in the United States; to compensate for delays in marketing caused by the regulatory process, the term may be extended for inventions that are subject to review by the Food and Drug Administration). At the end of that term, the invention enters the public domain.

2.2.1 Assignment vs License Although patent rights come into being only when a patent issues, patentable inventions may be treated as property even before issuance. For example, patent applications and notices of allowance may be viewed as property for income tax purposes. An inventor may assign rights to an invention at any time; in general, the further along the inventor has taken the application process, the more valuable his or her property rights in the invention.

The patentee may assign rights in a patent application or a patent, that is, sell all rights that he or she has in the patent. When he does so, he conveys the entire right to exclude others from making, using, or selling the invention. An assignment is equivalent to a sale of real estate. To pass legal title, an assignment must be in writing. While not essential, recording an assignment in the PTO establishes title against subsequent assignees who take from the same assignor.

A patentee may license the right to make, use, and sell the invention. A license may be exclusive or nonexclusive, for all or part of the claimed invention, for the remaining term of the patent or for a lesser term. It may be limited to a certain geographic area ("only in North Carolina and South Carolina"), provide for a fixed payment or royalties based on sales, or indeed any terms that suit the business needs of the parties.

2.2.2 Infringement Patent rights come into being only when the patent issues; others are free to make, use, and sell the invention before that time. The words "patent pending" may offer some psychological protection, since competitors do not know when the patent will issue, or what features of the product the inventor believes are patentable (U.S. patent applications are not available to the public), but afford no legal protection.

Anyone who makes, uses, or sells a patented invention during the term of the patent is a direct infringer. Anyone who actively encourages another to do so is an indirect infringer. Anyone who knowingly sells an item for which the only use is in connection with a patented invention is a contributory infringer.

Determining whether a patent has been infringed involves a thorough analysis of the claims and all the documents relating to the patent, including the original application, the prior art cited and discussed during prosecution of the application, written exchanges between the patent attorney or agent and the examiner, and the record of interference proceedings (if any). The test is whether the allegedly infringing product or process does the same work, in substantially the same way, and accomplishes substantially the same result as the patented invention.

Remedies for patent infringement include injunctions to prevent future infringement, damages to compensate the patent owner, attorneys' fees when appropriate, and costs. Damages may be trebled in the case of willful infringement (Miller and Davis, 1983).

2.3 International Filing

Patent laws vary from country to country, but certain features are common to all. Patents are granted for a specified period of time, and for novel and nonobvious inventions. In some countries, the invention must be "applicable to industry" (roughly equivalent to the "useful" requirement of U.S. law); some require that a patent, once granted, be exploited (i.e., the owner *must* make, use, or sell the invention in order to keep his rights in force).

Depending on the law of the country involved, applications may be filed by the actual inventor, in the name of the inventor, or by the assignee. Different types of patent protection may include patents of improvement, granted for an improvement of another patented invention; dependent patents, for inventions which cannot be practiced without infringing an earlier patent; and a type of patent known as an importation, revalidation, confirmation, or introduction patent, that gives the owner of a foreign patent local protection for a term limited to the unexpired term of the underlying patent. Inventor's certificates constitute recognition of inventorship and a grant of the rights and privileges provided by the national law; however, the exclusive rights are transferred to the State. Precautional patents provide that no patent relating to the subject matter of the patent will be granted without notice to the owner, who is given the opportunity to lodge objections within a stipulated term. Petty patents (for example, the German Gebrauchsmuster and the Japanese utility model) protect the shape or configuration of an object insofar as it serves some useful purpose (Baxter and Sinnott, 1992).

The United States is almost alone in having a "first to invent" patent system; most countries have a "first to file" system, where the first inventor to file a patent application is entitled to a patent, regardless of who actually invented first. In most countries, including the United States, the government has the right to make secret any patent application covering an invention which is of importance to the national defense. Once a secrecy order is given, the application proceeds through the normal examination stages, but is not published, nor is a patent granted, until the order is removed.

2.3.1 International Filing and the Patent Cooperation Treaty Before implementation of the Patent Cooperation Treaty (PCT) in 1978, patent applications were filed in each country where protection was desired. Although it does not provide for an "international patent" as such, the PCT has simplified the procedures that nationals or residents of member countries must follow when filing patent applications in other member countries. The PCT provides for centralized filing and searching of an international application (the "international stage"), followed by filing an application in each country where patent protection is desired (the "national stage"). Substantive examination of the application is carried out by each respective national patent office. The PCT preserves the right of priority of the Paris Union Convention and the Inter-American Convention, that is, an applicant who has filed in any member country may thereafter file a patent application for the same invention in any other member country within 12 months, with the effect that these later-filed applications will be treated as if they were filed on the first filing date.

In addition to the PCT route for obtaining international patent rights, the European Patent Convention (EPC) provides for centralized filing and examination leading to the grant of a "regional" patent, which matures into an individual patent for each of the member countries designated by the applicant. An applicant may, of course, file applications only in the desired countries.

Obtaining patent protection in African countries can be complicated by the variety of different patent systems involved. The African Intellectual Property Organization (OAPI) is responsible for implementing and applying common administrative procedures for the protection of industrial property (Baxter and Sinnott, 1992).

3. TRADEMARKS, SERVICE MARKS, CERTIFICATION MARKS, AND COLLECTIVE MARKS

Trademarks and service marks are believed to have originated with the medieval guilds, whose members affixed the mark of their guild to the goods they sold to identify it as the product of a particular craftsman or group of craftsmen. Like guild marks, modern trademarks serve two purposes: they identify the source of the goods, and they provide a marketing advantage for the owner of the mark (Miller and Davis, 1983).

A trademark is a symbol that allows a purchaser to identify goods or services that have been satisfactory in the past and those that have not. Service marks are identical to trademarks, except that they indicate the source of services, not goods. Trademarks and service marks encourage the production of quality products, and reduce the customer's costs of acquiring information about products and services. Most countries afford some form of trademark and service mark protection as an identification of the source and quality of goods and services (McCarthy, 1990). PTO trademark registration procedures are described in U.S. Patent and Trademark Office (1993).

A certification mark is any word, name, symbol, device, or combination thereof that is used to indicate that goods or services meet certain quality or regional origin standards. For example, the term "Roquefort" identifies a particular type of cheese that originates in a province of France; the "Underwriters Laboratories" and "Good Housekeeping" seals indicate that particular products meet the standards set by the owner of these marks. The mark must be one that buyers are likely to recognize as a symbol of guarantee or certification. Most titles or degrees such as Professor, Professional Engineer, MD, CPA, etc. are not used to certify the services performed by an individual, but rather to convey personal information about the individual performing those services.

Collective marks are used by members of a cooperative, an association, or a collective group or organization. While the organization itself neither sells goods nor performs services, its members do. Use of the mark allows members of the group to identify themselves as such (McCarthy, 1990).

3.1. Enforcement of Trademark Rights

Federal remedies for trademark infringement include injunctions, an accounting for profits, damages (including treble damages where appropriate), attorney's fees, and costs.

4. COPYRIGHTS

Copyright protection is available for original works of authorship. "Original" does not mean "new" or "novel"; it means only that the author did not copy the work from someone else. Consider *Romeo and Juliet*: an author could copyright a story about star-crossed lovers as long as it was not copied from Shakespeare.

4.1 Copyrightable Works

Copyrightable works include all original works of authorship "fixed in any tangible medium of expression, now known or later developed." Copyrightable works include literary works, musical and dramatic works, pantomimes and choreographic works, pictorial, graphic, and sculptural works, motion pictures and other audiovisual works, and sound recordings. Copyright protection does not extend to the idea embodied in the work, just the expression. Architectural plans, technical drawings, diagrams, and models are copyrightable (Nimmer and Nimmer, 1992).

Purely utilitarian works, including forms, contest rules, tests, and similar items are not protected by copyright. Since others are free to use the *idea* embodied in the work, there is very little protection available to the original author of, for example, an accounting system, a layout for a laboratory notebook or a method of doing business. Even though purely utilitarian designs are not copyrightable, fabric designs, jewelry designs, etc. may be copyrightable to the extent that the design is separable from its utilitarian aspect.

To the extent that a work is not "fixed," it is not copyrightable. For example, a dance routine is copyrightable only to the extent that it is filmed or written down in choreographic notation. Typefaces are usually considered to be noncopyrightable, perhaps because the subject matter—the alphabet—is limited and finite. However, the names of typefaces are subject to trademark protection.

Computer programs and databases are copyrightable to the extent that they incorporate the programmer's original expression of ideas, as distinguished from the ideas themselves (whether or not the idea is original). Microcode or firmware, which converts source code into object code, is itself copyrightable as a computer program (Nimmer and Nimmer, 1992). To the extent that a computer program lacks minimal originality or constitutes the only way of accomplishing a particular result, it is not copyrightable. Such a program embodies the idea itself rather than the expression of an idea.

4.2 Exclusive Rights

The owner of a copyright has the exclusive rights to do and to authorize the following: to reproduce the copyrighted work; to prepare derivative works based upon the work; to distribute copies or phonorecords of the work by sale, rental, lease, or lending; to perform the work publicly; and to display the work publicly. The right of reproduction allows the owner to exclude all others from reproducing the work in the form of a copy or phonorecord. Two exceptions allow radio, television, and cable television companies to record works temporarily for later transmission, and the owners of computer programs to make copies to utilize the program effectively.

The right of making derivative works allows the owner to prevent others from creating works based on the copyrighted work, such as translations, arrangements, dramatizations, films, abridgements, etc.

The right of distribution applies only to the first sale of a copy. Once a sale has occurred, the new owner can proceed to sell the work to another, but not copy the work.

4.2.1 Fair Use "Fair use" of a copyrighted work is not infringement. The concept of fair use balances the purpose and character of the use, the nature of the work, the amount and substantiality of the portion used, and the effect of the potential market for the work. One factor is whether the use is commercial in nature, or for nonprofit educational purposes. Educational purposes are traditionally a basis in favor of finding that the use is "fair." Under the current statute, limited photocopying by libraries and archives, and for classroom use, is allowed.

4.3 Ownership

A work may have a single author or joint authors. It may be a collection or a compilation, or a work for hire created for publication by another, either as an employee or an independent contractor. The ownership and duration of the copyright may hinge upon the classification of the work.

Ownership vests initially in the author or authors, or, in the case of a work made for hire, in the employer or other person for whom the work was prepared. Ownership may be transferred in whole or in part, may be bequeathed by will, or may pass as personal property. The individual rights may be transferred separately; thus, the right to make a movie and the right to translate a novel may be separated and transferred to different persons. Coauthors of copyrighted works are much as co-owners of other types of personal property; each has the right to use the property for his own purposes, but neither has the right to exclude the other from using it.

In the case of a single author, the copyright endures for the life of the author plus 50 years (70 years in most Berne Convention countries); for coauthors, for the life of the last surviving author plus 50 years. For works for hire, the term is 75 years from the date of first publication, or 100 years from the date of creation, whichever comes first.

The present U.S. copyright statute allows authors who have sold or otherwise transferred their rights to terminate the transfer by serving notice that they intend to do so during a five-year period beginning at the end of 35 years from the date of execution of the grant. This provision protects authors who have sold their works, but discover later in their careers that the works have become more valuable. If the author is dead, his or her spouse and children may exercise the right.

4.4 Notice, Registration, and Deposit

Under present U.S. law, an author has a copyright in a work as soon as it is fixed in a tangible medium of expression; a notice on published copies is no longer necessary to preserve the copyright. A notice of copyright consists of the symbol ©, the word "Copyright," or the abbreviation "Copr.," followed by the year of first publication and the name of the owner. For phonorecords, notice consists of the letter "P" in a circle, the year of first publication, and the name of the copyright owner.

Omission of notice does not invalidate the copyright, if

1. registration is obtained within five years, and
2. good faith efforts are made to affix notice to all remaining copies.

An innocent infringer incurs no liability for damages for infringing acts committed before receiving actual notice.

There is no need for examination: since others are free to create whatever they want as long as they do not copy the work, there is no need to insure that the work meets any particular standards. However, registration is a condition to filing a lawsuit for infringement.

Deposit of two copies of the work with the Library of Congress is required within three months of publication; however, deposit is not a condition of copyright protection. Registration requires deposit of at least one copy of a work. United States copyright registration procedures are described in U.S. Copyright Office (1984).

4.5 Enforcement of Copyrights

The owner of the copyright is entitled to sue for infringement. Available remedies include injunctions to prevent or restrain infringement, court-ordered licensing fees, and actual damages plus the defendant's profits. Costs and attorney's fees may also be recovered by the prevailing party. The defendant may establish his expenses to reduce the gross profit to a net amount. The plaintiff may choose to ask for statutory damages (a minimum of $250 and a maximum of $10,000) instead of actual damages, and a court may award as much as $50,000 statutory damages for willful infringement.

5. TRADE SECRETS

A trade secret has been described as any commercially valuable information that gives its owner an advantage over competitors that do not know it. A trade secret may be a machine or a process, an abstract idea such as a concept for a new product, or a compilation of data such as a list of customers. Trade secrets are confidential; however, not all confidential business information is a trade secret. Matters of common knowledge, or matters of general knowledge in a particular industry or trade, cannot be protected as trade secrets (McManis, 1988).

In some cases, an inventor may have the option of obtaining patent protection for an invention or relying on trade secret protection. A patent protects the invention for a period of time after it is disclosed; however, trade secret law protects it for as long as it remains secret.

Courts protect trade secrets under several theories. Some consider trade secrets to be a form of intellectual property, analogous to patents, copyrights, and trademarks. Others emphasize the breach of a confidential relationship, impropriety in ascertaining a secret, and use of a trade secret or idea known to have been improperly disclosed by another. For example, industrial espionage and bribery of a competitor's employees are an improper means of obtaining information, whereas "reverse engineering," discovery by one's own independent efforts or by inspection of a publicly distributed product, is usually considered to be proper.

6. APPENDIX

Professional societies involved in intellectual property law and related areas include the Section of Patent, Trademark and Copyright Law of the American Bar Association (ABA), the American Intellectual Property Law Association (AIPLA), the International Trademark Association (INTA, formerly the United States Trademark Association), and the World Intellectual Property Organization (WIPO). These groups sponsor numerous meetings, workshops, and courses throughout the year. Courses on various aspects of intellectual property are also offered by the Patent Resources Institute, Inc. (Charlottesville, VA), the Practicing Law Institute (New York, NY), and several universities.

Treatises, introductory texts, and practice handbooks dealing with intellectual property law, both U.S. and international, are available from Matthew Bender & Co., Inc. (New York, NY), Clark, Boardman, Callaghan (Deerfield, IL), and West Publishing Co. (St. Paul, MN), among others. The *Copyright Law Journal* and the *Trademark Reporter* deal with current developments in the areas of copyright and trademark law, respectively. The *United States Patents Quarterly* and the *Patent, Trademark & Copyright Journal,* both published by the Bureau of National Affairs, Inc. (Washington, DC), provide comprehensive coverage of U.S. court cases. Texts of newly issued patents are published in the *Official Gazette.* Information on court decisions, texts of recently issued patents, periodicals, news reports, etc. is also available on computer databases, including LEXIS (Mead Data Central) and WESTLAW (West Publishing Co.).

United States statutes dealing with intellectual property are found in Titles 15 (commerce and trade), 17 (copyright), and 35 (patents) of the United States Code (U.S.C.). Applicable regulations may be found in the Code of Federal Regulations (C.F.R.). Both are available online (LEXIS, WESTLAW). Trademarks, trade secrets, and unfair trade practices may also be the subject of state law.

The procedural aspects of the U.S. patent application process, federal trademark registration, and copyright registration are detailed in the *Manual of Patent Examining Procedure* (*MPEP*), *Trademark Manual of Examining Procedure* (*TMEP*), and *Compendium of Copyright Office Practices,* available from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402.

GLOSSARY

Assignment: A conveyance of all rights in property.

Certification Mark: A word, name, symbol, device, or any combination thereof, used to indicate that goods or services meet certain standards of quality or regional origin. The mark must be such that buyers are likely to recognize it as a symbol of guarantee or certification.

Claim: A numbered, single-sentence paragraph that provides a concise, formal definition of an invention; part of a patent application.

Collective Mark: A word, name, symbol, or device used by members of a cooperative, an association, a collective group, or an organization to identify themselves as such.

Copyright: A statutory right granted to the author of a literary or artistic work.

Design Patent: A patent granted for a new ornamental design.

EPO: European Patent Convention.

Infringement: A violation of the rights secured by a patent, trademark, or copyright; unauthorized use of the subject matter of a patent, trademark, or copyright.

Injunction: An equitable remedy granted by a court, forbidding a party to do some act, or restraining him in continuing to perform the act.

Intellectual Property: Includes patents, trademarks, copyrights, and trade secrets.

License: A conveyance of the right to make, use, or sell a patented article for a limited period or in a limited territory.

Notice of Allowance: A notice issued by the PTO, informing the applicant that a patent is to be granted.

OAPI: African Intellectual Property Organization.

Patent: A grant from a government that conveys to the patentee the exclusive right to make, use, and sell the invention for a specified term.

PCT: Patent Cooperation Treaty.

Plant Patent: A patent granted for a new, distinct, asexually reproduced variety of plant.

Property: The exclusive right to possess, enjoy, and dispose of a thing.

PTO: Patent and Trademark Office.

Service Mark: A word, name, symbol, device, or any combination thereof, adopted and used to identify services.

Specification: A detailed verbal description of an invention; part of a patent application.

Trade Secret: Any commercially valuable information that gives its owner an advantage over competitors that do not know it.

Trademark: A word, name, symbol, device, or any combination thereof, adopted and used to identify goods.

Utility Patent: A patent granted for a machine, process, composition of matter, or article of manufacture.

INTRODUCTION

The word "petroleum" is derived from the Latin—"petra" meaning rock and "oleum" meaning oil, "rock oil." Crude oil, natural gas, retrograde gas condensate, and volatile oils are all varieties of petroleum and are referred to as petroleum.

The petroleum industry as we know it today got its start in the mid nineteenth century. The very rapid growth of the industry came about with the development of the in-

digital Encyclopedia of Applied Physics

ternal combustion engine in the beginning of the twentieth century. However, archaeological evidence indicates that ancient man made use of oil and gas seeps. Asphalt, a weathered oil, was used to cement stones, to waterproof cisterns, and to caulk boats. Chinese references over 3000 years old indicate that the Chinese used petroleum in their lamps. The Chinese while looking for brine to make salt developed a drilling technique similar to modern cable tool rigs. The ancient Chinese also transported natural gas through bamboo tubing for the purposes of heating and light.

In more modern times, the exploration for and the production of petroleum were accelerated by the demand for low-cost energy necessary to satisfy our consumer-oriented society. Not just gasoline, but heating oils, diesel fuels, lubricants, and the raw materials for petrochemical manufacture are produced from petroleum. Fuel oil and natural gas have replaced coal for home heating purposes.

The various categories of petroleum can best be characterized by their temperature–pressure phase diagrams along with the temperature at which the fluid exists in the reservoir. This identifies the petroleum as being a dry natural gas, a wet natural gas, a retrograde gas condensate, a volatile oil, or a black oil.

Petroleum occurs in underground reservoirs consisting of porous and permeable rock into which the petroleum migrated from a source bed. In order to produce this petroleum, wells are drilled to provide a conduit between the reservoir and the surface. The wells serve as a pressure sink into which the petroleum flows. The initial or primary recovery of the petroleum is due to the energy initially present in the reservoir fluids. Gas in solution in the petroleum or hydrodynamic pressure provides this energy. Once the primary energy has been dissipated, a large fraction of oil may still remain in the reservoir as a result of the capillary nature of the reservoir rock. At this stage of production, water or gas may be injected into the reservoir to provide the energy to displace additional oil. This is an immiscible displacement and is referred to as secondary recovery. Improved or enhanced oil recovery results from the injection of special gases at miscibility pressures or of liquid chemicals, or the use of thermal energy. The injected fluids interact with the rock–oil system to create conditions favorable to oil recovery.

When the natural energy of the petroleum in the reservoir is no longer adequate to cause the petroleum to flow to the surface, artificial means are used to lift the petroleum to the surface. This can be done in a number of different ways, depending on the circumstance. Sucker-rod pumps and gas lift are the most common methods used.

Once the petroleum reaches the surface, it is processed before entering a pipeline. The purpose of surface processing of the petroleum is to provide the purchaser with a water-free, hydrocarbon-liquid–free natural gas or, in the case of a condensate or crude oil, to provide a water-free, emulsion-free, and solid-free liquid ready for processing at a refinery or gasoline plant.

The lead time required from project inception to the first production of petroleum may be anywhere from 5 to 10 years and require billions of U.S. dollars of investment. Reservoirs with large initial petroleum fluids in place are needed. The ultimate economics will depend on the rate of petroleum fluids recovery and the recovery efficiency of the petroleum from the reservoir.

1. DEFINITION OF PETROLEUM

Petroleum can be divided into five classifications: dry natural gas, wet natural gas, retrograde gas condensate, volatile oils, and black oils. Although this classification appears to be quite specific, there is a continuity of the phase state between that of a dry gas and a black oil. A dry natural gas consists primarily of methane with perhaps traces of ethane, propane, and heavier components. A wet natural gas also consists primarily of methane; however, it contains a higher percentage of ethane, propane, and butane with traces of pentane through hexane and heavier components. At surface conditions of temperature and pressure, a dry gas remains in a single phase, whereas a wet gas produces condensate (thus wet) consisting of propane through hexane and heavier components. In the reservoir, both dry and wet gases remain in a single gaseous phase.

Retrograde gas condensates most often are found as a single gas phase in the reservoir.

As the reservoir fluid is produced and the pressure in the reservoir drops below its retrograde dew point, liquid condensate precipitates within the pore space of the reservoir rock. Unless the condensate is very rich in intermediate hydrocarbons (i.e., ethane through hexanes), the liquid saturation seldom reaches the critical value where the condensate starts to flow.

Volatile oils are liquids in the reservoir. However, the reservoir temperature is very close to the critical temperature of the volatile oil, and once the reservoir pressure drops below the bubble-point pressure a large gas saturation forms very rapidly in the reservoir. Without doing a phase-behavior study, it is difficult in the field to distinguish a rich retrograde gas condensate from a volatile oil.

Black oils are found as liquid in the reservoir. The composition of the black oil is high in the C_{7+} fraction. The C_{7+} fraction characterizes the black oil. Black oils or crude oils are further broken down as being paraffinic, aromatic, naphthenic, and asphaltic. This means that in the case of a paraffinic crude the C_{7+} fraction consists primarily of paraffinic hydrocarbons. Penn Grade crudes are paraffinic. High–molecular-weight paraffinic hydrocarbons make excellent lubricating-oil stock. A barrel of Penn Grade crude oil may consist of as much as 60% lubricating-oil stock compared with an asphaltic crude, which may have as low as 10% lubricating-oil stock. If the crude is classified as aromatic, naphthenic, or asphaltic, it means that the C_{7+} fraction contains a predominance of aromatic, naphthenic, or asphaltic compounds.

Figure 1 is a plot of the C_{7+} concentration in petroleum against the initial gas/oil ratio (GOR) of the petroleum reservoir fluid (McCain, 1993). The gas/oil ratio is the number of standard cubic meters of gas that is liberated from a reservoir fluid per cubic meter of liquid or stock-tank oil at the surface. A GOR of infinity would be a dry gas whereas a GOR of less than 360 m^3/m^3 would be a black oil. As can be seen from the plot, there is a continuity between the gaseous and liquid states of matter. As the GOR increases, we approach volatile oil and retrograde gas condensates. In fact, these two classifications of reservoir fluid overlap on the plot. As the reservoir fluid or well-stream effluent becomes leaner in the C_{7+} fraction, the GOR increases. Wet gas can have a GOR as low as 9000 m^3/m^3 of oil. As in the case of volatile oils and retrograde gas condensates, retrograde gas condensate and wet gases can overlap. In summary, black oils are repre-

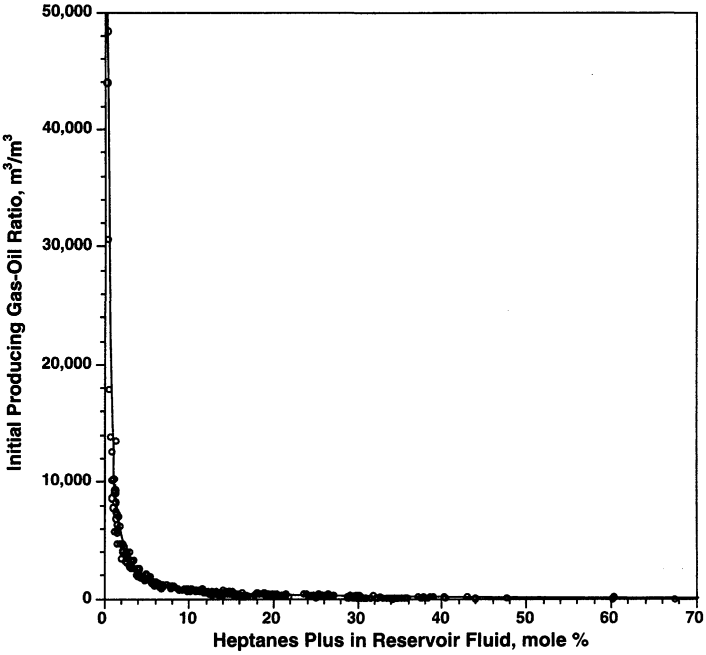

FIG. 1. Relationship between initial producing gas/oil ratio and heptanes-plus fraction in reservoir fluid (McCain, 1993).

Table 1. Classification of petroleum.

Classification	GOR (m^3/m^3)	CH_4 (%)	C_{7+} (%)
Dry gas	Infinity	>90	...
Wet gas	>9000	80–95	Trace
Retrograde gas condensates	530–9000	60–90	<12.5
Volatile oil	360–590	50–70	12.5–20
Black oil	<360	<45	>20

sented in the lower right of the figure and dry gases in the upper left. All other fluids are found in between with no sharp demarcation between these characterizations.

Table 1 is another way of illustrating this point. It shows the composition of petroleum under this classification system. Petroleum may also contain small amounts of nonhydrocarbons such as nitrogen, carbon dioxide, and hydrogen sulfide. Generally speaking, the concentration of nitrogen will range from 0 to 15 mole %, carbon dioxide from 0 to 4 mole %, and hydrogen sulfide from 0 to 6 mole % in petroleum. However, there are always exceptions. There are gas reservoirs that yield very high concentrations of both carbon dioxide and hydrogen sulfide. Table 2 illustrates some typical compositions of reservoir fluids.

2. PHYSICAL PROPERTIES OF PETROLEUM

The physical properties of petroleum reservoir fluids determine the calculation procedures that are used to predict the petroleum in place, the production performance, and the way the reservoir fluids are processed at the surface.

The five categories of petroleum reservoir fluids can best be described by their phase diagrams. The phase state of a reservoir fluid along with a knowledge of the rock and fluid properties is necessary to make reservoir performance calculations. The phase diagrams for these reservoir fluids are plots of pressure vs temperature that show the condition under which the fluid will exist as a gas, liquid, or both. Similarly, as shown in Fig. 1, phase diagrams also show a continuum between a dry gas and a black oil. The range of critical temperatures from that for a dry gas to that of a black oil can vary from

Table 2. Typical composition of reservoir fluids.

as low as −82.6 °C, the critical temperature of methane, to well over +600 °C for a black oil. The reservoir temperatures will range from as low as 32 °C to as high as 170 °C. Thus, in the case of a dry natural gas the reservoir temperature is considerably above the critical temperature of the natural gas, and in the case of a black oil the reservoir temperature is considerably below the critical temperatures of the black oil. In the case of a retrograde gas condensate, the reservoir temperature lies between the critical temperature and the cricondentherm or point of maximum temperature of the phase diagram.

The phase diagrams of natural gas will cover a much smaller temperature range because it consists of only very low–molecular-weight paraffin hydrocarbons when compared with a black oil that has in the mixture very large nonvolatile molecules. In going from a dry gas through wet gas, retrograde gas condensate, and volatile oil to black oil, the temperature range of the phase diagram increases dramatically.

2.1 Gas

2.1.1 Dry Gases Figure 2 shows the phase diagram of a dry gas. Since dry gas is primarily methane, the phase envelope is very small when compared with that of a black oil. The critical temperature of a dry gas will be in the range −82.6 to −20 °C, which is well below the reservoir temperature, line 1–2. The reservoir temperature is also well above the maximum temperature of the phase envelope. The fluid is a single-phase dry gas in the reservoir. Surface conditions are represented by point 3, also a single gaseous phase. As the reservoir is depleted, the pressure in the reservoir will drop from point 1 to point 2, the abandonment pressure.

The viscosity of the gas in the reservoir is low and its ability to flow will be primarily limited by the permeability of the rock matrix. Typically, the viscosity of dry gases at reservoir conditions will range between (0.013 and 0.030) × 10^{-3} Pa s.

2.1.2 Wet Gases The phase diagram of a wet gas is shown in Fig. 3. Here the reservoir temperature line and the pressure depletion path 1–2 in the reservoir lie much closer to the two-phase region of the phase diagram but still do not enter the two-phase region. The reservoir fluid remains in a single phase in the reservoir throughout the life of the field.

However, the surface condition of temperature and pressure lies within the two-phase region, point 3, and a low–specific-gravity liquid will condense at the surface. The viscosity of the wet gas at reservoir conditions of temperature and pressure will be in the range of (0.013 to 0.040) × 10^{-3} Pa s. The

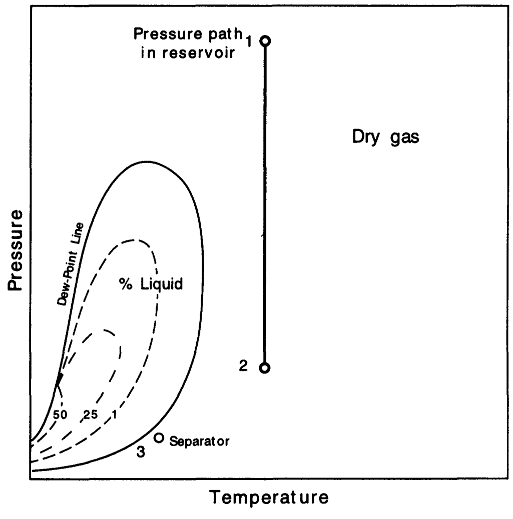

FIG. 2. Pressure–temperature diagram for dry gas reservoir.

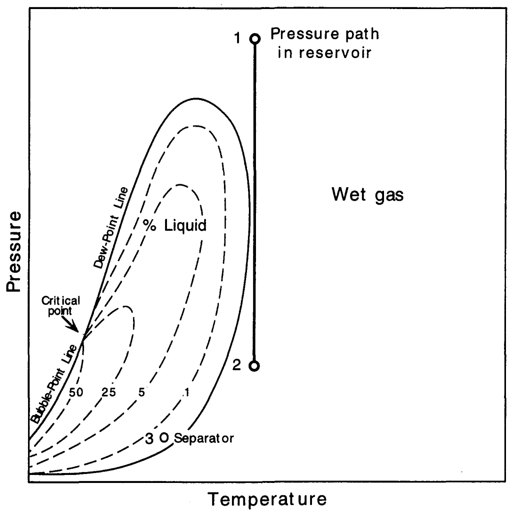

FIG. 3. Pressure–temperature diagram for wet gas reservoir.

stock-tank liquid or condensate produced from a wet gas is usually light yellow to water white and has a very low specific gravity in the range of 0.7389 to 0.8251. The specific gravity is calculated by comparing the density of the condensate with the density of water when both are at 15.56 °C (15.56/15.56 °C). During the 1920s and early 1930s, the condensate from a wet gas was used as gasoline to power oil-field vehicles.

2.1.3 Retrograde Gas Condensates In the case of a retrograde gas condensate, the reservoir temperature lies between the critical point and the point of maximum temperature, Fig. 4. At the original reservoir pressure, the gas exists as a single phase in the reservoir, point 1. As the fluid is produced, the reservoir pressure drops until the retrograde dew-point pressure is reached, point 2. At this point, liquid starts to condense in the reservoir. Generally, the liquid does not reach a saturation at which it flows. Upon further reduction in pressure, some of the liquid begins to revaporize; however, most of it is lost in the reservoir unless some enhanced recovery process is employed.

Point 3 represents the reservoir abandonment pressure. Point 4 represents the surface conditions of the separator. Retrograde gas condensate reservoirs generally range from 20 000 to 55 000 kPa and from 93 °C to as high as 170 °C. Fluid viscosity at reservoir conditions is in the range of (0.010 to 0.060) × 10^{-3} Pa s. The specific gravity of the stock-tank condensate is in the same range as the condensate of a wet gas, i.e., 0.7389 to 0.8251 at 15.56/15.56 °C. However, the condensate can range in color from water white through lightly colored to brown, orange, or green.

2.2. Oils

2.2.1 Volatile Oils In the case of a volatile oil, the reservoir temperature lies just below the critical temperature of the volatile oil. The critical temperature of a volatile oil is considerably lower than that of a black oil. When the reservoir pressure drops below the bubble-point pressure of the oil, a large gas saturation immediately forms in the reservoir. A pressure drop of (5–15) × 10^2 kPa may result in as much as a 50% gas saturation in the reservoir. The gas released in the reservoir is a retrograde gas and, consequently, a large part of the stock-tank liquid is produced from this retrograde gas. The stock-tank liquid has a specific gravity that is less than 0.8251 at 15.56/15.56 °C. The stock-tank liquid is usually orange to brown in color.

Figure 5 is the phase diagram for a volatile oil. Line 1–2–3 is at the reservoir temperature. Since the temperature is below the critical temperature, a volatile oil exists as a liquid in the reservoir, point 1. Point 2 is the

bubble point of the oil at reservoir temperature. Point 3 represents the reservoir abandonment pressure. Point 4 represents the separator conditions at the surface. At point 1, the reservoir fluid is undersaturated, that is, no gas evolves as the pressure drops until the bubble-point pressure is reached.

2.2.2 Black Oils The phase diagram of a black oil is shown in Fig. 6. The path 1–2–3 at constant reservoir temperature represents the reduction in pressure that occurs during the production of the reservoir. Point 4 represents the surface separator conditions. When the pressure is above point 2, the reservoir fluid is undersaturated, that is, no gas comes out of the solution as the pressure drops. At the bubble-point pressure, point 2, gas will start to come out of the solution and form a free gas phase in the reservoir. As the pressure drops, more gas comes out of the solution and flows to the surface separator with the oil. The specific gravity of the stock-tank oil is usually greater than 0.8251 at 15.56/15.56 °C. Stock-tank oil viscosity can range from 1.0×10^{-3} Pa s to very heavy viscous crudes having viscosities of many Pa s. The heavier crudes are usually void of the intermediate light hydrocarbons C_4 through C_{15}. The color of the stock-tank liquids usually range from light to dark brown. Pennsylvania Grade crudes, in which the heavy ends are highly paraffinic, are dark fluorescent green in color.

3. GEOLOGY AND OCCURRENCE OF PETROLEUM

Petroleum occurs in sediments deposited over geologic time. It is generally thought that petroleum originated in source beds consisting of mud and silt and was formed through the decomposition of plant and animal life. As the sediments were buried, the temperature and pressure increased, causing the organic matter to decompose thermally to form petroleum. The petroleum is expelled from the source rocks and migrates into layers of porous and permeable reservoir sands and carbonates. These sedimentary reservoir rocks are capped by an impermeable bed that "traps" the hydrocarbon and prevents further migration of the petroleum. The portion of the trap in which the petroleum occurs is called a petroleum reservoir.

3.1. Reservoir Traps

Reservoirs are generally classified according to the geological features under which they are formed. Cross sections of the different types of reservoir traps are presented in Fig. 7. Generally, traps are classified as structural, stratigraphic, or a combination structural/stratigraphic trap. In Fig. 7, example combination traps are referred to as stratistructural traps. Structural traps are a result of the deformation of the earth. Stratigraphic traps are caused by a change in the permeability and porosity in the reservoir bed.

3.2 Reservoir Rock Characteristics

Generally speaking, reservoir rocks are either sandstones or limestones; however, some reservoirs have been discovered in fractured shale. A knowledge of a reservoir's physical characteristics is of utmost importance in the management of the reservoir for maximum recovery of the petroleum it holds.

3.2.1 Porosity Porosity is the fraction of the total bulk volume of the rock not occupied by rock. Total porosity includes all the pore space in the rock, whereas effective porosity includes only the void space that is interconnected and through which fluids can flow. The pore space in a reservoir is filled with water and petroleum, that is oil and gas. Porosity is measured as a percentage of total

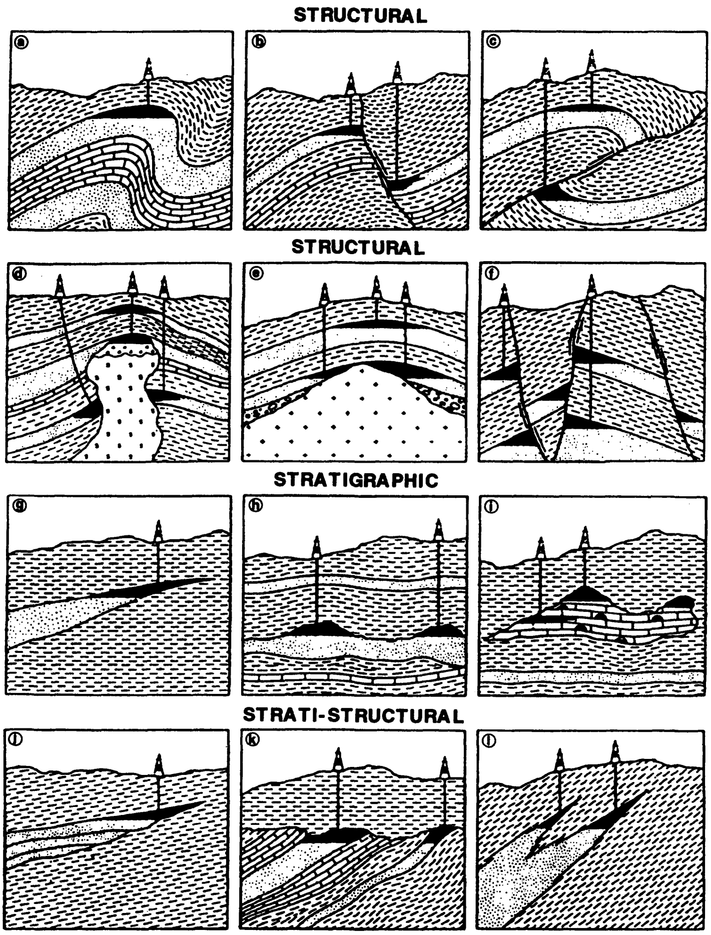

FIG. 7. Reservoir traps (courtesy Colorado School of Mines).

rock bulk volume, e.g., 20%–30% porosity. Porosity can vary from a few percent to as high as 35%–40%. Fluid content (saturation) of the pore space is measured as a percentage of the total pore space, e.g., 60% oil saturation and 40% water saturation.

3.2.2 Permeability Permeability is a measure of the ease with which a fluid can flow through the interconnected pore space of a rock. The unit of permeability is the square micrometer (μm^2), or 10^{-12} m^2. A permeability of 1 μm^2 will permit the flow of 1 m^3/s of fluid of 1 Pa s viscosity through an area of 1 m^2 under a pressure gradient of 10^{12} Pa/m. Or, stated another way, a permeability of 1 m^2 will permit the flow of 1 m^3/s of 1 Pa s viscosity through an area of 1 m^2 under a pressure gradient of 1 Pa/m.

Usually, there is more than one fluid flowing through the reservoir rock. Under these circumstances, we consider the relative permeability of the fluid, that is, the ease with which one fluid (of the two or more fluids present in the rock) will flow through the connecting pore spaces in the presence of the other fluids as compared with the ease with which the fluid will flow if it alone were present in the rock. Relative permeability then is the ratio of the permeability of a fluid flowing in the presence of other fluids to the permeability of the fluid if it alone were present in the rock.

3.2.3 Factors Influencing Rock Properties Sedimentary rocks are classified as sandstones, shales, limestones, and dolomites. The size and shape of the sedimentary materials as they were laid down, the presence of clay, the types of clay, and the presence of other minerals and the manner in which the sedimentary materials are cemented will affect the porosity and permeability of the reservoir rock.

4. DRILLING AND COMPLETION OPERATIONS

Drilling operations are conducted to provide a conduit between the reservoir rock and the surface for the production of oil and gas. Rotary drilling rigs are commonly used to drill wells. Drilling mud is pumped down the drill pipe and is returned to the surface in the annular space between the drill string and the earth, or a string of pipe called casing. The drilling mud must be capable of lifting the cuttings to the surface and controlling subsurface pressures encountered during the drilling process while minimizing damage to the reservoir rock.

The team responsible for the well gathers information during the drilling process to help evaluate the economic merit of the well. Drill cuttings are examined and identified. The drill cuttings may indicate zones of possible hydrocarbon accumulation. These zones are often tested with a tool run in the well on the drill string. This test, called a drill-stem test, gives an estimate of formation pressures, produced fluids (oil, gas, water), and potential flow rates for the well. Sometimes a larger sample of the formation is needed to estimate formation properties such as porosity and permeability. In these cases, a core is cut. A core is a solid, 7- to 10-cm-diameter cylindrical piece of the formation that may be up to 10 m or more in length. The core helps in characterizing the formation. The reservoir characterization helps the development team with reservoir management decisions such as well placement, completion methods, and secondary and enhanced recovery methods.

Well logs are another source of information for the evaluation team. Tools are run into a well on a cable to evaluate a section of the well bore before casing is set opposite this section. Logs run in this manner are called conventional open-hole wireline logs. These logs are run to estimate the porosity of the rock and the water saturation. The estimate of the water saturation permits an estimate of the hydrocarbon content of the formation. The porosity and water saturation of the rock give the evaluation team an estimate of the amount of hydrocarbon that may be present in the formation.

In some cases, it is desirable to have real-time porosity and saturation data rather than waiting for conventional wireline open-hole logs. In these cases, logging tools are run behind the drill bit as the well is drilled. These tools are called MWD (measurement while drilling) tools. When MWD tools are run, conventional wireline logs are still run.

The decision to abandon the well as a dry hole or to complete the well as a producer is made after all the available data are examined: the well logs, cores, and drill-stem tests. Petroleum must be present in an economic quantity as well as producible at economic rates before the decision is made to complete the well.

4.1 Directional and Horizontal Wells

Wells should be placed in the reservoir to maximize the economic recovery of oil and gas. In deep water, offshore fields can often only be economically developed from a single platform with multiple wells because of high platform costs. For this reason, offshore fields require the use of *directional* (or deviated) wells to develop the field efficiently and economically. In this case, the wells are drilled from an offshore structure and "steered" to the desired bottom-hole location selected by the development team of geologists, geophysicists, and petroleum engineers.

Another example of where directional wells are encountered is the Long Beach Unit near Los Angeles, California. Four man-made islands offshore act as "platforms" where over 1200 directional wells have been drilled to develop the Wilmington Field. A portion of the field lies beneath the city of Long Beach, California. The drilling rigs are soundproof and look like apartment buildings. Care is taken to survey each well bore so that the many well-bore paths do not accidently intersect.

Directional wells are drilled onshore whenever the bottom-hole objective cannot be reached by a vertical well.

When the well bore that penetrates the reservoir is horizontal, the well is referred to as a *horizontal* well. Horizontal wells are becoming an important method to improve the recovery from some reservoirs. Advances in reservoir characterization have identified reservoirs where horizontal placement of the well bore will enhance the drainage geometry and the ultimate recovery of oil from the well. Reservoirs having thin beds, vertical fracture systems, and compartmentalization are good candidates for horizontal drilling. Horizontal wells are more expensive to drill than a conventional or vertical well. Accordingly, the productivity from a horizontal well must be greater than a conventional well to justify the incremental cost of drilling. The incremental costs to drill a horizontal well may be as much as 30%–100% over the cost to drill a conventional vertical well. However, when the technology is appropriate, the productivity may be 2–6 times greater than a conventional completion (Fisher, 1988).

4.2 Casing and Wellhead Design

Pipe is placed in a well to provide a safe passage for the produced fluids and to protect formations (fresh water, for example) from contamination by the produced fluid; see Fig. 8. This pipe is referred to as casing and is cemented in the well for these reasons. Conductor pipe, set at 15–30 m, is cemented in the well, and provides a base for the surface wellhead equipment and an annular space for the drilling mud to be circulated to the surface.

After the conductor pipe is set, surface casing is set approximately 300 m below ground level to protect fresh-water sands. The surface casing is usually cemented completely from the surface to the bottom of the surface casing.

In deep wells, several strings of casing may be cemented in the well. The final casing that is set is referred to as the production casing or string. This casing is not set until after well logs are run and the decision is made to complete and produce the well. The production casing string and any intermediate strings may not be cemented all the way to the surface. Production casing is set to control well pressures and to protect formations during production. Figure 8 shows a production liner that has been set instead of running production casing from the surface to the producing formation. This is done to reduce costs.

When the reservoir fluid reaches the surface, it flows through the wellhead; see Fig. 9. Wellheads can vary greatly in design depending on the fluid pressure. The first element of a wellhead is the casing head, which helps support the weight of the casing or outer pipe. If there is more than one casing string, several casing heads may be used. Next is the tubing head, which is used to support the tubing string. Next comes the Christmas Tree; see Fig. 9. The Christmas Tree controls the

flow of gas and oil from the well and is installed on top of the tubing head. The Christmas Tree design can vary depending on the fluid pressure. Pressure gauges are installed on the Christmas Tree. Valves on the "Tree" control the flow from the well. A choke is also part of the Christmas Tree. The choke is an orifice in the line that controls the rate of flow of the well fluid. A choke can be fixed or adjustable.

4.3 Completion Types

Once the decision is made to complete the well, the type of completion must be considered. Completion refers to the manner in which the well bore opposite the producing formation is designed or equipped. Some of the advantages of the various completion methods will be presented.

Perforated production casing is a common method of completing a well in areas where the producing formation is consolidated. Casing is set through the production interval and perforated with a perforating gun; see Fig. 10. The holes in the pipe can be made with bullets or with a shaped charge. The jet from a shaped charge has a velocity of approximately 9500 m/s and can penetrate through the pipe and cement and more than a meter into the formation. The holes are approximately 1.3 cm in diameter and provide the conduit between the formation and the well bore. Production tubing is run from the surface to the perforated interval. The production tubing is anchored in the well by a tool called a packer. The packer also isolates the annulus between the production tubing and the production casing; see Fig. 10.

In some cases, the last string of casing does not run from the surface to the bottom of the well. This last casing string is referred to as a *production liner*; see Fig. 8. A production liner is a piece of pipe that is hung from the next to last casing string. The liner is cemented in the well and perforated. The pri-

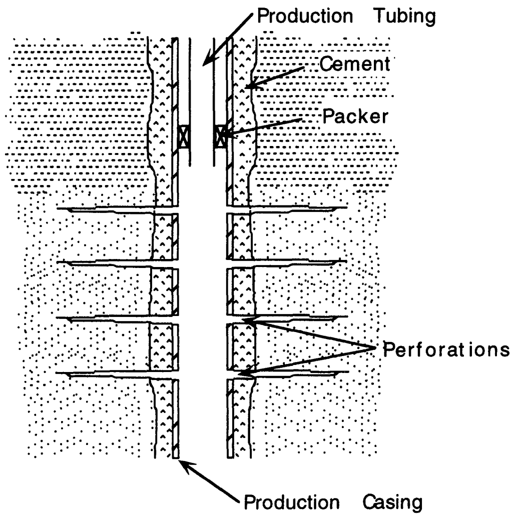

FIG. 10. Perforated casing completion.

mary advantage is a savings in the cost of casing since the last string does not need to be run from the surface to the bottom of the well. The disadvantage is a possible leak at the liner hanger.

In areas where the producing formation is unconsolidated and sand production is a problem, a *gravel-pack* completion is used to hold the sand in place and minimize the resistance to reservoir flow. In a gravel-pack completion, gravel is placed against the formation to hold the formation sand in place followed by a screen to keep the gravel in place. This method of completion is common in the Gulf Coast. New methods of completing unconsolidated formations are being tested today (1995).

A final completion method is an *open-hole* completion where the last string of casing stops above the productive zone. The well is drilled out below the casing into the zone of interest. In an open-hole completion, the restrictions to flow into the well bore are minimal compared with a perforated completion. This type of completion will only work in consolidated formations where the formation will not collapse.

4.4 Improving Well Performance

The value of the oil and gas is a function of how many barrels can be produced and the rate of production (deliverability). There are many formations where economic flow rates are not possible because the natural formation permeability is extremely low. *Hydraulic* fracturing is used to improve the formation flow rates. In these cases, a fluid is pumped down the well at high pressures and rates until the formation fractures. Once the formation has begun to fracture, a proppant (e.g., sand or bauxite beads) is pumped into the fractures. The pressure is then decreased, permitting the fractures to close on the proppant. The proppant-filled fractures provide a high-permeability conduit to the well bore for the produced fluids.

Acidizing a well may also improve the flow performance. Acidizing is the process of pumping an acid into the formation to improve the flow rate of the fluids from the formation into the well bore. Acidizing can be used to remove fine silica materials deposited during the drilling process. This fine silica material if *not* removed will restrict the flow of reservoir fluids. An acid can also be used to react with the formation rock and dissolve some of the rock. The formation may or may not be fractured during an acid job. Limestone and dolomite formations are good candidates for an acid treatment. An acid job in this case may include pumping 15% HCl (hydrochloric acid) that will react with the carbonate rock. There are acids that will react with quartz sandstone formations.

5. PETROLEUM RECOVERY MECHANISMS

Petroleum recovery can generally be classified into three steps: primary recovery, secondary recovery, and improved or enhanced recovery methods.

Primary recovery is that recovery in which the natural energy present initially in the reservoir is the main source of energy causing the displacement of petroleum to the producing well. The petroleum in the reservoir upon discovery is generally under pressure because of gas in solution in the petroleum liquid or hydrodynamic pressure or both. In the case of a gas reservoir, the gas itself is under pressure. When a well penetrates the reservoir, it provides the pressure sink to which the reservoir fluid flows. Because of the capillary nature of the reservoir rock and the flow of both oil and gas in the rock, oil recovery can vary from as low as 5% to as high as 50% of the liquid petroleum initially in place. On the average, primary recovery generally varies around 5%–30% of the oil initially in place.

In the case of a dry gas or wet gas reservoir, the production of the gas depletes the reservoir energy to the point where the production rate is no longer economical and the well is abandoned. In this case, the recovery factor varies from 60% to 90% of the gas initially in place.

In the case of a retrograde gas condensate reservoir, liquid condensate will drop out in the pore spaces of the reservoir rock as the pressure in the reservoir drops. Liquid dropout will reach a maximum and then as the pressure further declines some of the liquid condensate will revaporize. In the case of a rich retrograde gas condensate, the loss of liquid in the reservoir can be quite large when the abandonment pressure is reached. To prevent this liquid dropout, dry gas is quite often recycled into the reservoir to maintain the pressure and thus prevent the liquid from condensing.

In the case of a volatile oil reservoir, a small reduction in reservoir pressure below the bubble-point pressure of the volatile oil creates a large gas saturation. As a result, considerable liquid saturation can remain in the reservoir on abandonment by simple pressure depletion. Similarly, reinjection of dry gas into the reservoir to maintain pressure can reduce the loss of hydrocarbon.

After the primary energy in the reservoir has been dissipated, as much as 70%–95% of the oil may be left in the reservoir. The injection of water or gas into the reservoir to provide the energy to displace the oil to the producing well is referred to as *secondary recovery*. The displacement of the oil by gas or water is an immiscible fluid process, and because of the capillary effects, some of the oil is not displaced and a residual saturation of oil remains in the reservoir.

Improved or *enhanced oil recovery* results primarily from the injection of special gases at miscibility pressures or of liquid chemicals, or the use of thermal energy. The injected fluids interact with the rock–oil system to create conditions favorable to oil recovery by

1. lowering the interfacial tension between the oil and displacing fluids, thus reducing or eliminating capillary effects,
2. swelling the oil,
3. reducing the oil viscosity,
4. modifying the rock wettability, and/or
5. creating favorable phase behavior.

The viability of any improved oil recovery process depends on two factors, the unit displacement efficiency and the volumetric displacement efficiency. Unit displacement efficiency is the effectiveness of the displacing fluid displacing the oil in the *rock volume contacted,* whereas volumetric displacement efficiency refers to the fraction of total reservoir volume contacted by the displacing fluid.

Unit displacement efficiency is determined by the interfacial forces between the displacing fluids and displaced fluids. If the interfacial tension between the displacing fluid and displaced fluid is high, the capillary forces will be high and oil retention will be large. On the other hand, as the interfacial tension between the fluids is lowered the capillary forces will be lower. At an interfacial tension of zero, the fluids become miscible and the capillary forces are completely eliminated. At this point, the unit displacement efficiency is 100%.

The volumetric displacement efficiency is a function of mobility of the displacing and displaced fluids. The lower the viscosity of a fluid, the more mobile the fluid. A fluid of low mobility displacing a fluid of high mobility displaces the fluid in a pistonlike manner, whereas a fluid of high mobility displacing a fluid of low mobility will cause fingering and bypassing of the low-mobility fluid resulting in a lower volumetric displacement efficiency.

Improved oil recovery processes attempt to maximize both the unit displacement efficiency and the volumetric displacement efficiency. It is not always possible to do both at the same time. Application of improved oil recovery processes usually entails substantial risk because of their technological difficulties and front-loaded financial requirements.

5.1 Primary Recovery Mechanisms

5.1.1 Solution-Gas Drive In a solution-gas drive reservoir, the reservoir energy is derived from the light hydrocarbons, primarily methane, that are in solution in the oil in the reservoir. As the oil is produced and the reservoir pressure drops, light hydrocarbons come out of the solution and form a gas phase. The remaining gas in the solution plus the gas phase drives the oil to the well bore as the pressure declines. Since the gas is more mobile than the oil, the producing gas/oil ratio increases as the pressure decreases until a pressure is reached where the gas/oil ratio peaks and then starts declining. Up to this point, the reservoir energy is sufficient for the oil to flow up the tubing of the well. However, as the pressure decreases a pressure will eventually be reached where the well is put on artificial lift. Solution-gas drive reservoirs leave large quantities of oil in the reservoir. Recoveries are of the order of 10%–15% of the original oil in place.

5.1.2 Gas-Cap Drive Oil reservoirs can exist with a cap of gas over the oil. This gas cap is a source of energy along with the gas in solution in the oil to provide energy to move the oil to the well bore and lift it to the surface. As oil production proceeds, the gas cap expands into the reservoir originally containing the oil. The larger the gas cap, the smaller the rate of pressure drop as the oil is produced. This has the advantage of keeping gas in solution in the oil. As the gas cap expands and encroaches on a producing well, the gas/oil ratio may suddenly increase. Oil recovery will normally be in the range 20%–40% of oil originally in place.

5.1.3 Water-Drive Reservoirs In an active water-drive reservoir, the reservoir pressure declines relatively slowly as the oil is withdrawn from the reservoir and is replaced by water from an aquifer underlying the reservoir. The gas/oil ratio remains relatively constant because the pressure decreases very slowly, which keeps the gas from coming out of solution and forming a gas saturation. Water production from a well will increase gradually as the water encroaches into the reservoir. When water production gets too high, the well is abandoned since it becomes uneconomic to operate. Oil recovery from a water-drive reservoir will range from 30% to 75% of the oil originally in place, but is highly dependent on the depositional character of the reservoir as well as the drive mechanism.

5.1.4 Gravity Drainage In the case of gravity drainage, the fluids in a reservoir segregate in the reservoir according to their densities. Gravity drainage can play an effective role in the recovery of oil from a reservoir. By proper control of production rate, wells that are drilled into the bottom of the reservoir structure produce oil by gravity drainage of the oil into the well bore. Gravity drainage can be a very effective production mechanism, and recoveries can reach as high as 80%–90% of the oil originally in place.

5.1.5 Combination Drives Most often a combination of producing mechanisms exists in a reservoir under primary production. A common combination is one in which both water and gas-cap gas displace oil toward a producing well with perhaps some assistance from gas in solution in the oil. The degree to which each mechanism participates in the primary production of the oil is specific to the particular reservoir and the environment in which the reservoir exists. Since the water, oil, and gas are immiscible with one another, the capillarity of the reservoir rock traps large amounts of oil that are left behind once the primary production phase is completed. This oil provides the challenge to improved or enhanced oil recovery processes.

5.2 Secondary Recovery

5.2.1 Water Flooding The process of injecting water into a reservoir to displace oil was called a secondary recovery process because the process produced a second yield of oil after the field was depleted by primary production. Water flooding began accidentally in 1865 in the Pithold City area of western Pennsylvania. In the late 1800s, wells were being abandoned in the Bradford Field of Pennsylvania. In those days, there were no rules and regulations governing the abandonment of wells. Operators walked away from the wells, sometimes pulling casing, without plugging the wells. Fresh water from shallower horizons would enter the producing formation and stimulate production. These operations were named "Dump Floods." When operators realized that water was stimulating production, they deliberately started injecting water. By 1907, water injection had a significant impact on production in the Bradford Field. It was not until the 1930s that water flooding operations were reported in the midcontinent, i.e., Kansas, Oklahoma, and Texas. However, it was not until the late 1940s and early 1950s that water flooding operations became common practice. About 50% of the current oil production in the lower 48 states is attributed to water flooding.

Water flooding is usually conducted in the form of a pattern flood under different spacing conditions. Patterns can vary among line drives, 5-spot, 7-spot, and 9-spot: see Fig. 11. In some cases, a peripheral pattern is used, in which wells around the periphery of the field or lease are used for injection purposes. The type of spacing and pattern used depends on the location of existing wells, geometry of the reservoir, cost of drilling new wells, and the nature of the offset operations.

5.2.2 Gas Injection, Pressure Maintenance The injection of air or natural gas into a reservoir to stimulate oil recovery occurred well before the advent of water flooding. In the early 1900s, most secondary recovery projects involved gas injection. In gas-injection pressure maintenance operations, the gas can be directly injected into the oil-bearing formation. This is usually done through a pattern injection, that is, 5-spot or line-drive pattern, in order to obtain uniform distribution of the injected gas. Reservoir configuration must also be taken into consideration. In oil reservoirs having a gas cap, gas is often injected into the gas cap using wells in the crest of the structure. Such formations having structural relief and high permeabilities also benefit from gravity drainage. The number of wells required will depend on well injectivity and aerial coverage.

In the case of a retrograde gas condensate reservoir, economics may dictate the injection of a dry gas to maintain the reservoir pressure at or above the dew-point pressure to prevent the dropout of retrograde liquid condensate and thus the loss of liquid in the reservoir. If the retrograde gas condensate reservoir has been produced by pressure depletion, cycling dry gas through the reservoir will recover some of the liquid condensed in the reservoir by vaporization into the gas phase. Whether to cycle or not to cycle depends on the economics and the amount of liquid lost in the reservoir. If dry natural gas is unavailable, an inert gas such as a stack gas or nitrogen has been used. Nitrogen has

also been mixed with dry natural gas if not enough dry natural gas was available to maintain the desired pressure.

5.3 Improved Oil Recovery Mechanisms

Improved oil recovery results primarily from the injection of miscible gases and liquid chemicals or the use of thermal energy. Gases employed are hydrocarbon gases, carbon dioxide, or nitrogen. Liquid chemicals employed are polymer solutions, surfactant solutions, or hydrocarbon solvents. Thermal methods use steam or *in situ* combustion.

The lead time for the implementation of an improved oil recovery process from the time of first inception to the time of the first incremental volume of oil produced is anywhere from two to ten years depending on the complexity of the process and the reservoir to which it is to be applied.

The chemical requirements for improved oil recovery are also quite large, as shown in Table 3.

5.3.1 Polymer Flooding Polymer flooding is often referred to as improved water flooding. A high–molecular-weight polymer is added to water to lower the mobility of the water. Mobility of a fluid is defined as the permeability of the rock to the flowing fluid divided by the viscosity of the flowing fluid. The mobility of the water can be reduced either by increasing the viscosity of the water by adding polymer to the water or by reducing the permeability of the water to the rock by polymer adsorption and retention on the porous matrix of the rock. Improved volumetric sweep efficiency results. Polymer concentrations vary from 250 to 2000 ppm.

Table 3. Chemical requirements for improved oil recovery processes.

Process	Kg chemical/m^3 of oil recovered
Liquid chemicals	
Polymer flooding	
Polymer	5.5–8.5
Micellar polymer flooding	
Polymer	3.0–4.2
Surfactant sulfonates	20.0–48.0
Co-surfactant alcohols	2.8–28
Gases	
Carbon dioxide miscible flooding	1400–2700 standard m^3 CO_2/m^3 of oil recovery
Thermal	
Steam flooding	1–3 m^3 of water as steam/m^3 of oil recovered
In situ combustion	1400–5300 standard m^3 air/m^3 of oil recovered

There are a number of general requirements for the polymers used in polymer flooding. The polymer in solution should

1. reduce mobility of the water solution;
2. propagate through the reservoir rock without plugging;
3. experience minimum loss on the reservoir rock;
4. have adequate mechanical, chemical, thermal, and biochemical stability; and
5. be economical.

Polymer flooding should be initiated as early as possible during the course of a water flood while the oil saturation is still high. The higher the producing water/oil ratio at the start of the polymer flood, the higher the risk of failure. By initiating a polymer flood early, oil production is accelerated such that the cumulative water/oil ratio at the economic limit is much lower than if initiated later in the life of the flood.

There are two types of polymers used in polymer flooding, partially hydrolyzed polyacrylamides (PHPA) and biopolymers, the latter also known as polysaccharides and xanthan gums. PHPA is a synthetic polymer and is the most commonly used polymer for polymer flooding. Biopolymers are produced by fermentation. Biopolymers control mobility by viscosity increase only, whereas PHPA controls mobility by permeability reduction and viscosity increase.

The amount of polymer solution injection into a reservoir varies widely. Generally speaking, successful slug sizes are 15% of pore volume or greater. Incremental oil recovery from polymer floods over that of conventional water flooding may only be of the order of 2%–3% of the oil in place at the end of the water flood. Even so the process is still economic.

5.3.2 Miscible Flooding In miscible flooding, a fluid is injected into a reservoir that at reservoir pressures either is first-contact miscible with the reservoir crude oil or develops miscibility with the reservoir crude oil through a multicontact mixing process. The approach is applicable to medium and light crude oils. The fluids injected can be light hydrocarbon gases, nitrogen, flue gases, and carbon dioxide. Carbon dioxide is by far the most commonly used of the gases because of its unique properties. For a gas to become miscible with a crude through a multicontact mixing process, there is a minimum pressure requirement. This pressure is referred to as the minimum miscibility pressure, MMP. When carbon dioxide is injected into a reservoir at or above the MMP, light to intermediate components in the oil are transferred to the carbon dioxide, and when the enrichment of light to intermediate components in the carbon dioxide becomes large enough the gas at the leading edge becomes miscible with the oil and displaces the oil miscibly. As pointed out previously, the miscible displacement approaches 100% unit displacement efficiency. The MMP can be lowered by enriching the gas with intermediates. If, for example, the existing reservoir pressure is below the MMP for pure carbon dioxide, enrichment of the carbon dioxide with intermediate hydrocarbon will lower the MMP to the point that it will be at or below the reservoir pressure. In this case, there is a transfer of the intermediates into the crude oil, enriching the oil to a point where the injected rich gas becomes miscible with the crude. Although miscible displacement with a gas achieves high unit displacement efficiency, the mobility of the gas is higher than that of the crude oil and results in low volumetric displacement efficiency, i.e., fingering and bypassing of oil. To overcome this problem, alternate injection of water with carbon dioxide to improve the carbon dioxide mobility has been practiced with limited success.

Operating problems with carbon dioxide miscible flooding can be severe if the proper precautions are not taken. Corrosion, scaling, and asphalt precipitation are some of the problems encountered.

Carbon dioxide forms a highly nonideal solution with crude oil, resulting in swelling of the crude and in the lowering of the crude viscosity. Both of these effects enhance oil recovery.

The magnitude of additional oil recovery by CO_2 miscible flooding after water flooding is generally in the range of 8%–15% of the oil in place at the start of the flood; however, there are exceptions.

Large volumes of carbon dioxide are required for oil-field flooding. Gross carbon dioxide/oil ratios have varied from as low as 900 to as high as 4600 standard m^3 of carbon dioxide per m^3 of stock-tank oil recovered. Carbon dioxide cost will determine the cutoff. Sources of carbon dioxide can be varied: that occurring naturally in reservoirs, byproduct of ammonia plants, power-plant stack gas, and manufactured carbon dioxide. Reservoirs that contain carbon dioxide are presently being used to supply carbon dioxide for oil-field flooding, primarily because they can supply the volumes and rates at reasonable costs. Produced gases containing high concentrations of carbon dioxide are often recycled.

Of all the enhanced oil recovery processes, carbon dioxide miscible flooding is one of the most frequently applied.

5.3.3 Thermal Methods Thermal recovery methods can be classified into two broad categories: that in which heat is injected from an external source and that in which heat is generated *in situ*. Of the various possibilities, only steam injection and forward or concurrent combustion have proven viable commercially.

5.3.3.1 Steam Injection. Steam injection can be broken down into two different processes, steam flooding or continuous steam injection and cyclic steam injection or stimulation. About 72 187 m^3 of oil per day were produced in the United States in 1992 through steam injection (Moritis, 1994). The great majority of this oil is produced in California.

When steam is used, thermal expansion, viscosity reduction, and steam distillation are the principal mechanisms by which oil is recovered. Steam distillation is an important mechanism. The lighter the crude oil, the more important the distillation effect becomes. One characteristic that makes steam so useful as an injection fluid is that it carries a large amount of heat per unit mass compared with other fluids.

Steam flooding is generally applied to heavier crude oils ranging in specific gravity from 0.9000 to 1.000 and viscosities from 0.10

Pa s to several thousand Pa s. The viscosities of heavy crude oils are very sensitive to temperature. In continuous steam flooding, the steam moves out into the reservoir until it condenses, heating the rock and oil to steam temperature. The condensed water is produced, and an expanding steam zone efficiently displaces the crude oil. Generally, the equivalent of about one-third of the additional oil recovered is consumed to generate the required steam. However, because of environmental drawbacks, natural gas is now the preferred fuel to generate the steam.
